Incidentally Dr. Stein carried out very important surveys of the Kuen-Lun range (Fig. 2), and connected his own surveys with the trigonometrical survey of India, thus definitely fixing the exact geographical position of Khotan. Also he was enabled to do a great service to archæology by detecting and exposing the remarkable forgeries of ancient documents in "unknown scripts," the work of a clever rascal named Islam Akhun and a few confederates, which had been sold to travellers as genuine antiques, and had long mystified the learned into whose hands they had come. It was the appearance in India of these forgeries (together with a few genuine relics from Dandan-Uiliq, which had given the forger the idea of his deception) which first impelled Dr. Stein to the systematic exploration of the ruined "cities" from which they were said to have come. He has now cleared up the mystery: we now know what is genuine in the way of written documents from Turkestan and what is not. But, above all, Dr. Stein has discovered really new archæological material in the Kharoshthi tablets from Niya and in the Brahmi documents in a non-Indian tongue from Dandan-Uiliq. To students of Buddhism the relics of religious art from Dandan-Uiliq, the Rawak Stupa, and Yotkan will provide material for very important work.

H. R. HALL.

BRITISH ASSOCIATION MEETING AT CAMBRIDGE.

IN a former article (NATURE, April 21), a preliminary forecast was given of the local arrangements for the meeting of the British Association, to be held at Cambridge from August 17 to 24. The programme is now in an advanced state of preparation, and copies may be obtained after July 25 on application to the local secretaries at Cambridge. It may be of interest to give a short account of the arrangements in amplification of the incomplete summary already published.

It is expected that meetings of a sub-committee appointed by the International Meteorological Committee at Southport in September, 1903, to combine and discuss meteorological observations from the point of view of their relations with solar physics, will be held at Cambridge during the session of the association. The committee consists of twenty-two members, of whom eighteen represent the observatories or meteorological institutions of the Continent and America. The primary object of the meeting in Cambridge will be to constitute the organisation of the committee, and prepare a scheme of operations. The members of the committee will take part in the proceedings of Section A, particularly the subsection which deals with cosmical physics, under the presidency of Sir John Eliot, F.R.S.

The conference of delegates of corresponding societies will meet on Thursday, August 18, and Tuesday, August 23, at 3 p.m., in the large lecture-room, Gonville and Caius College.

Mr. Balfour will assume the presidency, and deliver an address in the Corn Exchange on August 17, at 8.30 p.m. A plan of the Corn Exchange may be seen in the reception room, and reserved seats secured up to 6 p.m. on Wednesday, August 17. For the con-

venience of visitors, a small number only of the seats will be allotted on Monday afternoon, and a considerable number of places in all parts of the building will be held in reserve for those who arrive on Wednesday, August 17.

At 3 p.m. on Thursday, August 18, the High Sheriff of Cambridgeshire will entertain the association at a garden party in the grounds of Emmanuel College, and at 5.30 p.m. the Registrary of the university will deliver a lecture at the theatre on the growth and origin of the university. At 9 p.m. there will be a reception of the association by the local committee in Trinity College.

On Friday afternoon, August 19, the mistress and resident staff of Girton College will entertain 500 members of the association at a garden party, and in the evening Prof. George Darwin will deliver a lecture in the theatre on ripple-marks and sand-dunes.

Saturday, August 20, will be devoted to excursions to places of interest in East Anglia. The local committee hopes that prominent members of the association will, so far as possible, take part in the excursions, which promise to be of considerable interest. A set of excursion guides and a map, which has been specially prepared by the Director-General of the Ordnance Survey, will be given to each member of the association.

The following is a list of the excursions:—

Audley End and Saffron Walden.—Audley End House will be visited by permission of the Lord Howard de Walden; the church and museum in Saffron Walden form other items in the programme.

Brandon and Didlington Hall.—The most attractive features of this excursion will be the flint knapping industry at Brandon, Lord Amherst's Egyptian collections, rare books and illuminated MSS. at Didlington Hall.

Cromer.—Mr. Clement Reid, F.R.S., has arranged an attractive itinerary for those interested in the geology of the Norfolk coast.

Dykes of Cambridge.—This excursion includes an inspection of the well-known Fleam Dyke and Devil's Ditch, under the guidance of Prof. Ridgeway; opportunity will also be afforded for botanising on the dykes. By the invitation of Mr. Richard Marsh, trainer to H.M. the King, tea will be provided at Egerton House, Newmarket.

Ely.—A visit to the cathedral, a building of exceptional architectural interest, under the guidance of the Dean, forms the most important feature of this excursion.

Wicken Fen and Upware.—Members will travel from Cambridge to Upware in steam launches. This excursion is likely to be of considerable interest to geologists, entomologists, and botanists.

Hatfield and St. Albans.—A visit to Hatfield House, by permission of the Marquis of Salisbury, visits to St. Albans Abbey, the site of Verulam, the sites of the battlefields of St. Albans, and the orchid houses of Messrs. Sanders, form the chief attractions.

Lincoln.—The exceptional architectural and archæological features of Lincoln seemed to the committee sufficient justification for arranging an excursion to this city, in spite of its distance from Cambridge. The Mayor of Lincoln invites members to tea in the Castle grounds.

Norwich.—The cathedral, the hospital of St. Giles, and St. Andrew's Hall are the most important buildings to be visited. Hospitality is offered by the Mayor of Norwich, and by Mr. and Mrs. James Stuart.

Sandringham, Lynn, and Castle Rising.—This excursion, which is likely to prove one of the most popular, includes visits to the Lynn churches, the castle and church at Castle Rising, also the grounds, kennels, stables, and dairy at Sandringham. Tea will be provided by invitation of H.M. the King.

Wisbech.—The Lord Lieutenant of Cambridgeshire has kindly invited members of the association to visit the old-world town of Wisbech, and facilities will also be afforded for inspecting the woad works.

The committee is greatly indebted to the authors the excursion guides for the full and interesting accounts which they have written of the places to be visited.

On Saturday the master and fellows of Peterhouse invite 600 members of the association to an evening party at 9 p.m.

On Sunday evening at 8.30 p.m., there will be a performance of unaccompanied sacred music by the combined choirs of King's, Trinity, and St. John's Colleges in the Chapel of King's College.

On Monday, August 22, the Lord Lieutenant of Cambridgeshire and the Mayor will entertain the association at a garden party in the Botanic Garden at 4 p.m. On Tuesday afternoon Mrs. Sidgwick, principal of Newnham College, invites 500 members to a garden party in the college grounds. The large room of the Cavendish Laboratory has been placed at the disposal of the committee for the exhibition of specimens. For information as to exhibits, application should be made to Mr. P. V. Bevan, the Cavendish Laboratory.

Arrangements have been made for members to have exceptional facilities for visiting the Botanic Garden, University Laboratory, the Observatory, the University Press, as well as college buildings and gardens. Cambridge schools and the Addenbrooke's Hospital may also be inspected at stated times, and visits have been arranged to several works in Cambridge, and to nursery gardens at Sawbridgeworth and Broxbourne.

In a subsequent article some account will be given of the sectional proceedings, together with a list of some of the colonial and foreign guests.

MODERN PRINTING PRESSES.

THE recent issue of M. A. Ducrot's "Presses modernes typographiques," published by the house of Gauthier-Villars, Paris (7 f. 50 c.), provides an opportunity for a short account of modern printing presses. The work is copiously illustrated, and describes, from a mechanical point of view, every kind of machine, from the small but handy platen to the awe-inspiring rotary, whilst the intermediate classes of cylinder machines are represented by many varieties, both of the single and double kind.

The only English work of a similar nature, devoted exclusively to machinery, is Wilson and Grey's "Modern Printing Machinery," published so far back as 1888, and therefore not up to date. This is to be deplored considering the great advance made in that department of the printing craft.

Although artistic printing was not altogether an unknown quantity during the nineteenth century, much progress was made in a general way during the latter part of that century, which also marked the introduction of machinery, but its general adoption was a matter of time. Through William Morris's work at the Kelmscott Press, much impetus was given to what may be termed the decorative side of printing, but the invention of the many processes of reproduction in connection with letterpress illustration, and the enormous development of such processes, have necessitated printing machinery of a different and much improved character in order to cope successfully with the demand for graphic literature.

That American engineers have in recent years taken the initiative in this direction will be admitted, but it is some consolation for English printers to observe that the home manufacturers are beginning to realise the situation, and are endeavouring to make amends and thus regain their position in the field.

In looking abroad it is customary to associate Messrs. Hoe's name with some of the best of American machinery, whilst for that of French origin the late M. H. Marinoni was looked upon as the best manufacturer of machinery especially adapted for newspaper or magazine work. To specify other names in either country would require space, although in fairness to Germany it must be said that many really good machines of various kinds are now before the trade and at work in this country.

To the lay reader it may be explained that the various classes of machinery used for letterpress printing are divided under certain heads, and may be broadly grouped as follows:—(1) rotary machines; (2) double cylinder perfecting machines; (3) single cylinder one-feeder machines; (4) single cylinder two-feeder machines; and (5) platen machines.

Commencing with the rotary kind, as its name implies, the action is that of continuous rotation whilst the machine is in motion. Although there are a few machines on the market with flat type beds that print from the reel, this class of machine generally prints from a surface made from either stereotype or electrotype plates, and curved to the cylinder similar to the one which gives the impression—the paper as it is unwound from the reel passing between the printing and impression cylinders continuously whilst the machine is running.

The paper is made to the required width and wound on reels; sometimes these webs contain paper two or three miles long, the length being regulated by the weight or thickness of the material. Such machines are used mostly for newspaper work, or magazines of a non-illustrated character, where a large number of copies are required, and each section or copy is cut and folded before it leaves the machine. They are also made in duplicate, quadruple, or even larger sizes, so that the machine is self-contained, and will produce just as many duplicate copies as it is constructed for.

It is true that illustrated work is now attempted on rotary machines, and whilst no doubt further improvements will be made in due course, the results are not altogether satisfactory so far, although illustrations in line are more successful than those produced by the half-tone process.

Perfecting machines have two cylinders, and are used mostly for newspaper or magazine work of shorter numbers, and occasionally for bookwork. These print both sides of the paper, which is in single sheets, before it leaves the machine, but the double impression is two distinct operations. Although this class of machine has been used for a great number of years, it is not adapted for the best class of bookwork owing to the difficulties of ink set-off. These machines, and all other than the rotary kind, print from a flat printing surface.

The single cylinder (one-feeder) is *par excellence* adapted for the best bookwork, whether illustrated or not. Of this class there is a great variety, the English make being called the "Wharfedale," and built on the stop-cylinder principle, that is, the cylinder over which the sheets of paper are carried, and which gives the impression to the printed sheet as it revolves, is stopped or locked on the return travel of the machine, when it is automatically released and revolves again as the type carriage or bed travels forward once more.

Other single cylinder machines are those of the two-revolution kind, that is, the cylinder revolves continuously in the same direction, once whilst the sheet is being impressed and again whilst the type bed is travelling back to its original position, thus making two revolutions for each copy printed. This class of machine is well represented by the Miehle and Century, both of which are of American manufacture, and are admirably adapted for high-class illustrated work of the magazine order because the inking facilities are so well considered.

Another kind of single cylinder machine is the two-feeder, and it may be described as being somewhat similar to the ordinary Wharfedale, but it has a longer travel for its type carriage, with an arrangement at both ends of the machine for inking and rolling the forme. Unlike the stop-cylinder of a single feeder machine, which is stationary on the return travel, the impression cylinder of the two-feeder immediately reverses on the completion of the revolution on the principle of the old "tumbler" machine. In doing this a fresh sheet is seized by a second set of grippers or fingers attached to the cylinder. By this method a sheet is printed at each propulsion of the machine in either direction.

Those of the platen kind are used for smaller work, mostly of a commercial character, and the action is somewhat similar to that of the old hand press, because both type and paper are impressed on the flat. They are made in many sizes, and some will print almost as large a sheet as the old hand press. Although one operator only is required, he will, with the aid of power, produce at least three or four times as much as two men at hand press with equally good results, provided the worker is a skilled hand.

CHAS. T. JACOBI.

CANCER RESEARCH.

As Dr. Bashford remarks in his introductory note to the report of the Cancer Research Fund,[1] the solution of the problem of the cause of malignant disease in man is really the logical destination and centre towards which all channels of cancer research must converge, rather than the starting point thereof. The zoological distribution of cancer has therefore formed one of the first lines of inquiry to be undertaken by the Cancer Research Fund, founded about two years ago, for investigating this dire disease. By the willing cooperation of many workers, a most interesting series of tumours has been obtained from the various domestic animals, from the mouse and hen, and from three species of fish, proving that malignant disease is not confined to man. The malignant growths of man seem to be incapable of transmission to animals, but a malignant new growth from one animal may occasionally be transmitted to another individual of the same species. This has been carried out by Jensen, of Copenhagen, and by Borrel, of Paris. Through the kind collaboration of Prof. Jensen, a specimen of epitheliomatous tumour of the mouse was obtained and successfully transplanted into mice, but not into other animals, thus confirming Jensen's results.

The last half of the report contains an account of Dr. Bashford and Mr. Murray's investigations on the cytology of malignant growths, illustrated with a number of drawings. The results obtained are practically the same as those of Prof. Farmer, Mr. Moore, and Mr. Walker, already detailed in these columns (NATURE, vol. lxix. p. 319), viz. that in the cancer process there is a transformation of the normal

[1] "Scientific Reports on the Investigations of the Cancer Research Fund. No. 1. The Zoological Distribution, the Limitations in the Transmissibility, and the Comparative Histological and Cytological Characters of Malignant New Growths." (Taylor and Francis, 1904.)

adult tissues into modified reproductive or "gametoid" tissue. This, however, does not completely explain malignancy; there may possibly be in addition conjugation of cells or of nuclei. Let us hope that before long Dr. Bashford and his colleagues may give us further information on these and other points so necessary for the complete solution of the cancer problem.

The reports of the cancer research laboratories of the Middlesex Hospital [1] contain several papers which are, however, for the most part of purely medical interest, *e.g.* cancer in certain organs, and various methods of treating the disease. A report by Prof. Karl Pearson on cancer statistics collected by Messrs. Hillier and Tritsch is of considerable interest. For this the histories of 3000 cases of cancer were carefully analysed, and the results of Prof. Pearson's mathematical analysis are:—(1) as regards age incidence frequencies, that cancer is far more likely to occur in childhood in the male than in the female; (2) as regards a family history of cancer (that is, heredity in cancer), there seems to be a slight correlation between a case of cancer and a family history of cancer, but this is so slight as to be within the probable error of random sampling; and (3) that there is little or no relation between the presence of cancer and a tubercular family history, but there is a relation between the presence of cancer and the presence of tuberculosis.

The first report of the Liverpool Cancer Research Fund [2] has also recently been issued. This fund has been instituted by Mr. Sutton Timmis, who has vested in two trustees a sum of 10,000*l.*, which is administered by a committee empowered to spend 1000*l.* to 1500*l.* per annum until the fund is exhausted or the cause of cancer discovered. A cytolytic milk has been prepared by injecting a cow with carcinomatous material, but the cases treated with it are not yet sufficiently numerous to allow an expression of opinion as to its value. Investigations are also being made into malignant growths of man and animals by Dr. Albert Grünbaum, who has been appointed director of these researches.

Mr. Cecil H. Leaf in a booklet [3] discusses the clinical causes and prevention of cancer of the breast, with an analysis of 100 cases. Of the 100 cases, 84 were married and 16 single, and the author thinks that very early marriages and errors in lactation may act as exciting causes. In 35 of the cases there was a definite history of injury, and unsuitable corsets are suggested as taking some share in the production of mammary cancer. Diet, *e.g.* excessive meat eating, use of alcohol, and of salt, could not, as has been suggested by some, be ascribed as a cause of the disease. Finally, some suggestions are made with the view of prevention.

R. T. HEWLETT.

ELECTRICAL TRANSMISSION OF PICTURES AND SCRIPT.[4]

THE problem of distant electrical vision is one to which much speculation and experimenting have been devoted. Before this problem can be attempted with any hope of success, however, the preliminary one of the electrical transmission of photographs over a distance has to be solved. This problem, it may be stated at once, has been mastered, and it is now possible to transmit photographs in this manner, and successful results have been obtained over telegraph and telephone lines 800 kilometres long.

It does not need much consideration to see how important such a process would be for journalistic and police work if it could be industrially exploited, and it were possible simply to hand a sketch or photograph in at the telegraph office and send the same as one now sends an ordinary telegram. The evening papers would be able then to publish photographs taken at the seat of war in Korea on the same day. Unfortunately, with the apparatus at present to be had, the time taken to transmit a half-plate photograph is half an hour. The cost of the use of a telegraph line of any length for half an hour would be, it is needless to point out, prohibitive. The lessening of the required time of transmission is, however, simply a matter of further development, and no good reason can be seen why in a few years' time the process should not be an adjunct to every existing telegraph line.

The author of the present work has devoted considerable time to this subject, and his booklet consists of an exact description of the apparatus and processes he has worked out. The author is to be commended on the very precise and careful way in which he has described every detail, so that it would be possible for anybody, with the help of this book, to reproduce, without any original work, the same results as he has obtained himself.

The method shortly consists of the following:—A ray of light is made to pass systematically all over the transparent film to be transmitted. After passing through the film it impinges upon a selenium cell the resistance of which varies proportionally to the amount of light which passes through the photograph. These varying currents pass through the line and are received in a moving coil galvanometer the pointer of which, in moving, inserts or takes out resistance in a high tension circuit, according as the current flowing in the moving coil changes. In the high tension circuit a small vacuum tube is connected, and it follows that the illumination of this tube is proportional to the light passing through the plate at the transmitting end of the line. This vacuum tube now passes over the sensitised photographic paper in synchronism with the ray of light over the transmitted plate, and thus a reproduction of the same is obtained. The transmitted film and sensitised paper are each wrapped on a glass cylinder. These cylinders are rotated by motors, and synchronised once each revolution. Only one wire is needed for the transmission, with, of course, an earth return.

In the case of the transmission of handwriting and half-tone illustrations, the same are got up on metal foil with electrically non-conducting ink. A conducting point then travels over the metallic foil, and closes and opens the sending circuit according as it is travelling on a marked or an unmarked place. The receiver used by the author is a modification of that described above, the essential point being the use of the vacuum tube fed with the Tesla currents. The speed reached is 500 written words per hour. For a half-tone illustration a strip ½ cm. wide and 10 cm. long can be sent in 100 seconds.

It would seem that there is not very much practical value in the transmission of handwriting; the type printing telegraph of to-day fulfils all ordinary requirements, and it would be only very seldom that a transmission of handwriting would be required. It is to be hoped, however, that this electrical "distant photography" will make rapid progress.

NOTES.

We deeply regret to see the announcement that Dr. Isaac Roberts, F.R.S., died at Crowborough on Sunday last.

The monument erected in the Place Breteuil, Paris, to the memory of Pasteur, was unveiled on July 16 by President Loubet. The ceremony was attended by the members of the diplomatic body, by prominent men of science, and by representative Government officials. Speeches eulogising the services rendered to science by Pasteur were delivered by the French Minister of Public Instruction, the Prefect of the Seine, and the president of the Paris Municipal Council. Prof. Herrera, of the University of Brussels, spoke in the name of the foreign subscribers. The monument is the work of M. Falguière.

The Postmaster-General introduced into the House of Commons on Monday a Bill for the regulation of wireless telegraphy. The Bill makes no attempt to create a State monopoly in wireless telegraphy, but merely aims at regulating its use in the country in a way that shall prevent the undue clashing of conflicting interests. The Government has at present no jurisdiction over telegraphy unless both ends of the system are within the United Kingdom or within the three-mile maritime limit. It is proposed to deal with the matter by means of licences. It is obvious that the peculiar conditions under which wireless telegraphy is worked, particularly the fact that neighbouring installations cannot at present be operated without interfering with one another, make it very desirable that the Government should be able to exercise a certain amount of authority in such questions, for example, as the selection of sites for transmitting stations. The great strategical value of wireless telegraphy to the Navy makes the matter of still more importance.

In connection with wireless telegraphy, we note that Mr. Duddell has recently been carrying out some experiments for the Post Office in Bushey Park with the new thermo-galvanometer which he exhibited at the recent Royal Society soiree. This instrument is capable of directly measuring the current received by the aërial at the receiving station, and thus affords a means of making scientific experiments on many of the problems connected with the subject which have long waited for a satisfactory elucidation.

The weather report issued by the Meteorological Office for the week ending July 16 shows that from the beginning of the year the rainfall has equalled or exceeded the mean in all districts except the north-east and east of England and the midland counties, where it is still an inch below the average. In the north of Scotland the fall is $4\frac{1}{2}$ inches above the mean. The temperature for the week was above the mean in all districts, amounting to 6° in the midland counties, where the maxima reached 85°. The same value was recorded in south and east England. On Sunday last the maxima were still higher, reaching 91° in parts of Hertfordshire. Thunderstorms have occurred in many places.

The Bombay branch of the Royal Asiatic Society will celebrate its centenary on January 17, 1905.

The International Botanical Congress will meet in Vienna in 1905 from June 12 to June 18.

The deaths are announced of Prof. Albert Rilliet, of Geneva; of Prof. V. Merz, formerly of Zürich; and of Prof. Karl Bopp, formerly of Stuttgart.

The death is announced of Prof. F. Knapp at the age of ninety-one. Prof. Knapp was for many years professor of applied chemistry in the Chemical Institute at Brunswick. He was a former student and son-in-law of Liebig.

Signor Pietro Blaserna has been elected president and Signor Francesco d'Ovidio vice-president of the Reale Accademia dei Lincei, of Rome; Prof. Giuseppe Gabrielli has been appointed librarian.

Dr. E. Rupp, of Marburg, and Dr. F. Dolezalek, of Berlin, have been raised to the rank of professors; Prof. F. Schilling, of Göttingen, has been appointed at the technical school of Danzig, and Prof. von Margold, of Aachen, has also been appointed there, both as professors of mathematics.

The specimens and other material collected by the Scottish Antarctic Expedition have arrived at the headquarters of the expedition in Edinburgh. The *Scotia*, with the members of the expedition on board, is expected to reach the Clyde to-day.

Provisional arrangements have been made by the American Society of Civil Engineers and the Canadian Society of Civil Engineers for the forthcoming visit of members of the Institution of Civil Engineers to the United States and Canada. Broadly, the visit will commence with a week spent in New York and the neighbourhood. Thence, a journey will be made to Montreal by a special train placed at the disposal of the party. A week will be spent in Canada, for which similar special travelling facilities will be provided; and this part of the tour will be concluded at Chicago, whence the party will proceed (again by special train) to St. Louis, which is expected to be reached on September 30. The party will leave Liverpool by the Cunard ss. *Etruria* on September 3, and may expect to reach New York on September 10.

The following is an abridged summary of the prizes offered by the Belgian Academy for 1904 and 1905:—For 1904, in mathematics and physics, critical phenomena in physics, viscosity of liquids, study of n-linear forms where $n>3$, thermal conductivity of liquids and solutions, each a prize of 600 francs; unipolar induction of Weber, 800 francs. In natural sciences, the Cambrian rocks of Stavelot (Belgium), 800 francs; modifications produced in minerals by pressure, 600 francs; development of Amphioxus (see *Bulletin*, 1904, No. 4, for corrected announcement), 1000 francs; effects of osmotic pressure in animal life, and Devonian flora of Belgium, each 600 francs; heterœcism of parasitic fungi, 800 francs; and physiological action of histones, 1000 francs. All memoirs to be written in French or Flemish, and sent in before August 1, 1904. For 1905, in mathematics and physics, combinations of halogens, 1000 francs; physical phenomena accompanying mutual dissociation of liquids, 800 francs; linear complexes of the third order, 600 francs; principal terms in the periodic deviations of the vertical, 600 francs. In natural science for the same year, effect of albuminoids in nutrition, reproduction of Dicyemidæ, formations intermediate between the Bruxellian and Tongrian in Brabant, geological age of certain Oligocene deposits in Belgium, sexuality of the individuals resulting from division of a single ovum in certain diœcious plants; prizes, 1000 francs for each of these five subjects; silicates of Belgian rocks, &c., 800 francs. In addition to these ordinary prizes the academy will award the following:—June 30, 1905, a Charles Lemaire prize relating to public works; June 30, 1904, a Louis Melsens prize for applied chemistry or physics; December 31, 1904 a Charles Lagrange prize for

terrestrial physics; on May 1, 1906, a Selys Longchamps prize for researches on the Belgian fauna; on December 31, 1904, a Théophile Gluge prize for physiology; and in 1906 a François Deruyts prize for higher synthetic or analytic geometry.

MR. BALFOUR presided on July 14 at the annual dinner of the Royal Economic Society, of which he is vice-president. In proposing the toast "The Royal Economic Society," he said in the course of his remarks:—"If a man of science once lets the public think that he is speaking not in the interests of his science, but in the interests of his party, if he once allows the view to get abroad that his expression of opinion may have its origin in his scientific views, but has a double parentage, and that the scientific views are in some sense moulded in conformity with our political differences, his whole authority from that moment will absolutely vanish. So far as political economy is a science at all—and I am the last person to deny it that proud title to distinction—it must be absolutely international in its character. People talk of an English, a German, a French, or an American school of political economy. In so far as they talk in that way they show conclusively that political economy to that extent has not yet thoroughly earned its title to a position among the sciences. There is no such thing as English physics as distinguished from German physics, or German mathematics as distinguished from French mathematics. I do not say there may not be certain schools having the impress of great teachers belonging to one or the other nationality, but *qua* science and as a science political economy must be, and is, and will be, absolutely international in its character. Let everybody who has the chance, not only treat economic problems in a strictly objective spirit, but let him make it clear that that is the spirit in which he is trying to treat them. Thus and thus only will the student and the investigator obtain that authority over the changing forces of ordinary public opinion which it should be the proudest boast of men of science to obtain, which if they truly pursue science in a scientific spirit they have always obtained in the past, and I cannot doubt for a moment they will always obtain in the future."

The second part of vol. v. of *Annotationes Zoologicae Japonenses* contains the description of a new deep-sea polychæte annelid by Prof. A. Isuka, additional notes on Japanese cicadas by Prof. S. Matsumura, and the first part of a biological and geological essay on the island of Hokkaido by Mr. E. Klocke.

IN reply to a question of Mr. Morrell, not answered orally in the House of Commons, Sir W. Anson stated that the Board of Education is aware that those interested in agricultural investigation recognise the value of the drift maps prepared by the Geological Survey as a basis for soil maps. Superficial deposits are being mapped in all districts where work is going on in connection with the survey. Thirty-five 6-inch maps of North Staffordshire have been published with drift, and others of South Wales and of the area around Leicester are in course of preparation for publication. The board does not contemplate the publication of drift maps on the 6-inch scale for the entire country, but manuscript maps of any part surveyed on this scale may be obtained at the cost of copying, and whatever information with reference to superficial deposits the officers of the survey have shown upon their field maps of other parts of the United Kingdom is available for reference at the offices of the Geological Survey.

IN *La Nature* of July 9, M. J. R. Plumandon, of the Puy de Dôme Observatory, contributed an interesting article on the dryness of the air. "Relative humidity," or the percentage of saturation of the air with aqueous vapour, plays a more important part in meteorology than "absolute humidity"; its variations produce or dissipate clouds, and give rise to fine or wet weather, it is always irregularly disseminated in the atmosphere, its diurnal variation following inversely the range of temperature, and its annual variation generally exhibits a maximum in winter and a minimum in summer. But almost everywhere it exhibits another minimum in spring-time which frequently exceeds that of summer. The minima, or in other words the periods of dryness of the air, present the greatest interest, owing to their irregularity both as regards date and intensity. M. Plumandon shows by means of very clear diagrams that the annual minimum is more marked, and occurs at varying periods, according to the greater altitude of the station. Near Paris, at a height of 50 metres, it always occurs in spring, while on the summit of the Pic du Midi (2859 metres) it occurs at all seasons. At Toulouse (194 metres) the greatest dryness of the air occurs nearly always in summer, but sometimes also in spring. At Clermont-Ferrand (338 metres) it occurred in spring in twenty-one years out of twenty-five, and at the summit of the Eiffel Tower (also 338 metres) it occurred in March or April in seven years out of eleven. On the Puy de Dôme (1467 metres) it took place in twenty-one years out of twenty-two during the cold season, between September 20 and March 1. The diagrams also show the intensity of the minima in the various months.

M. POTIER has presented a large and valuable collection of pamphlets and works on physics to the French Physical Society for distribution among any members of the society who are interested in the particular branches of which they treat.

IN several recent numbers both in this and last year's volumes of the *Bulletin international* of the Cracow Academy, Prof. Ladislaus Natanson discusses the phenomenon of accidental double refraction in liquids and its connection with the theory of relaxation. The author further criticises papers by M. St. Zaremba, who also contributes a number of writings on the same subject to the same journal.

IN the June number of the *Journal* of the Royal Microscopical Society, Mr. Keith Lucas describes a microscope in which the usual planed sides of the body-tube and limb are replaced by geometric slides. The instrument thus involves an adaptation to biological and other microscopes of a device the use of which has hitherto been generally restricted to measuring microscopes.

FROM Messrs. Ulrico Hoepli, of Milan, we have received the latest issue of their "Biblioteca scientifico-politecnica," a catalogue extending to more than three hundred pages, and comprising scientific and technical works and periodicals published both in Italy and in other countries, up to the end of 1903. In all cases where foreign works have been translated into Italian the translation is mentioned in this catalogue.

A SECOND and enlarged edition has been issued of Prof. Augusto Righi's small book on "La moderna teoria dei fenomeni fisici," in which the author describes modern views on radio-activity, ions, and electrons. The book forms the third of a series published by Nicola Zanichelli, of Bologna, under the title "Attualità scientifiche." It extends over 165 pages, and contains a fairly complete bibliography of the subject.

IN a paper on "Edge Corrections in Condensers," communicated to the *Proceedings* of the American Academy of Arts and Sciences, Mr. J. G. Coffin works out a number of electrostatical problems in two dimensions by the conformal transformation of Schwarz and Christoffel. The problems here considered include as particular cases many of the cases solved in Prof. J. J. Thomson's book, and they have application to condensers, such as one formed of two silvered glass plates, the capacities of which have not previously been determined.

IN his presidential address to a joint meeting of the American Physical and Mathematical Societies, delivered in February last, Mr. Arthur G. Webster chose as his subject "Some Practical Aspects of the Relations between Physics and Mathematics." The address has been reprinted in the *Physical Review* for April, and deals with the work of the late Prof. Willard Gibbs, the endowment of research, and the relative parts played by mathematical and physical teaching and general culture in the education of the physicist in schools and colleges.

SOME interesting properties relating to the polarisation of electrodes are described by M. E. Rothé in the *Bulletin* of the French Physical Society, No. 214. In particular the author obtained a deposit of hydrogen on a platinum wire with a single Daniell cell when the anode was a large lamina, although 1.7 volts would be required to decompose water in ordinary circumstances. This deposit ceased when the anode became polarised by the absorption of oxygen. It thus appears that gas may be deposited on a *single* electrode when the electromotive force is just sufficient to overcome the counter-electromotive force of that electrode alone.

AN account of the department of international research in terrestrial magnetism of the Carnegie Institution is given in *Terrestrial Magnetism and Atmospheric Electricity*, ix., 1. The object of the department will be to investigate such problems of world-wide interest as relate to the magnetic and electric conditions of the earth and its atmosphere, not specifically the subject of inquiry of any one country but of international concern and benefit. Among the problems suggested are a magnetic survey of ocean areas and unexplored regions, international observations of the variations, including the establishment of secular variation or repeat stations throughout the globe, observations in ocean depths and atmospheric regions (for which the first step consists in devising suitable instruments), and other problems.

AT the recent show of the Royal Agricultural Society, the new Just-Hatmaker process for drying milk was exhibited. The milk is fed continuously on two cylinders, one-eighth of an inch apart, and revolving inversely. These are heated by superheated steam within, and have a surface temperature of 110° C. The milk passing between the revolving cylinders forms a thin layer on each, becomes evaporated to dryness, and is stripped off as a thin sheet of milk solids, all within a single revolution. The thin sheets are reduced by sieving to a powder, which can be compressed into tablets. Mixed with warm water the powder immediately forms a liquid having all the properties of boiled milk. The advantage to travellers of having milk in a concentrated form—the powder contains only 6 per cent. of moisture—is obvious. Moreover, the dry milk as it leaves the machine is completely sterilised. With rennet or acid we find that the mixture of dried milk and water curdles, but the curd is not coherent, a property which may add to its digestibility but destroys its value for certain culinary purposes. Owing to its cooked taste, the new product can never replace fresh milk, so that its introduction is no menace to the British milk industry; on the contrary, farmers should benefit if the milk supply associations they deal with possess this apparatus for drying any surplus over the daily requirements. The public will find that discrimination is necessary in the purchase of the dried milk, as it can be made from either whole or separated milk.

WE have received a copy of the fifth annual report of the Plymouth Municipal Museum and Art Gallery, in which an unusually large number of presentations to that institution are recorded.

IN the July issue of *Bird Notes and News* the Society for the Protection of Birds directs attention to the extent of the trade in cage-birds, and the evils attendant on the capture and maintenance in captivity of such birds. The subject is emphasised in the case of the linnet by a special leaflet, "A Linnet for Sixpence," in the course of which it is stated that sixty per cent. of these birds perish during the first week of captivity, in addition to others killed in capture and the number of hens wantonly destroyed by their captors. The practice of selling in London cock-linnets in paper-bags for sixpence is specially deprecated.

THE *Popular Science Monthly* for July contains an illustrated account by Prof. Bashford Dean of the zoological station at Misaki, Japan. The station, which was removed to Misaki in 1897, now contains two buildings with convenient workrooms, for which fittings and books are periodically sent from Tokyo in accordance with the needs of investigators. The great feature of the station is the crew of fishermen, who are accustomed to carry on their trade in deep water, with lines which may be as much as a mile in length, and often bring up rarities. The shallow water of the bay yields numerous interesting types—among others a giant Balanoglossus—while from deep water further out are obtained the remarkable shark Mitsurikina, perhaps identical with the Cretaceous Scapanorhynchus, the frilled shark (Chlamydoselachus), and one of the Port Jackson sharks, in addition to numerous interesting invertebrates, such as swarms of glass-sponges and specimens of the stalked crinoid Metacrinus.

IN No. 10 of vol. ii. of the *Circulars and Agricultural Journal* of the Royal Botanic Gardens, Ceylon, the director, Mr. J. C. Willis, gives an account of the history of the institution; originally simply a botanic garden at Peradeniya, it has gradually developed into one of the greatest botanical and agricultural establishments in the tropics, comprising six botanic gardens with a cultivated area of 256 acres in different climates and elevations, three experiment stations of a total cultivated area of 360 acres, and forest reserves for scientific purposes of 850 acres. There is a European staff of nine, including four botanists, an entomologist, and a chemist, and well equipped laboratories, library, museum, and herbarium, all open freely to workers from abroad. No less than twenty-two scientific men have visited Peradeniya for purposes of original research during the last seven years, and the institution now publishes a botanical journal devoted to pure research.

"THE Fungous Diseases of Fruits in Michigan" forms the title of a special *Bulletin* prepared by Mr. Longyear and issued by the Michigan State Agricultural College. The author has brought into a small compass the diagnoses of fungal pests which attack common fruit trees and plants, together with hints as to preventive or remedial treatment.

SEEING that no comprehensive account of the flora of Norfolk Island has been published since Endlicher's "Pro-

dromus Floræ Norfolkicæ," which came out in 1833, the contribution to this subject presented by Mr. J. H. Maiden to the Linnean Society of New South Wales last year is eminently useful. The paper begins with a critical enumeration of the flowering plants and cryptogams, in which the author deals with a number of synonyms and doubtful references, besides adding several new records for the island. A somewhat novel feature for a flora is a separate list of plants of economic and horticultural value. The author reserves for a second part his observations as to origin and distribution.

SOME interesting ecological observations of certain swamp areas in Michigan and Arkansas counties, U.S.A., are recorded by Dr. S. M. Coulter in the fifteenth annual report of the Missouri Botanical Garden. On the island of North Manitou, in Lake Michigan, a small lake, having no outlet, is being filled up by the encroaching vegetation. The pioneer plants are the peat-mosses, followed by cranberry and leather leaf, *Cassandra calyculata*; tamarack, *Larix Americana*, and black spruce crowd on the shrubs, and as the ground gets drier deciduous trees obtain a foothold. In the swamp region of the St. Francis River two characteristic trees are found, the tupelo gum, *Nyssa uniflora*, distinguished by having a continually increasing dome-shaped base, and the bald cypress, *Taxodium distichum*, which develops a conical butt and peculiar "knees."

DR. N. ZARUDNY has returned from his last journey to Persia, and has brought back rich ornithological collections.

WE learn from the *Bulletin* of the Russian Society of Naturalists of St. Petersburg that the biological station which has been established near Alexandrovsk, on the

FIG. 1.—The biological station on the Norman coast of the Kola peninsula, North Russia. View from the north-west, at low water. The pumping machinery and a covered sea-water basin are shown on the left.

Norman coast of the Kola peninsula, is now in working order. It is provided with all the necessary apparatus for pumping sea-water to a basin and an aquarium, as well as with a special sailing boat and all apparatus required for fishing and dragging. During last summer the exploration of the bay and its nearest surroundings proved that both yield rich material for research. The sea-bottom opposite the Dog's Cape of Catherine Island is covered with Lithothamnium, upon which there are many annelids (*Nereis pelagica*, *Glycera capitata*, &c.), numerous worms, the *Cucumaria frondosa* and *C. calcigera*, *Psolus phantapus*, many Ophiuridæ, Planariæ, Nemertinæ, a variety of crustaceans and molluscs, two Actiniæ, one of which is the *Actinoloba dianthus*, the deep-water medusa, *Pectyllis arctica*, and many other forms of life. Altogether it appears that within a distance of less than one and a half miles from the station there is already a deep-water fauna which lives at the comparatively small depth of from 20 to 70 fathoms.

IT has been generally considered that the naphtha wells of the Kuban province of north-western Caucasus take their origin in the Sarmatic and Mediterranean layers of the Tertiary deposits of that region. The mining engineer, W. I. Wind, brings forward (in the *Bulletin* of the St. Petersburg Society of Naturalists, 1904, No. 4) some data tending to prove that naphtha in Kuban originates also in deeper lying Tertiary strata which consist of a dark, almost black clay, containing enormous quantities of remains of fishes (chiefly Meletta), as well as thin layers of carbonised plants.

A NEW instalment of "Flora Caucasica critica," by N. Kuznetsoff, N. Busch, and A. Fomin (fascicules 3 to 6), appears in the *Memoirs* (*Trudy*) of the St. Petersburg Society of Naturalists, vol. xxxii., part iii. A special fascicule of the same volume is devoted to the memory of A. Beketoff, and contains the following works:—"The Influence of the Concentration of Solutions on Respiration and Exchange in Plants," by V. Palladin and Mme. A. Komleva; "The Influence of Wounds on the Formation of Unassimilable Albumens and Nucleo-proteids in Plants," by I. Kovshoff; "The Vegetation of the Povyenets District of Olonets," by E. Ispolatoff; "On the Vegetation Covering the Sands in Taurida," by the same author; "The Influence of Exterior Conditions on the Division of Nuclei in the Roots of *Vicia faba*," by V. Sablin; and "On the Influence of Saccharose on the Respiration of Seeds," by S. Woicehowski.

A NEW edition of Dr. H. R. Mill's "Elementary Class-book of General Geography" has been published by Messrs. Macmillan and Co., Ltd. The book, which first appeared in 1889, was largely re-written in 1900, and has again been thoroughly revised. Recent political changes and colonial developments have been noted, and all statistics have been brought up to date by reference to the returns of the censuses of 1900 and 1901, and to recent official publications.

A SELECTION of the brilliant lectures and essays of the late Prof. W. K. Clifford, together with a biographical sketch of the author, has been published by Messrs. Macmillan and Co., Ltd., in their sixpenny series. In their cheap form these essays and addresses should be widely read, and there is every reason to hope that Clifford's influence will be increased greatly by the publication of his teachings at this small cost.

WE have received from Messrs. John J. Griffin and Sons, Ltd., a copy of a new issue of their illustrated catalogue dealing with apparatus for the study of magnetism and electricity. Among other novelties, particulars of which are given in the catalogue, we notice moving coil voltmeters and ammeters which can be obtained at a reasonable price, and apparatus for showing Prof. Elihu Thomson's experiments on the electromagnetic repulsion between an alternating electro-magnet and a conducting ring. The convenient arrangement of the catalogue and the large number of illustrations it contains should render the publication of real service.

A NINTH edition of the late Prof. Babington's "Manual of British Botany" has been published by Messrs. Gurney and Jackson. The book has been enlarged from the author's manuscripts and other sources. The work of editing the new edition has been done by Messrs. Henry and James Groves. Species, varieties, additional characters and remarks which have been inserted by the editors are printed in smaller type, and where introduced in the text

are enclosed in square brackets. A fresh account of the genus Hieracium has been drawn up by Miss R. F. Thompson and included in the book. A conspectus of the groups and species from the "Handbook of British Rubi," by the Rev. W. Moyle Rogers, has, by permission, been added as an appendix.

SINCE its publication in 1894, Preston's "Theory of Heat" has been regarded as a standard work on the subject. Teachers and students will welcome the new edition which has just been published by Messrs. Macmillan and Co., Ltd. The revision, necessary in view of the recent progress made in this branch of physics, has been done by Mr. J. Rogerson Cotter, of the University of Dublin. Among the changes in the new edition may be mentioned the transference of the section on the dynamical equivalent of heat from chapter viii. to chapter iv., a few unimportant omissions, and the addition of some hundred pages of new matter. The additions have been enclosed in brackets. Mr. Cotter has succeeded in bringing the book well up to date, and in this way has ensured a continued popularity for an excellent treatise.

AN interesting and simple mechanical model devised for the purpose of illustrating to students the gas laws and the nature of Carnot's cycle is described by Dr. F. B. Kenrick in the May number of the *Journal of Physical Chemistry*.

WE have received a copy of the *Chemikalien-Zeitung*, a new journal to be published fortnightly under the editorship of Dr. R. Pauli, Berlin. The journal will be devoted to matters relating to the manufacture and application of chemical substances in the industries. One of the chief objects of the promoters is to produce by means of the fortnightly publication a work of encyclopædic character dealing with this aspect of technical chemistry.

WE have received vol. i., No. 1, of the *Memoirs* of the College of Science and Engineering, Kyoto Imperial University, a publication containing original papers by members of the university. Among other papers worthy of notice are "Synthesis of Indigo and its Methyl Derivatives," by M. Kuhara and M. Chikashigi, and "Defects of Uncarburetted Water Gas as Fuel for Laboratory Use," by M. Chikashigi and H. Matsumoto.

IN the *Physikalische Zeitschrift* (No. 12, 1904), Messrs. Elster and Geitel describe a new form of electroscopic apparatus for the investigation of feebly radio-active bodies. With this a large number of different kinds of earths, minerals, lavas, and water deposits has been examined. The activity of the sedimentary deposits from the hot springs at Baden-Baden is remarkably high, the sludge deposited at the source having approximately the same activity as uranyl potassium sulphate. As the distance of the deposited matter from the source increases, its activity falls off rapidly.

SOME recent experiments by M. Henriet communicated in the *Comptes rendus* (vol. cxxxviii. p. 1272, 1904) show that formaldehyde is present in considerable quantity in the atmosphere. The method of estimation consists in aspirating the air through a tube containing red oxide of mercury heated to 250° in which the formaldehyde is oxidised to carbonic acid, which is then absorbed in potash bulbs. The carbonic acid already present in the original air has to be subtracted from the amount thus found, and the difference corresponds to formaldehyde. In 100 cubic metres of normal air formaldehyde is present to the extent of 2–6 grams.

IN view of the high atomic weight of radium and the remarkable ionising properties of the salts, it would not have been surprising if the electrolytic properties of radium bromide had been altogether abnormal. That this is not the case is clearly shown by the recent measurements of Kohlrausch and Henning, published in the *Verhandlung* of the German Physical Society (vol. v. pp. 144–6, March 15). The electrical conductivity is perfectly normal over the range from N/20 to N/12,000, and closely resembles that of the corresponding barium salt. The molecular conductivity rises from 100·0 to 123·6 over this range of dilution, and the limiting value is given as 125. The mobility of the radium ion is therefore 57 as compared with 56 for barium, and 53 for strontium and calcium. It is of interest to note that Runge and Precht's value for the atomic weight would give an altogether abnormal value, 67, for the ionic mobility.

WE find in the *Bulletin* of the Society of Naturalists of St. Petersburg (1904, No. 3) an interesting paper, by N. Karakash, based on a recent journey of A. Zhuravskiy and on previous exploration, giving some idea about the little known eastern portion of the tundras of Arkhangelsk, which is known as the Bolshezemelsk tundra, and lies between the Petchora and the northern Urals and the Pai-hoi Range. This portion of the tundra has not the flat and marshy character which it has in the west, but it is covered with mounds, hills, and narrow low ridges of Boulder-clay, reaching a height of 100 and occasionally 200 feet, and a length of from 12 to 20 miles. Between these mounds and hills are found countless lakes, marshes, and spaces which can be described as true patches of the tundra. All these hills are undoubtedly of morainic origin, the Boulder-clay having only been washed by water on its surface and covered here and there with sand. As to the boulders, they consist of granites, porphyrites, gneisses, and various metamorphic slates, as also of limestones and sandstones. The latter contain Devonian, Carboniferous, and Carbo-Permian fossils, such as are well known from the western slopes of the Urals, as also Permian and Jurassic fossils, such as are known further south in the basin of the Petchora. Traces of a post-Glacial sea have only been found near the shores, but it is known from the previous researches of Barbot-de-Marny, Tchernysheff and others that large spaces of north-eastern Russia, up to a level of about 120 metres, were covered by the sea during the post-Glacial period.

OUR ASTRONOMICAL COLUMN.

RADIAL VELOCITY OF THE ORION NEBULA.—From the measurement of a series of spectrograms of the three brighter stars in the trapezium of Orion, Messrs. Frost and Adams have determined the radial velocity of those parts of the nebula located by these stars. Seven plates of the star θ^1 Orionis (October, 1903, to February, 1904) gave a mean velocity for the nebula of +19·3 km., three plates (December, 1903, January and February, 1904) of the star Bond 640 gave 18·0 km., and one plate (March 8, 1903) of the Bond star 619 gave +14 km. The general mean was +18·5 km., which is slightly higher than the values obtained by previous observers, *e.g.* +17·7 km. obtained by Keeler in 1890–91. Surprise is expressed as to the low value determined for the last named star, as the plate measured was an exceptionally good one, but the observers hesitate to draw conclusions from the results obtained from one plate.

The radial velocities of the stars themselves were also determined from the dark-line spectra on the same plates, and the provisional values are given for the two Bond stars. Regarding θ^1, the peculiarities of the spectrum and the binary character of the star will necessitate the study of a much greater number of plates before definite values can be obtained. For Bond 640 a mean value of +20 km. was determined, whilst for Bond 619 a value of +48 km., strikingly greater than that of the nebula, was obtained.

The same observers also publish the results of similar

observations of four stars of the Orion type (9 Camelopardi, κ Cancri, μ Sagittarii, and δ^1 Lyræ) which have variable radial velocities (*Astrophysical Journal*, No. 5, vol. xix.).

MASS AND SHAPE OF JUPITER.—At the June meeting of the Royal Astronomical Society, Mr. Bryan Cookson read a paper giving the results of a series of heliometer observations of Jupiter's satellites made by him at the Cape Observatory during 1901–2.

Within two months of the opposition of the planet he made 783 observations of the satellites in distance and position angle. The values obtained for the mass were

$$1 : 1047{\cdot}69 \pm 0{\cdot}09 \text{ and } 1 : 1047{\cdot}66 \pm 0{\cdot}06$$

during 1901 and 1902 respectively. These agree very well *inter se*, but differ considerably from Prof. Newcomb's adopted value of 1 : 1047·35, a difference which has yet to be explained or eliminated.

The value for the compression-constant of the planet was also different from the adopted value, being 11 per cent. greater. As determined in the paper, the ellipticity is 1 : 15·8, but direct measurements of the equatorial and polar diameters gave 1 : 16·5. Part of this difference may be real, but part may be due to the difficulty experienced in measuring the planet's diameter (*Observatory*, No. 346).

"REVERSALS" IN SUN-SPOT SPECTRA.—In a paper appearing in No. 5, vol. xix., of the *Astrophysical Journal*, Mr. W. M. Mitchell, of the Princeton (N.J.) Observatory, publishes the results of four sets of observations, made during March and April with a Rowland grating spectroscope (20,000 lines) attached to the 23-inch refractor of the Halsted Observatory, of the lines reversed in sun-spot spectra in the region λ 6770 to λ 4915. The number of lines more or less affected in this region was more than 270, and Mr. Mitchell gives a table containing about 70 lines which were found reversed, and 6 lines which were thinned. In the region C–D about 35 per cent. of the lines affected were seen reversed, whilst for a further 5 per cent. the appearance of reversal was too uncertain to give definite results. The C line was observed partially reversed on April 8, but the *b*, E, and D groups were never affected. D_3 was not seen at all.

ESCAPE OF GASES FROM THE EARTH'S ATMOSPHERE.—In a communication to the *Philosophical Magazine* (June, 1904) Dr. Johnstone Stoney directs attention to a recent letter from Mr. S. R. Cook, published in NATURE (March 24), on the "Escape of Gases from Atmospheres." After stating that he arrived at the same conclusion as Mr. Cook, by the same methods, thirty or forty years ago, and has since had to abandon that conclusion, Dr. Stoney shows that the flow of helium from springs into the earth's atmosphere is from 3000 to 6000 times more than can be accounted for by the minute quantity dissolved by the rain in falling, yet the relative quantity of helium in the atmosphere apparently remains constant. Therefore, he says, helium *is* escaping from the atmosphere, the rate of escape being equal to that of the influx. Further, Dr. Stoney also shows that theoretically the conditions under which the flights of gaseous molecules take place in the upper atmosphere sufficiently explain the outflow, as it would only be necessary for the chance of escape for each molecule to occur once in several days in order to account for the amount received by the atmosphere from the earth.

FORTHCOMING RETURN OF ENCKE'S COMET.—In No. 6, vol. i., of *Knowledge and Illustrated Scientific News*, Mr. Denning publishes a few notes in reference to the return of Encke's comet during the coming autumn. Due at perihelion on January 4, it should be observable in large telescopes about August or September, and will be nearest the earth, at a distance of about 35,000,000 miles, in the third week in November. On October 4 it will apparently be about half-way between β Andromedæ and α Trianguli, thence, travelling westward, it will arrive at about 5° N.E. of β Pegasi on November 1.

The present period, according to Prof. Seagrave, is about 1206d. 20·25h., and during the coming apparition the favourable conditions of 1805, 1838, and 1871 (period 33 years) should be repeated. It is possible that early in December, when close to Altair, the comet may be visible to the naked eye.

THE UPPER CHALK OF ENGLAND AND ITS ZONES.

WE have received two important contributions to our knowledge of the Upper Chalk in this country. The one on "The Upper Chalk of England" is the third and concluding volume of Mr. Jukes-Browne's memoir on the Cretaceous rocks of Britain, issued by the Geological Survey (price 10*s*.). It is a goodly volume of 566 pages, in which the stratigraphical features of the Upper Chalk and the fossils of the successive zones are very fully dealt with. As in previous volumes, Mr. William Hill has contributed particulars of the microscopic structure of the Chalk. The ample topographical and palæontological descriptions of the Chalk will enable the student readily to ascertain what is known, and the author has been fortunate in being able to embody the results of a great part of the recent work accomplished by Dr. Rowe. In one chapter he discusses the bathymetrical conditions during the formation of the Upper Chalk, pointing to facts presented by the Chalk rock-beds which indicate a general upheaval of the British area. Later on, during the period of the Micraster and Marsupite zones, evidence of subsidence is afforded, and this was probably succeeded by re-elevation during the time of the Belemnitella zone. This volume contains a general account of the economic products of the Chalk, including water-supply, and reference is made to the bournes or nail-bournes, notable examples of which, as at Croydon and elsewhere, have recently manifested themselves. The Chalk escarpments and other features of Chalk districts are described. There is also a general list of all the known fossils from the Chalk of England, with references to zones and localities, and there is a full bibliography. Mr. Jukes-Browne is to be congratulated on the completion of this exhaustive work. We only wish that it had been somewhat better illustrated.

Turning to the other work, "The Zones of the White Chalk of the English Coast, part iv., Yorkshire," by Dr. Arthur W. Rowe, we find a work of a little more than a hundred pages, with twenty-two beautiful photographic plates and other illustrations, issued by the Geologists' Association (vol. xviii., part iv., price 3*s*.).

The previous portions of Dr. Rowe's work on the zones in Kent and Sussex, in Dorset and in Devon, have been already noticed in NATURE. The present part is the result of "42 days of steady work" on the cliff-sections and adjacent chalk-pits of the coast near Flamborough Head. The time seems limited (as the author observes), but as he went fortified with the accumulated knowledge and experience of many years' assiduous study, and was accompanied, as before, by Mr. C. D. Sherborn, he was ready and able to make the fullest use of his time. When he refers to the region as "a veritable *terra incognita*" we can hardly agree with him, despite his own saving clauses. But that he has enriched our knowledge to a very large extent, as he invariably does, was inevitable, and all geologists will rejoice.

The essay itself fills the reader with enthusiasm, for it is written with vigour and with a heartiness that is contagious. The work proved less easy, though not less interesting, than was anticipated. The record of the fauna was found to constitute "a veritable zoological romance."

It was "wholly impossible to institute any valid comparison between this marvellous coast and any of the sections which we had previously described." The variations in the distribution and range of the species, the rarity of zonal guide-fossils, the hardness of the rocks, to say nothing of the difficulties of getting at the strata, were alike remarkable. At the same time the results of Dr. Rowe's work afford "overwhelming proof of the validity and homogeneity of the zonal theory," and we cordially commend the work to all students. In an appendix Mr. G. W. Lamplugh contributes some notes on the conditions of accumulation of the Yorkshire Chalk, and refers to the finding of an ammonite, 3 feet in diameter, beneath which was an agglomeration of small fossils, evidently protected from decay by the huge ammonite. He remarks that a considerable portion of the Chalk was probably due to the pulping-down of calcareous bodies by lowly organic agencies. Referring back to Mr. Jukes-Browne's volume

(p. 343), we learn also from Mr. W. Hill that "As a whole the amorphous material of the Upper Chalk appears to be made up almost entirely of the débris of calcareous organisms."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Dr. Harold A. Wilson has been elected senior lecturer in physics at King's College, London, and Mr. S. C. Laws junior lecturer.

On July 27 Sir Thomas H. Elliott, K.C.B., Secretary to the Board of Agriculture, will open the extensions of the Midland Agricultural and Dairy Institute at Kingston-on-Soar.

Prof. Chantemesse has, at his own request, been transferred to the chair of hygiene at the University of Paris, vacant through the death of Prof. Proust. The chair of experimental pathology thus vacated has been filled by the appointment of Dr. Roger to succeed Prof. Chantemesse.

We learn from *Science* that Mrs. Henry Whitman, of Boston, has made public bequests amounting to more than 40,000*l.*, including 22,000*l.* to Radcliffe College and 2000*l.* to Harvard University; and that Mr. George Ehret, of New York, has given 2000*l.* to the permanent fund of Hamilton College.

Mr. H. A. Clark, late assistant lecturer in engineering at the University of Leeds, has been appointed head of the engineering department of the Northern Polytechnic Institute, London. Mr. Clark was Ramsbottom scholar at Owens College, Manchester, a Whitworth scholar, and is an associate of the Royal College of Science.

The first annual report of the University Extension Guild has now been published. The object of the association, which was founded last December, is "to promote among all classes, at times convenient to all, the extension of university teaching." The report states that the work accomplished and the influence exerted by the guild have been considerable, and give great hopes of success in the future. The honorary secretary of the guild is Mr. Max Judge, 7 Pall Mall, S.W.

The Montgomery County Council recently discussed a resolution, passed at the Swansea conference of county council delegates, recommending to county councils the establishment of schools of forestry, and the giving of grants to existing colleges. The chairman said all are agreed that planting is a very desirable agricultural improvement, and that the management of woods in many cases leaves much to be desired. It would be, he continued, for the advantage of the country if the council provided forestry instruction in addition to the instruction they had provided in other branches of rural pursuits, and at his suggestion delegates were appointed by the council to attend a conference to be held for the purpose of discussing the question.

The Prince of Wales, who was accompanied by the Princess of Wales, on July 16 laid the foundation-stone of the new buildings of the Working Men's College, which was founded by F. D. Maurice. The plans of the new buildings show a hall to accommodate 250 persons, common rooms, club rooms, and gymnasium for the students, a library fitted for 10,000 books, and a museum. There are added electrical and chemical laboratories, with which the old college was not equipped. Altogether there is teaching space provided for 700 students. Replying to an address—read by the principal of the college, Prof. A. V. Dicey—the Prince of Wales expressed his cordial sympathy with the aims and objects of the college, which are to bring within reach of the working classes the means of knowledge and culture. As the Prince of Wales said later, "the Working Men's College has seen its aims fulfilled and its pioneer work taken up and extended by those numerous and great institutions for commercial and technical instruction which have been established in the capital and in all parts of the Empire."

The importance of establishing a national school of forestry was recently urged by the Association of Chambers of Commerce. The following reply has been sent to the association by Sir Thomas Elliott, on behalf of the Board of Agriculture:—"The President of the Board of Agriculture and Fisheries fully recognises the importance which attaches to the question of afforestation and to the provision of a national system of instruction in forestry. Steps have already been taken in more than one direction to give effect to the recommendations of the departmental committee which was appointed in 1902, under the chairmanship of Mr. R. C. Munro Ferguson, M.P., to inquire into the subject. Through the agency of the Commissioners of Woods and Forests a school of forestry has been established in the Forest of Dean, and a movement is on foot for securing a suitable area of land in Scotland for the purpose of demonstrating scientific forestry. The Board has taken steps to secure the establishment of at least two lectureships in forestry in England, and some of the leading universities and agricultural colleges have been giving attention to proposals under this head. The agricultural departments of the University College of North Wales, Bangor, and of the Durham College of Science, Newcastle-upon-Tyne, appeared to offer special advantages as centres of instruction in forestry, and grants in aid of the establishment of schemes of education in the subject will be made by the Board to those institutions. The Board hopes that the arrangements thus made will result in a considerable improvement of the facilities available in this country for the acquirement of a knowledge of practical forestry."

The following are among the awards of Carnegie research fellowships, scholarships, and grants for the academic year 1904–5, under the Carnegie trust, for the universities of Scotland:—Fellowships.—*Physical*, D. B. McQuistan; *Chemical*, C. E. Fawsitt, Dr. J. C. Irvine, W. Maitland; *Biological*, J. Cameron, Dr. F. H. A. Marshall, H. J. Watt; *Pathological*, C. H. Browning, J. C. G. Ledingham, S. A. K. Wilson. Scholarships.—*Physical*, P. D. Innes, H. W. Malcolm, J. H. Maclagan Wedderburn, J. R. Milne; *Chemical*, Adam Cameron, W. A. K. Christie, F. W. Gray, J. Johnston, F. J. Wilson, J. Wood; *Biological*, Margaret T. Hamilton, W. D. Henderson; *Agricultural*, S. F. Ashby, C. Carter; *Physiological*, J. S. Rose; *Pathological*, C. M. Campbell, R. D. Keith, W. G. Rodger. Grants.—*Physical*, G. A. Carse, Prof. MacGregor, T. Oliver, W. Peddie; *Chemical*, Prof. G. G. Henderson and Dr. Gray, Dr. A. N. Meldrum; *Biological*, Dr. J. H. Ashworth, Dr. J. Beard, Cyril Crossland, Prof. J. Cossar Ewart, Prof. Paterson, Dr. John Rennie, W. G. Smith, Dr. D. Waterston, Dr. J. H. Wilson, Prof. R. Patrick Wright and A. N. M'Alpine; *Anatomical*, E. B. Jamieson; *Pharmacological*, Prof. R. Stockman; *Pathological*, Dr. J. K. Love, E. Bramwell, Prof. Carstairs C. Douglas, A. H. Edwards, Dr. A. Goodall, J. M. Kirkness, Prof. Robert Muir, Peter Paterson, W. B. Inglis Pollock, B. P. Watson, Dr. J. M. Bowie, Dr. James Scott, D. C. Watson. The twenty-four scholarships, twelve fellowships, and thirty-five grants awarded for 1904–5 amount in all to 5300*l.* The amount expended by the trust under this scheme for 1903–4 was 3400*l.*

SOCIETIES AND ACADEMIES.

London.

Royal Society, May 19.—"On the Liquefied Hydrides of Phosphorus, Sulphur, and the Halogens as Conducting Solvents." Parts i. and ii. By D. **M'Intosh**, B. D. **Steele**, and E. H. **Archibald**. Communicated by Sir William Ramsay, K.C.B.

In this paper the behaviour of phosphuretted hydrogen, sulphuretted hydrogen, hydrogen chloride, bromide, and iodide as conducting solvents has been investigated, and, in order to try and explain certain abnormalities in the variation of conductivity with concentration of their solutions, the following physical constants have been determined. (1) The vapour pressure curves from which the melting and boiling points are obtained. (2) The densities at various temperatures. (3) The molecular surface energies; from these it is seen that the hydrides of phosphorus and chlorine when liquefied are more or less associated to form complex molecules, whereas the remaining compounds occur as simple molecules. (4) The viscosity temperature coefficient. This was measured in order to compare with

the temperature coefficient of electrical conductivity. (5) Solubilities and conductivities. A large number of substances were examined, and it was found that many organic compounds containing oxygen or nitrogen dissolved readily in HCl, HBr, HI, and H_2S, and formed solutions which conducted well.

Inorganic substances, on the other hand, did not dissolve, or if so only in the merest traces. An exception to the latter generalisation occurs in the case of H_2S dissolved in HBr; these liquids mix in all proportions, but the mixture does not conduct the current.

June 16.—"On Flame Spectra." By Charles de Watteville. Communicated by Arthur Schuster, F.R.S.

In order to obtain the spectrum of any substance, it has generally been considered sufficient to introduce a small quantity of it into an already formed flame. In the course of a photometrical investigation of flames which had been coloured by injecting the spray from saline solutions into the gas to be burnt, M. Gouy discovered in the spectra of the flames several new lines belonging to the metal contained in the solution (*Annales de Chimie et de Physique*, 5th series, vol. xviii., 1879). Instead of appearing throughout the whole flame, as did the previously known lines, these new lines were only emitted in the vicinity of the inner blue cone—the origin of the Swan spectrum.

The method employed by the author is, in short, that which has been introduced by M. Gouy.

The lines in the spectra obtained under the conditions of his experiments are very much more numerous than is the case when all the portions of the flame do not participate in the production of the phenomena. Moreover, the flame spectra extend sufficiently far into the ultra-violet in order to enable the line 2194 of tin to be observed.

The lines which are found in the flame spectrum are those which are the strongest lines in the arc spectrum. In certain cases, some of the more intense arc lines are absent, whereas less intense arc lines are to be found in the flame spectrum. On the other hand, none of the characteristic lines of the spark spectrum are ever seen in the flame spectrum.

There is a most striking similarity between the flame spectra of iron, of nickel, and of cobalt, and the oscillatory spark spectra of the same metals in the region included between about 4300 and 2700 Angström units. The similarity of the two spectra is so great that, except for very small differences of intensity, the oscillatory spark spectrum, which is photographed as a comparison spectrum in the centre of the flame spectrum, appears to be a prolongation of the latter. In the ultra-violet the spectrum of the flame appears to fade away a little more rapidly than that of the oscillatory spark, but it is probable that this difference would be reduced by prolonging the time of exposure, since it is, of course, the radiations of the shortest wave-length which are most absorbed by different media.

It is very probable that the reason for this similarity between the spectrum of the flame and the spectrum of the oscillatory spark is entirely a question of temperature. On the one hand, the increase in the number of lines of the flame spectrum obtained by the use of the sprayer may be attributed to the fact that the hottest regions of the flame take part in the production of the phenomena, and, on the other hand, the diminution in the number of lines in the spark spectrum when the spark becomes oscillatory is due to a diminution of its temperature.

NEW SOUTH WALES.

Royal Society, May 4.—Prof. F. B. Guthrie, president, in the chair.—Prof. F. B. **Guthrie** delivered the presidential address, in which he gave a *résumé* of the condition of chemistry and chemists in the State. Of the teaching institutions, the university made ample provision for teaching chemistry; about 300 students were in attendance at lectures, and about 150 doing practical work in the laboratories. In conclusion, stress was laid upon the necessity for centralising chemical research work. At present there existed the opposite tendency—to decentralise it as the departmental work grew. Personally, he would like to see established a central scientific institute, where all the scientific work could be conducted. Failing this, a great deal could be done in consolidating scientific work and increasing its efficiency by the creation of a controlling science department, which would administer the different scientific establishments under departmental control. This would be of great advantage in research, especially where it required the cooperation of more than one branch of science. Investigation into subjects of national importance could then be carried out in continuity.

June 1.—Mr. C. O. Burge, president, in the chair.—Possible relation between sun-spots and volcanic and seismic phenomena and climate: H. I. **Jensen.** This paper is a sequel to the author's note communicated to the Royal Society of New South Wales on June 4, 1902. The paper is divided into two parts. In the first part it is shown that while there has been a marked rise in solar activity since the middle of 1902, seismic and volcanic disturbances have fallen off on the earth, both in violence and frequency, almost to a minimum. In the second part of the paper various sun-spot and meteorological theories are considered. The climates of Australia and Mauritius are discussed, and the occurrence of heavy rains at sea during drought periods, the retreat of glaciers during cold winters, and the diminution in the number of cyclones during sun-spot minima are ascribed to the same cause, namely, the feebler circulation of the atmosphere due to the diminution in the amount of heat received from the sun during sun-spot minima. An index to literature and tables of earthquake and eruption statistics follow.—On the absence of gum, and the presence of a new diglucoside in the kinos of the Eucalypts: H. G. **Smith.** In this paper, which is the first of a series dealing with Eucalyptus kinos, the author shows that the supposed gum occurring in many Eucalyptus kinos is not gum, but a peculiar tannin diglucoside.—On some natural grafts between indigenous trees: J. H. **Maiden.** The author obtained from George's River a composite log which in bark and timber showed the absolute fusion of white or cabbage gum (*Eucalyptus haemastoma*, variety *micrantha*) and stringybark (*Eucalyptus capitellata*). The red timber of the former contrasts well with the pale brown of the latter, and the fusion of the two timbers is perfect. Such instances of the organic union of two species of the same genus have been rarely recorded.

THE GEOLOGIST AS GEOGRAPHER.

North America. (The Regions of the World Series.) By Prof. Israel C. Russell. Pp. viii+435; 7 coloured maps and 39 other illustrations. (London, Edinburgh, and Glasgow: Henry Frowde, 1904.) Price 7*s.* 6*d.* net.

THE geologist might well rest content with the usefulness of his science even if its only harvest were the revolution which it has wrought in man's conception of his mundane surroundings as expressed in the new geography. It may be that here and there the geographer still lingers who is satisfied to bound his ideas at the surface of things and to lose hold of reality in his dream of eternal seas and everlasting hills. It is true that the old geography still persists in children's school-books as ancestral customs still linger in children's games, and that the delineation of county boundaries and the names of obscure villages are still drilled painfully into the youthful mind as essentials of earthly knowledge. But the antique trammels have at least been loosened; and not in the Americas only is it that a new world has been discovered by the geographer.

We could not wish for a better exemplification of new spirit than may be found in the lucid description of a great continent which lies before us. Prof. Russell quotes with approbation the saying that "geography is the geology of to-day," and throughout his book we are made to feel that in its every aspect the present condition of the land is the evanescent expression of all preceding time. It is not without cause that "prehistoric" time is relegated, in his chart on p. 309, to the period preceding the Archæan, and that from the beginning of geological evidence he regards all time as historic.

To the geologist the sea is only land inconveniently covered by water, and we are therefore prepared to find that Prof. Russell's idea of the North American continent is not bounded by the coast-line, but includes the submerged "continental shelf." The first chapter of his book deals with this shelf, its structure, its river valleys, its marine life and its geological history, with that of the land margin by which it is bounded.

Then, in chapter ii., the topography of the land is described under the broad headings of (1) coastal plains and plateaus; (2) Atlantic mountains; (3) continental basin; (4) Pacific mountains; (5) Antillean mountains. This part of the book is vitalised by the author's wide personal knowledge of the continent, gained in the service of the U.S. Geological Survey, and by his keen sympathy in wild nature. With vivid touches of description, sure and true, and free from the cloying sentiment by which such attempts are too often overclouded, he brings before us the feeling aroused in him by the varied scenes of the wide continent. There are many passages which we should have liked to reproduce, but, lacking space, we must content ourselves by referring, as examples, to the bird's-eye view of the prairie plains (p. 97); to the expression of their straining monotony (p. 103); to the sketches of the fantastic Bad Lands (p. 111), of the glorious summits of the Californian Sierra (p. 151), and of the dense forests around Puget Sound (p. 240).

The third chapter deals with the climate of the continent, and, like every other part of the book, goes back to first principles in the course of the exposition, so that the untrained reader may gather much general as well as special knowledge by a studious perusal of it. We imagine that if the writer had been a Canadian his southern boundary for the "boreal zone," as shown on the map, plate iii., would have been somewhat differently arranged, and that it would not have included Vancouver Island and the coast of British Columbia, nor have divided Manitoba from the greater part of North Dakota. The description of the agriculture of this zone is contained in the following sentences:—

"On account of the low mean annual temperature [of the northern portion of the zone], and especially because of the shortness of the growing season, agriculture is of small importance. Along its southern border, more especially in south-eastern Canada and Newfoundland, such small fruits as currants, huckleberries, raspberries, blackberries, cranberries, &c., grow wild and yield abundant returns when cultivated. In favoured localities white potatoes, turnips, beet, and certain varieties of the apple, as well as the more hardy cereals, are cultivated with moderate success" (p. 202).

As practically the whole of Canada, except small portions of the south of Ontario and Quebec, is relegated to this zone, the above statement is decidedly inadequate. We notice also that in the margin of the map referred to there is a letterpress indication to symbols which are not visible on the map.

The plant life of the continent is described in chapter iv., wherein the characteristic features of the great forests, the cactus plains, the treeless prairies, the sage-brush lands, and the Arctic tundra are in turn presented. In this part we recognise that the author shares the repugnance felt by every good American to the term "desert" as applied to the arid lands of the western States. So, in the map which forms the frontispiece to the volume, all the sage-brush and cactus country is swept into the "grassland" division, to which term, however, the qualification, "partly with Scrub, &c.," is added in the index. Yet, even allowing for the potential irrigation of limited oases in the future, there are vast stretches that must remain, as at present, worthy only of the name of desert, and such herbage as they have is desert-herbage. In concluding his account of the plant life, the author refers briefly to the slow migration of forests under geological changes of climate by which nature, like a careful husbandman, secures a rotation of crops.

"The suggestion in this connection furnished by geologists is that we are living in a spring-time following the great winter, known as the Glacial epoch, and that the tropical, temperate, and subarctic forests are migrating northward in an orderly march, and each in turn ascending higher and higher on the more lofty mountains" (p. 257).

The discussion of the animal life occupies another chapter (v.), and here we are given a succinct account of the life-regions and life-zones, with lively descriptions of the best known representative mammals, in which again it is shown that America is or was blessed by the abundance of large herbivores and the rarity of dangerous carnivores. And how ill she deserved the blessing is also shown.

As for the birds, why!—"when one attempts to write an account of the birds of North America, the heavens seem darkened with such a multitude of varied and beautiful forms and the air filled with such a discordant clamour mingled with the sweetest of music that failure to convey an adequate idea of the countless numbers and diversity of the feathered throng within the compass of a few pages must be recognised from the start"!—wherein, somehow, we feel that The Eagle, for once, has flapped his wings.

Chapter vi., describing the geology of the continent, is the longest in the book. It claims, and defends the claim, that North America should be regarded as "the most typical" of all the continents by reason of its comparatively steady growth from one main nucleus and the resultant simplicity of its general structure. An outline of its evolution from the earliest recorded time is presented, with the inevitable incidental exposition of the fundamental principles of geology; the relation of the past to the present is clearly brought out; and the mineral resources of the continent, but more especially of the United States, are somewhat fully reviewed.

Then follows a chapter (vii.) on the aborigines, in which the author guardedly agrees with Powell "that the primordial occupancy of the continent antedates present geographical conditions, and points to a remote time which can be discovered only on geological and biological investigation" (p. 357), and he states the lines of evidence which have led to this provisional conclusion. The sad history of the outcome of the European invasion upon the original inhabitants, whether Eskimo or Indian, is briefly retold, and it is acknowledged that the Canadian Government has been less unsuccessful than that of the United States in its dealings with the natives; but the whole record is pitiful.

It is mentioned in the preface that much curtailment was found necessary in the treatment of the economic phases of geography, and in a foot-note, reference (p. 408) is made to the omission, through exigencies of space, of chapters that had been written on the geography of fisheries, forestry, mining, commerce, agriculture, &c. As it stands, the book is so full of information that he will be indeed a hardy reader who can assimilate all that is provided and still desire more. The volume concludes with a short chapter (viii.) on political geography, and in the footnote already referred to it is explained that space has been found for this part "for the reason that it presents a view of political adjustments not usually taken and in a way perhaps pessimistical, which may awaken opposition." The different kinds of political boundaries to be found on the continent are then considered, and a lament is raised that so many of the boundaries should be arbitrary where the conditions were so favourable for an ideal subdivision of territory. Here once more the wings of The Eagle are spread. The essential conditions of an ideal nation are defined (p. 421)—conditions that naturally find their fulfilment in the United States. Then (p. 423):—

"In North America, perhaps, several such eligible sites for a definite number of people might be chosen, but in no case without the drawing of unnatural boundaries. The continent, as is shown by its geology and geography, is a unit, and the most typical of comparable size of any on the earth. These same conditions point to a single political unit. Arguing from geographical relations simply, and not considering the racial differences and local self-interests, the one boundary in North America should be the shore boundary, except at the 30-mile-wide Isthmus of Panama."

In illustration of this chapter, a coloured map is given, showing in vividly contrasting pink and blue the areas respectively under "two radically different principles of government—the monarchical and the republican," or "the countries self-governed" and "those still acknowledging allegiance to hereditary rulers."

But surely there is a touch of unscientific prejudice in the insistence upon this distinction. Is not the Government of Canada to all intents, except in name, as purely democratic as that of the States—nay, is it not even more democratic when we take count of the political state of the negroes, the Indians, and the Chinese immigrants south of the border? And shall San Domingo and the Central American "republics" bear the colour of Freedom on the map which is denied to the Dominion?

Throughout the book we find that the author is at his best when describing those portions of the continent which lie within the States, but this is pardonable, or even commendable, since he is thus the better able to give the acceptable tinge of personal experience to his descriptions. Nevertheless, it is probable that Canadian geographers will feel that the background of the picture is sometimes a little out of perspective. Certainly they will object that the name of their charming mountain-resort Banff should be spelt *Bamf* (p. 126). G. W. L.

TWO METHODS OF DEFENDING FREE TRADE.

The Return to Protection. By William Smart, M.A., D.Phil., LL.D., Adam Smith Professor of Political Economy in the University of Glasgow. Pp. x+284. (London: Macmillan and Co., Ltd., 1904.) Price 5*s*. net.

Free Trade. By the Right Hon. Lord Avebury, P.C. Pp. x+164. (London: Macmillan and Co., Ltd., 1904.) Price 5*s*. net.

NOW that everyone has made up his mind as to the advisability or not of an alteration of our fiscal policy, and the question is relegated to the

political arena to be settled by political methods, it seems unnecessary to recapitulate arguments which should be familiar, and we may be content to refer readers to Lord Avebury's "Free Trade," where they will find two chapters of the "Essays and Addresses" recently reviewed in NATURE expanded and brought up to date. In it are many illuminating, if familiar, statistics and telling arguments for use by the convinced free trader; but it is not likely that a tariff reformer will be influenced by these, for it is quite obvious that his case is neither understood nor met. It is no use to repeat that we have progressed wonderfully since 1846, when the whole argument of the reformer is that the continuance of this progress is threatened. It is quite time that free traders realised that a picture of the distress prevalent in the 'thirties does not carry conviction to those who say that free trade has been good, but there are now changed conditions and a better way. This position is not essentially absurd, and Lord Avebury's arguments, loose and inconclusive as they are in many cases, will not affect it.

On the other hand, no tariff reformer can afford to neglect Prof. Smart's argument. It would not have been surprising if, after fifty years' almost unquestioned acceptance in Great Britain of the principle of free trade, those to whom it had become axiomatic had been found unprepared to meet a sudden attack from new quarters, and with quite unusual weapons. It would be idle to deny that the attack has been sharp, that the defenders have learnt much, and that economic science has benefited by the examination, revision, and modification of its doctrines. No one can now speak on the subject of foreign trade or tariffs without a careful analysis of the possible effects of the sudden changes artificially introduced by the policy of foreign nations or of combined capitalists. Prof. Smart is one of those found ready to meet the attack, and tariff reformers will find it difficult to move him or the readers of his book except by the hard blows of rigid and convincing logic.

For future readers there is a delightful note in the preface that the book "was written during the universal discussion which accompanied and followed Mr. Chamberlain's propagandism of Preferential Tariffs, and Mr. Balfour's advocacy of Retaliation." It may be hoped that the implied prophecy will be fulfilled, and that the book may occupy a permanent place as the best statement of the case for free trade in 1904. Perhaps because Prof. Smart was "a Free Trade manufacturer in this country, and a Protected manufacturer in the United States," before he became a teacher, his writings are always marked by a simple practicalness as well as by lucid reasoning. There is an almost complete absence of the use of technical terms, but without them it is found possible to disrobe arguments in favour of this or that modification of freedom of trade of their speciousness, and to show exactly in what circumstances they are true. Prof. Smart finds the most deeply rooted reason of the very general (foreign) approval of protection in the idea that "the continued existence of a nation, as a nation, depends on its finding employment for its own people." No proof has ever been offered either from theory or statistics that protection regularises the demand for labour, whether permanently by stereotyping an existing division of labour, or temporarily by diminishing the amplitude of the fluctuations related to the periodic ebb and flow of commercial credit. It is true that when an industry is well established, capital invested and labour specialised, much temporary loss may ensue if a sudden artificial diversion of the channels of trade is made, and it often appears that this might be met by protection; and it is certain that a sudden removal of protective barriers, already existing, would be disastrous. Backed by such reasoning, there is always a strong minority in favour of protection, just as there used to be strenuous opposition to the introduction of machinery, while the uncombined majority of consumers is often mute. This line of argument at best supplies a case for specific and temporary protection, and is completely dealt with by Prof. Smart when he shows that as a matter of history it has not proved possible to restrict protection to any point that economic science might assign.

"When a Government once adopts the protectionist faith, it is driven by force of circumstances, not to select and categorise, but to tax everything; and when it tries to let in some things free, or at a reduced rate, is met with a storm of opposition from hundreds of vested interests."

Without assenting to or denying the plea that protection can be advantageous in some cases, it is shown that practically vested interests are established, and that science gives way to political exigencies, a condition in which the pushful and unscrupulous succeed better than the deserving.

The treatment of the possibility and use of retaliation is marked by similar appreciation of the reasons alleged in its favour, and practical examination of its difficulties in detail. In the absence of any specific proposals, it is always open to a retaliator to say that the plans analysed are not the ones in question, but most of the possible cases are considered, and the special difficulties in England's way are shown.

"So far as I can see, the only part of Retaliation for which we are prepared is the threat of it. So great is the power of the British Lion's roar that it even seems enough to show that he is opening his mouth ominously. Suppose the other beasts of the forest do not fall down and creep to his feet, what then? Would it not be better to change his mind? It will scarcely be dignified to pretend that he was only going to yawn."

Prof. Smart admits the possibility of dumping, but considers that its extent is much exaggerated, that in the nature of things it is temporary, and that there is no practical remedy. The reader is left with the impression that a remedy would not be refused on any pedantic grounds if a strong case were made out. The absence of pedantry, and the broadness of view which marks the whole book should make it at the same time of great service to the hot-headed free trader, and a not disagreeable corrective to the tariff reformer who is not too sure of his ground.

A. L. B.

PLACE-NAMES OF SCOTLAND.

Place-names of Scotland. By James B. Johnston, B.D. Second edition. Pp. cxi+308. (Edinburgh: David Douglas, 1903.) Price 6*s.* net.

THE author of this work aims to do for Scotland what Dr. Joyce in his "Irish Names and Places" has already done for Ireland. It is a laudable attempt and one that is full of interest. Not only do we get here an alphabetical list of a large number of the place-names of Scotland, with explanations of their origin, but introductory chapters dealing at some length with the different sources from which have sprung the characteristic names of North Britain. Thus Mr. Johnston gives an account of the Celtic, Norse, English, Roman, Norman, modern, and ecclesiastical names, aiming to make his treatment of the subject no mere dilettante trifling, but a work based on historic evidence. He has in many cases ransacked old books and documents to get the older forms of the words as a guide to their original meaning, and this is really the most valuable part of the task he has undertaken. Had he consistently followed out his own principles enunciated in the introduction, his work would have been of a much higher order and free from the defects which too obviously encumber it. As it is, many of his derivations are quite as fantastic as the "mouth-esk-burgh" for Musselburgh, which by the laws of phonetics he solemnly rejects.

The real reason for the inequalities which even a second edition of the book, after twelve years' interval, has failed to remove is the author's inadequate acquaintance with the Gaelic language. As he admits himself, the Celtic names constitute the largest and most complicated portion of his task.

"The Celt's warm, emotional heart loved to seek out the poetry and colour in the world around, and many of his place-names show that 'stern nature was his daily companion, and friend.' Indeed, the majority of Celtic names give either the simplest possible description of the site named, or describe some prominent feature, or else the colouring or appearance of it as it strikes the eye."

In view of this, it is obvious that a thorough knowledge of the original language spoken in the country, as well as of the topography, is essential to the writer who would adequately discuss the meaning of the place-names; without it there must necessarily be much juggling with words.

If Mr. Johnston really knew the Celtic laws of aspiration and eclipsis, he would never say that the Gael loves to speak of the "Shawms of David," nor would he, when deriving Nairn from G. an earrann, find it necessary to suppose that Auchenairn must be Auchencairn through loss of c. Clachnaharry is clach na h'aire, "stone of watching," and yet he cannot think what Altnaharra is unless allt-na-charraigh, "stream with the pillar or rock," or from marbhaidh, "of the slaughter."

Allt, which is a streamlet passing through a ravine, he interprets sometimes as a glen or river. Kil, so common in the place-names of Scotland, becomes at one time cill, church, at another caol, narrow, again cul, back, and yet again coille, a wood, in the most arbitrary fashion. Auchter suffers in the same way, being uachdar or achadh just as suits his fancy. Take the three words ending in ellan. Killellan, we are told, is "church of St. Fillan," Inellan, en eilean, "bird-island," Balmaclellan, "village of John Maclellan." On the same principle Balmaghie becomes in this book "village of Macghie," whereas it more probably means "wind-swept town," like Tonderghie, not far away from it, which means "back to the wind." Another form of the word, Balmuchie, ludicrously appears as "the house or farm of swine." Banavie, he says, is probably not the "Vicus Bannavern" of St. Patrick's birth; why *probably* in a matter so entirely certain by every form of evidence?

Mr. Johnston says "every 'ness' is Norse, this being the Icel. nes, Dan. Naes, a nose," and he admits that it may be traced in names like Stromness and Deerness. Yet when he comes to Alness he has recourse to the extraordinary derivation G. ath'n-innis, "ford of the island" (the Black Isle). It would indeed take as violent a stretch of imagination to suppose that the Cromarty Firth was fordable at Alness as to imagine that Rogart means "red enclosure," "from the Old Red Sandstone here." As a matter of fact there is no Old Red Sandstone there, only granite. But these derivations are no less ingenious and far-fetched than that for Belleville, near Kingussie, which in a footnote Mr. Johnston says is in G. bail-a-bhile (*sic*), "village at the brae-top." Who with any claim to Celtic literary knowledge does not know that Belleville is the name which James Macpherson of Ossianic fame gave to the house which he built in the eighteenth century, thus superseding the former name of the place, which was called Raitts? No Highlander would translate allt grad as "*ugly* burn," or write achadh *tu*as for "field above" as the derivation of Auchtose. Ptolemy in his ancient map did not apply the name Varar, as here alleged, to the Moray Firth, but to the estuary of the Farrar, now the Beauly.

Many of the most beautiful ancient names in the country, such as the names of farms, little hills, lochs and rivulets, as well as hundreds of names beginning with prefixes such as tigh, allt'tobar, Ceann, Cnoc, &c., are left wholly untouched. One wonders on what principle the author selects some of the names he inserts and omits others. There are not more than about 500 names worthy of note in his own county of Stirling, he says. Why! there are almost as many in many a parish.

Yet for all its defects Mr. Johnston has written a book which is a good foundation for a better, and will have a fascination for a great many people, and it is quite true, as he says, that the historian, the philologist, the antiquarian, and the anthropologist will, each and all, find in it sidelights both helpful and interesting.

AN IMPRESSIONIST TEXT-BOOK OF PAPER MAKING.

Chapters on Papermaking. Vol. i. By Clayton Beadle. Pp. 151. (London: H. H. Grattan, 1904.)

THERE is a "mission" for science in relation to industry which is to re-infuse into its reiterated routine operations that measure or kind of interest which we know as "intelligent." Our factory workers are not the craftsmen of the past centuries; division of labour makes this difficult, and in many cases impossible. But though shut out from the "joy" of the craftsman, and far removed from that higher order of appreciation which makes the craft of the Oriental a part of his religion, our workers can cultivate an intelligent interest in their work. The book before us is directed to this particular aim, and is especially justified in regard to the art of papermaking, not only because modern papermaking is in all essential respects based on the ancient craft, but the various operations are interdependent on such obvious lines that whatever particular section of the work a man may be engaged in, he can easily acquire and keep an intelligent grasp of the whole.

The book may be described as a series of studies of special points, largely and evidently such special points as have from time to time challenged the interest of the author in the course of his occupation as chemist to one of our oldest and most important paper mills. There is no essentially logical sequence in these studies, but we agree with the author that there is no occasion to multiply routine text-books. It is obvious, therefore, that there is no call to read the chapters in any particular order. The subjects treated may be briefly summarised as follows:—Raw fibrous materials and cellulose; bleaching and general view of the chemistry of the operations; the whole question of the function of water in relation to the manufacturing operations, as well as the physical and chemical points involved in the relation of water to the celluloses; paper in relation to the entire range of its applications, and the destructive agencies which it is required to resist and survive.

In dealing with these subjects the author follows the original method, that is, he develops his theme largely by original observations and investigations, trusting to the particular perspective of his own experience to give the subject-matter its cohesion. The result is quite satisfactory. There is room for contributions of this kind.

As a particular illustration of the author's methods, we may mention the statistical discussion on pp. 90–93 of the total contribution of basic matters in working-up a rag pulp, both engine sized (resin) and tub sized (gelatin and soap), in relation to the sulphate of alumina required to be used. This subject might be very much extended to involve many of the most interesting developments of modern chemical science, *e.g.* the ionisation of salts and the peculiar functions of the organic colloids in relation to electrolytes in solution. There is no doubt that the reactions in the beater will not be understood until studied in relation to these questions.

In a discussion of the theory of the bleaching process, the author returns to some questions arising in the study of one of the systems of electrolytic bleaching, which was based upon the circulation continuously of the electrolysed ($MgCl_2$) solution between the electrolyser and the potcher. There is no doubt that this condition gives an unexpected maximum of bleaching efficiency, possibly because energy may be carried in some particular forms not necessarily expressed in the simple oxidising actions of the solution, as, *e.g.*, on HI or As_2O_3. In this connection it is to be noted that Brunck advances a similar hypothesis in relation to ozone and its oxidising reactions (*Zeitsch. angew. Chem.*, 1903, p. 894).

Further, according to the specification of recent patents (Schuckert), the addition of certain organic compounds, more particularly resin (soda resinate), to a solution of an alkali chloride to be electrolysed enables a very much higher concentration of "bleaching chlorine" to be economically worked. Certainly there are points here which should attract investigators to a re-examination of the phenomena.

On the general question of bleaching actions, the author is somewhat discursive, and there are one or two inaccuracies and omissions in small but not less essential points. Thus, on p. 90, the reaction of sodium sulphite as an "antichlor" is stated to add to the alkalinity of the pulp. The normal sulphites in oxidising to the normal sulphates do not affect the balance of alkalinity. In cases where potassium iodide is decomposed by a paper, *i.e.* by a constituent of the paper, with liberation of iodine, the methods of Wurster should certainly have been imported into the investigation. The investigations of Russell should have been noticed, and the subject connected with the general question of autoxidation.

We mention such points to show that the methods of the author are suggestive rather than exhaustive, and paper mill chemists especially will find these lectures full of matter to set them thinking, observing, and in turn investigating a number of phenomena which they might otherwise neglect or pass over.

We apply in conclusion the text which opened this brief review:—There is the human side even to the highly competitive production of modern times, and authors who contribute to this aspect of industry, and notably to the pleasure of the worker, are deserving of the particular encouragement of a large circulation.

THE DEVELOPMENT OF THE HUMAN BRAIN.

Die Entwicklung des menschlichen Gehirns wahrend der ersten Monate. Untersuchungsergebnisse von Wilhelm His. Pp. iv+176. (Leipzig: S. Herzel, 1904.) Price 12 marks.

THIS work, as its title indicates, deals with the development of the human brain during the first four months. Half of the book, on the development of the cerebral hemispheres and the origin of the intramedullary tracts, is original matter, and continues the work already commenced in 1890 by the author's paper on the organisation of the medulla. The re-

maining half of the book deals with the early histogenesis of the nervous system, and is practically a recapitulation of the author's previous results, all, however, carefully re-studied in the light of additional material, and copiously illustrated with original photographs.

Apart from its scientific value, for which, indeed, the author's name is a sufficient guarantee, the book is a striking testimony to the debt neurology owes the late Prof. His, for not only is the entire work, comprising practically all that is known of the development of the human brain, based on the author's own observations, but most of the facts here described owe their first explanation to Prof. His.

In the introduction, the author briefly describes his methods, chief of which is his "graphic reconstruction," originally described by him in 1880, the only difference being that photographs of serial sections are now used instead of drawings. Following this is a tabular statement of the embryos used, and a discussion of the difficulties of age estimation, and the introduction closes with an earnest appeal for systematic measurements of all prematurely born embryos at gynæcological institutions.

The first portion of the book deals with the development up to the close of the first month, and commences with an account of the author's myelospongium, which, in opposition to Koelliker, he believed to be a syncytial network formed by the union of outgrowths from the spongioblast cells.

The author originally held that connective tissue cells took part in the formation of the definitive neuroglia, and especially that this was the mode of origin of Deiter's cells; in the present work, however, he agrees with the majority of neurologists that the original neural plate is alone concerned in the formation of the supporting tissue.

The author's "Keimzellen," as he showed in 1891, form both nerve cells and glia cells, and, as Schaper maintained in 1897, they are merely undifferentiated cells of the myelospongium in active multiplication, not, as the author originally supposed, a special form of cell to be distinguished from all other cell-elements in the neural plate.

The author gives a brief criticism of recent papers in opposition to the neurone conception, on behalf of which, it will be remembered, Prof. His was one of the first advocates; in particular he deals with Bethe's paper of 1903, in which the nerve is made to arise from a linear syncytial cell series which also later forms Schwann's sheath; His shows that Bethe is really dealing with the mesenchymatous sheath, which in the lower vertebrates, *i.e.* chick, appears very early; in man, as His's photographs clearly show, there is no possibility of confusing the growing end of the non-medullated nerve bundle with the surrounding tissue, and especially is this the case with Meynert's "fremdartiger" strands, as these grow into regions of the myelospongium practically free from cells. This portion of the book closes with a full description of the neural tube of an embryo at the end of the fourth week, "Embryo N" already described in previous papers.

The second portion of the book deals with the development of the cerebral hemispheres, and commences with a description of the author's well-known models; this is followed by a detailed account of the histogenetic differentiation of the hemispheres up to the close of the first month, and is illustrated by numerous exceedingly clear photomicrographs. A few pages follow on the blood vessels of the fore-brain. The last twenty-five pages deal with the origin of the intramedullary tracts.

The whole book is written expressly for the professed neurologist, and abounds in tabular statements, references to individual embryos, and so forth; but there is much, especially in the earlier parts of the book, which is also of interest to the student of general morphology, and it is on behalf of such students that we could wish the numerous excellent photographs of brain sections had been provided with reference letters.

No bibliography accompanies the book, a want duly apologised for in the preface. It should also be noted that, as indicated above, the whole development of the brain is not dealt with; in the author's words,

> "Ich theile mit, was mir mehr oder minder abgeschlossen vorliegt. Die Zwischenkapitel hoffe Ich, falls mir Leben und Arbeitskraft bleiben, in absehbarer Zeit zu können."

All zoologists will regret that this hope is not destined to be fulfilled. G. C. C.

THE TURBELLARIA AS PARASITES AND PARASITE-CARRIERS.

Die Turbellarien als Parasiten und Wirte. By L. von Graff. Pp. vi+65. (Graz: Leuschner und Lubensky's Universitäts-Buchhandlung, 1903.) Price 14.50 marks.

PROF. VON GRAFF'S latest work dealing with the Turbellaria is no less interesting than any of its predecessors, and students of parasitology must stand greatly indebted to him for putting together in such an accessible and stimulating form a full summary of all that is at present known of parasitism amongst the Turbellaria. The first half of the work is devoted to an account of the anatomy of six species of parasitic rhabdocœls. Although all of these have been previously described by von Graff himself, or by other writers, the ampler accounts here given clear up many doubtful points and supply precise information not hitherto available on various anatomical features. This part of the work is illustrated with three plates of great excellence.

The second part is devoted to considerations of a more general character. It includes a list of all known Turbellaria which have adopted a parasitic or commensal habit Amongst them von Graff distinguishes four principal grades of parasitism, namely, (1) occasional commensalism; (2) ectoparasitism; (3) occupation of some chamber in the body of the host which communicates with the exterior; and (4) endoparasitism. The author points out that the effects of parasitism of the second and third grades do not pro-

duce any very marked results on the parasite. The development of organs of adhesion is not greater than in the free-living species. Eyes may or may not be present, and the size of the pharynx varies with the species. The character shared by the largest number of representatives of these groups appears to be the loss of cilia, especially on the dorsal surface. There is hardly an indication of that increase in size of the genital glands so conspicuous in endoparasitic forms where the eyes and adhesive organs are frequently absent, the pharynx and nervous system much reduced, whilst the body, on the other hand, is invariably completely ciliated. As might be expected, the number of families represented in grades (2) and (3) is greater than the number of those which contain endoparasites; the majority of the latter belong to the Vorticidæ. The hosts most affected by parasitic Turbellaria are holothurians, crustacea, and mollusca. Other echinoderms, worms, tunicates, and vertebrates are also preyed upon to a lesser extent.

Von Graff makes some interesting comments on the classification of the platyhelminthes. The species of the genus Temnocephala usually regarded as transitional forms between the Turbellaria and monogenetic trematodes might, he points out, be referred with equal justice to the vorticid genus Derostoma. Again, Fecampia, when sexually ripe, agrees in characters of systematic importance with the cestodes. In fact, "the more thorough our knowledge of the platyhelminthes becomes, the more difficult it is to define the classes of the phylum. But just as so-called bad species are of value to the student of evolution, so these 'bad classes' of the flat-worms supply him with arguments which are the more convincing in that they rest on the sure ground of ascertained morphological facts."

The work concludes with a useful list of the very numerous parasites with which the Turbellaria themselves may be infected. These range from symbiotic algæ and bacteria to trematodes and nematodes. It is curious that the first recorded orthonectid, found by Keferstein in *Leptoplana tremellaris* thirty-five years ago, has not yet been adequately described. It differs considerably from the other orthonectids noticed since then.

F. F. LAIDLAW.

OUR BOOK SHELF.

Applications of the Kinetic Theory to Gases, Vapours, and Solutions. By W. P. Boynton, Ph.D. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1904.) Price 7s. net.

THERE are probably few mathematicians who can follow the long and difficult investigations by which it has been attempted to dispense with the second law, and to represent thermodynamical properties of matter as the changes which must necessarily take place in a molecular system for which the principles of dynamics and the laws of probability are assumed to hold good. Such attempts have been found practically in every case to involve some *further* assumption, whenever a kinetic theory has been applied to the consideration of irreversible phenomena, and Mr. Burbury has unearthed this inevitable assumption when it has escaped the attention of writers of several recent papers. It is probably as impossible to build up an irreversible thermodynamical system out of reversible dynamical elements without any assumption as it is to build up a Euclidean geometry without some axiom of parallels.

But apart from such considerations as this, a kinetic theory is of considerable use to the ordinary physicist in furnishing him with a mechanical representation of the properties of matter in its various states. Dr. Boynton has taken as his standard the requirements of a reader who is familiar with the elements of the calculus, and he has produced a book which will be of great value to students both of physics and of chemistry.

It is perhaps unfortunate that those English physicists who are most competent to write books like the present one are usually too much tied down by other duties to undertake such work, especially as the task is in most instances an unprofitable one to the author. It is therefore satisfactory to find that Dr. Boynton's book is written so much on the lines of an English text-book that it seems well suited for introduction into this country. The features which we particularly like are, firstly, that the author is careful to give his readers no excuse for believing he has proved a result when he has only given an elementary investigation of it, and secondly, that instead of introducing irrelevant philosophical digressions or views of his own, he has kept strictly to an exposition of commonly accepted theories.

It is much to be wished that the same could be said of all the books which find their way into our class-rooms from the other side of the water. It is because they do not generally come up to the present standard of excellence that the difficulty of writing English text-books that are worth writing is to be regretted.

G. H. B.

Handbuch der Physik. By Dr. A. Winkelmann. Second Edition. First part of vol. iv., Electricity and Magnetism. 140 figures. Price 12 marks. First part of vol. vi., Optics. 170 figures. Price 14 marks. (Leipzig: Barth, 1904.)

EVERY student of physics will share the satisfaction of the editor of this treatise that a second edition was called for so soon; for he has found it to be an indispensable storehouse of expert knowledge in all branches of the subject, and the need for another edition enables it to be brought once more abreast of the rapidly advancing tide of knowledge.

The book is of the nature of an encyclopædia, for each section is written by an expert in the section; twenty-two of the leading physicists of Germany collaborate in this way with Dr. Winkelmann, the editor, in its production. Of the two parts before us, that on electricity and magnetism is contributed by Drs. Graetz and Auerbach, while the part on optics is the work of Drs. Czapski, von Rohr, and Eppenstein.

References are brought up to the middle of 1902. Thus amongst electrical instruments the Dolezalek electrometer finds a place; the large amount of recent work on the properties of dielectrics is very amply discussed, including the double-refracting properties for electric waves. Great stress is laid on the important advances made in the construction and standardisation of standard cells.

The optical portion is wholly occupied with geometric optics and applications to optical instruments. The fact that the writers are connected with the firm of Zeiss is a sufficient guarantee of the quality of their contributions. The only regret that one feels in glancing through the book is that the tremendous

amount of material to be dealt with makes compression a *sine qua non*. It is only a taste we get; but the voluminous references to original sources forming the extensive footnotes point the way to a fuller feast. It is as a reference book that the chief value of the volume will be found; it is not intended for consecutive reading.

Each paragraph is a highly condensed account of a particular part of the subject. Thus von Rohr concentrates into a few pages the principal facts treated at more adequate length in his treatise on photographic objectives.

Again, von Seidel's method for dealing with the aberrations of lenses is limited to what seems very scanty treatment when the importance of the method is taken into consideration. But for fuller information the author is obliged to refer to a forthcoming work by A. König and himself—there is only room for outlines in a work like the present.

The work throughout is produced with the thoroughness which is characteristic of German publications. We look forward to the completion of the entire book.

Laboratory Exercises in Physical Chemistry. By Frederick H. Getman. Pp. viii+241. (New York: Wiley and Sons; London: Chapman and Hall, Ltd., 1904.) Price 8s. 6d. net.

THE title of this book might lead one to expect that what is really a distinct want had at length been met. Beyond the title, however, there is little in it that merits favourable comment; both in conception and in execution it is most inadequate. One finds, for example, that viscosity and surface-tension are accorded fourteen pages, of which four are purely theoretical and wholly out of place, whilst solubility is disposed of in four and a half pages. Again, we discover molecular volume in the chapter on thermometry, and polarimetry in the chapter entitled "The Spectroscope"! Not only is the author hopelessly deficient in the general sense of proportion and arrangement, but in matters of detail he is equally at fault. He actually (p. 30) introduces the temperature correction of the barometer into the calculation of a vapour density by Victor Meyer's method—the only method given—and does not even succeed in doing it correctly. He defines the unit of resistance as the international ohm (p. 153), and then gives his data in terms of the Siemens mercury unit (p. 172), which is never defined or even mentioned. Turning to his practical instructions we encounter the same thoughtlessness and omission of important details. The student who carried out a series of conductivity measurements at different dilutions according to the instructions on p. 177, for example, would obtain truly wonderful results, for no mention is made of the necessity of having two pipettes so adjusted that one withdraws exactly the same volume as the other delivers. What, again, is a student to make of the instruction on p. 178—"About 20 c.c. of a N/32 solution of pure sodium hydroxide is titrated with the dry acid of which the basicity is sought"? These instances suffice.

In closing the volume one can only express the hope that there may speedily be forthcoming a book which shall be in fact what this is in pretension.

Les Animaux domestiques. By J. Anglais. Pp. 103; illustrated. (Paris: Schleicher Frères et Cie., 1904.)

THE object of this volume may be best described by paraphrasing the first portion of the introduction, where Dr. Anglais states that it has been his aim, with the aid of a number of ingeniously planned coloured plates, to describe the essential characteristics, both external and internal, of a certain limited number of types of our most familiar domesticated animals. It is addressed to all who desire to make themselves acquainted with the leading features and characteristics of such animals, without the drudgery of long and profound practical study, and to acquire a general idea of their physiology and the history and object of their subjugation by man. As many details as possible of the peculiarities of the external form and of the internal anatomy are displayed in the illustrations and described in the text, so that it is hoped the work will serve in the case of some readers as an epitome of comparative anatomy and morphology, while for others it may form a starting point for more detailed study. The animals selected for illustration are the horse, the cow, the sheep, the pig, the dog, the cock, and the goose, each being illustrated and described on the same plan.

The illustrations of each species are five in number, and are printed on both sides of the cards, which are cut out to the shape of the animal, and so arranged as to fold over one another. The first shows the external form, the second the skeleton, the third the vascular system, the fourth the muscles, and the fifth the nervous system and viscera.

So far as anatomy can be learnt by means of diagrams, the work appears to deserve all that is claimed for it, and it will probably prove of considerable assistance to artists. Whether all the subjects selected for illustration would meet with commendation at the hands of breeders may, perhaps, be open to question. R. L.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Traction of Carriages.

IN tentative answer to your correspondent, p. 270, I suggest the following:—

The best angle of traction on a rough or irregular surface is at an upward inclination to its general slope. This upward slanting pull can be applied to a two-wheeled vehicle, and to the fore-wheels of any vehicle, but not to the hind wheels—especially if they are far away.

Consider, further, the summit of a hill, and let a waggon be so elongated that its hind wheels are still ascending while the horse is descending: his pull is exerted at a very bad angle on this part of the load, and in extreme cases the hill might almost act as a detent.

I should like to take the opportunity of saying that whether the traditional heavy draught of a long-bodied carriage is well founded or not, I am convinced that the ordinary hanson cab is badly balanced, and that a horse would be better with some load on his back, except when descending a hill. The comfort of a wheelbarrow over a balanced cart is considerable.

Though it may be easy to overdo the loading, nothing can be worse than a constant upward pressure on the chest of a horse: a pressure which at present automatically increases on an up grade, thus tending to deprive the animal of part of his own weight, on the existence of which the efficacy of every locomotive depends.

OLIVER LODGE.

Lobster Hatching.

PERHAPS your readers interested in economic marine biology may care to know, as a small contribution to the record of times and seasons, that the berried-lobsters kept at the Port Erin Biological Station started hatching out their young on July 15. So far the loss after hatching has been under 1 per cent. We find the best food for the young lobsters to be finely teased up fresh liver of the common shore crabs. W. A. HERDMAN.

Biological Station, Port Erin, Isle of Man, July 22.

THE PRESENT STATE OF AGRICULTURAL EDUCATION IN ENGLAND.

WE have just received from the Essex Education Committee a little illustrated pamphlet which tells us what is being done in that county for the education of the agricultural community. It represents a different system from any prevailing elsewhere, hence it may be worth while to examine it not only on its own account, but from the more general point of view of the organisation of rural education, so great is the diversity of procedure in the various counties.

The centre of the Essex system is a set of laboratories, chemical and botanical, in Chelmsford; here samples of manure, foods, soils, seeds, &c., are tested for the local farmers; here also various investigations in connection with the field experiments or with special problems arising in the agriculture of the county are carried out. The laboratories form primarily an investigating and advisory centre; at the same time a considerable amount of direct instruction is given there, mainly in the form of short courses for adult students. There is a winter school of agriculture giving a nine weeks' course, shorter courses still in horticulture and dairying, Saturday classes for the instruction of elementary schoolmasters, and a series of occasional lectures on market days for farmers. From this centre also emanate the lecture courses given in the winter up and down the county.

Of course, this does not exhaust all the work being done in this direction by the Essex County Council; at Dunmow there is an intermediate school with a strong agricultural side, and at one end of the scale there are scholarships to be won at Cambridge, at the other classes in such manual operations as ploughing, shepherding, farriery, &c. On the whole, then, the Essex farmer is not badly served; he has a scientific organisation working out the local problems which he can consult for technical advice, and a recognised system of education by short courses is being developed for him, though as yet it is in a somewhat imperfect state.

But it is noteworthy that neither the Board of Agriculture, which has charge of all higher education in agriculture, nor the Board of Education can even advise, much less control; the whole scheme is managed by a committee "which, with the single exception of the Chairman, consists entirely of Essex farmers." All honour to such a committee for the open-minded way it has attacked the problem, but in the end so restricted an administration cannot make for efficiency.

The county unit for educational purposes is valuable, always provided the central authority is active to coordinate, to give continuity of policy, to prevent, on the one hand, overlapping agencies, and on the other to see that the whole field is covered. It would be easy to point out the weak spots in the Essex programme, the scanty provision for secondary and the neglect of primary instruction of a rural character, but the county authority is working hard according to its lights and to its resources. Turn to the neighbouring counties, and the need of some central stimulus is seen; Herts does about as little as it can, a few lectures and some courses on cottage gardening represent its method of shelving its duties, while in Suffolk we are informed that part at least of the technical instruction money goes in 5*l.* doles to village flower shows! These counties and many others like them have but slender funds to devote to technical education, so slender that it does not seem to be worth anyone's while, inside the county or out, to see that they are rationally spent. The only authority which has any power is the Local Government Board, the auditor of which has to see that the expenditure is on something that can be made to square with a definition of technical education!

The time has come when either the Board of Education or the Board of Agriculture (and it is also a pressing matter that one or other of these bodies is made wholly responsible for agricultural education) should step in and tell the county councils what they ought to do and how they must set about it. By this time experiments enough have been made, for it is well known what sort of work will succeed and what schemes are feasible; in one county or other every sort and grade of rural education has had a trial, and some survive to do excellent work of their kind. Only a central authority knows what has answered elsewhere and can be made to answer again; at present we see county after county embarking on schemes foredoomed to failure, schemes which each committee thinks to be new inventions instead of the obvious mistakes into which every beginner falls unless he has the forethought to get up his subject. The free experimenting of the last ten years has done its work; it is time now to apply the successful results. And unless the central authority does intervene in earnest, it is not too much to say that the purely rural counties will never get any agricultural education at all; they are poor and unenterprising, they are isolated and bitterly averse to cooperating with neighbouring counties as feeble as themselves (even east and west Sussex cannot join forces to support the same agricultural school), lastly, they are angry at being called upon to meet the unexpectedly heavy demands for elementary education, and will divert as much of the "whisky money" to that end as they can. It is not that the country is without agricultural education; we have now many organisations as good as anything in America or Germany, which have equally won the confidence of the farmers for whom they were designed. Among others, we need only instance the Kent and Surrey joint scheme which makes a centre of the Wye College, or the Cheshire School at Holmes Chapel, but whole tracts of the country that are even more in need of similar work are absolutely blank, and are likely to remain so unless a central authority can step in with some power and a determination to shake the self-complacency of the backward county councils.

From another point of view the lack of a central authority with a wide general outlook is even more disastrous—there is no provision for the furthering of research. Now it is not only a truism that any scientific teaching that is to be of value must be based on research, but anyone who has had experience in that line has learnt that you can only secure the sympathy and cooperation of farmers by instituting investigations in which they are interested. A course of lectures on agricultural chemistry would go unheeded, little more attention would be paid to a course on manures; but offer them the results of some first-hand experience in the shape of experiments dealing with a problem of local importance, and they will come to hear and remain to discuss. How does the American Department of Agriculture seek to commend itself to its farmers? Almost wholly by research. Principal Reichel's article, again, in the reports of the Mosely Commission, tells us how the great Canadian agricultural college at Guelph only took root when it got hold of the farmers by experiments followed by discussion. Yet the Local Government Board, which passes many curious things masquerading as education, draws the line at research, and even the Board of Agriculture, which has some money

to spend on furthering higher agricultural education, has decided that research is outside its purview.

Yet if there is one field of work of proved public utility which wants the fostering of a central authority it is agricultural research. To begin with, when it is only possible to raise one crop in a year the progress of an agricultural investigation is necessarily slow, and requires to be continued without any external pressure to produce a result quickly. Again, the problems of the nutrition of plant or animal are so complex that the investigator, eliminating variables to obtain a crucial test on some particular point, appears altogether unpractical to the farmer. Now that the main principles of the action of manures and their adaptation to particular crops and soils are known, original investigation, which is really breaking new ground, will not appeal either by its methods or even by its results to the ordinary man. It will be done for the benefit of the teacher and the expert, and will get translated into practice by modifying the instruction or advice which they give to the actual working farmer. But research of this kind will never obtain the support of the county councils, except so far as it is undertaken out of pure keenness by individuals on the staff of the various teaching institutions; the county councils require demonstrations of the application of known principles to local conditions and experiments for the enlightenment of the current generation of farmers. Even with such trials it is difficult to secure the necessary continuity of policy; Somerset has just discontinued its experimental farm after a very few years' trial, and there is a local movement directed against another county experimental farm which is very ominous in view of the pressure on educational funds brought about by the new Bill. For permanent investigations, "travaux à longue haleine," we have in this country only Rothamsted and the Royal Agricultural Society's station at Woburn; Rothamsted has but 2500*l.* a year (each American State gets at least 4000*l.* a year for its experiment station!), and is asking for further funds to enable it to do more than continue to exist, yet it does not appear to have convinced the Board of Agriculture that research is part of education or is worthy of assistance. As to the Woburn farm, who can say what will happen through the financial straits into which the society has been driven by its show at Park Royal? But in any case compare these two solitary agencies with the great organisation possessed by the United States, of which we get a personal impression in Prof. Armstrong's paper in the Mosely Commission reports. Yet it cannot be argued that we need such work any less than America, for even if in England itself "agriculture only stands for shillings where commerce stands for pounds," the proportion is very different when we look at the Empire as a whole. Teachers and investigators are being constantly called for; how are the experts to be trained, the teachers to be inspired, if there is no adequate provision for research at home? Up and down our dependencies men may be found doing expert work in agriculture, men whose knowledge, both of agriculture and of science, has been acquired by working as assistants in commercial analytical laboratories; these men are doing excellent work, but they cannot wholly escape from the defects of their training.

Nobody familiar with the facts can fail to recognise the enormous advance that has been made within the last twelve years, before which time agricultural education did not exist for the ordinary farmer; now it is good "in parts," and the time is ripe for a strong central administration to take the work in hand, level up all round, and put research, which should be the mainspring of the whole, on a sound independent footing.

TWO BOOKS ON LOCAL NATURAL HISTORY.[1]

MR. TREGARTHEN'S brightly written and exquisitely illustrated book is absolutely redolent of the breezy uplands and the surf-beaten beetling cliffs of the western duchy, and is evidently the work of a sportsman-naturalist of the old-fashioned and best type. It is true that the author deals with his subject more from the sporting than from the natural history aspect—and to a great extent with the methods of sport belonging to a bygone day—but perhaps it is none the worse for this, being entirely free from all traces of that "faddism" which tends to taint the work of many of the self-styled field-naturalists of to-day. Whether he is describing fox-hunting in the olden time, the habits and wiles of foxes and their cubs, dilating on the fascinations of digging out badgers from their subterranean retreats, or narrating the perils attendant on a midnight descent through a tortuous adit to the rocky cave where dwell the seals, he is equally delightful and fresh. All the photographs of animal life, to say nothing of those which portray the striking coast scenery of the Land's End district, are admirably well chosen and well executed, the one of fox cubs herewith reproduced being only a sample of the general excellence of style.

Although ostensibly devoted to sport, the work contains here and there some interesting observations with regard to the fauna of the county. We are told, for instance (p. 165), that hares are almost non-existent in this part of the country, their scarcity being due apparently not to excessive persecution, but to the unsuitableness of the climatic or other physical conditions. Some years ago, upwards of 150 of these animals were turned out in various parts with the result that within a comparatively short period nearly all had disappeared. It is satisfactory, however, to learn that the badger (why will the author call it one of the most ancient of animals?) is as abundant as the hare is scarce, the author stating that it generally shares a burrow with the fox. Seals, too, thanks to their wariness and the almost inaccessible caves they select for their abode, show no signs of decrease on the northern coast.

To the naturalist, the description of the seal-caves and their living denizens is, indeed, the cream of the whole book, and many readers would, we feel sure, long for an opportunity of beholding the scene described, were it not for the attendant dangers and difficulties. The particular visit described was made by night at low-water, when the entrance to the cave was barred by exposed boulders, thus rendering it impossible for the seals to escape. "We advanced to the edge of the water," writes the narrator when describing the visit, "with a torch in each hand, holding them well up, and forward at full arm's-length. It was the sight of a lifetime. Five huge beasts, two grey, the rest a dirty yellow, mottled with black spots, lay swaying on the sand, prepared to make a rush—they can shuffle down a slope at a great pace—if we entered the pool; and these were not all, for in dark recesses beyond I saw indistinct forms move, and once I thought I caught the gleam of liquid eyes."

The numerous species of sea and shore birds frequenting the Land's End claim the author's attention in the concluding chapter, where reference is also made to several of the rarer birds of the land. Both

[1] "Wild Life at the Land's End; Observations of the Habits and Haunt of the Fox, Badger, Otter, Seal, Hare, and of their Pursuers in Cornwall." By J. C. Tregarthen. Pp. xii+236; illustrated. (London: John Murray, 1904.) Price 10*s.* 6*d.* net.

"In the King's County." By E. K. Robinson. Pp. viii+352. (London Isbister and Co., 1904.) Price 6*s.*

magpies and green woodpeckers are stated to be more common at the present day than was formerly the case, while it is only of late years that the pushing starling has taken to breed in the district. With a bare reference to the account of the author's last sight of a pair of Cornish choughs—possibly the last of their kind—we must take leave of a charming volume.

In any work devoted to outdoor life in Norfolk the element of sport is certain to loom large, next to which birds will probably claim a considerable share of the author's attention, and Mr. Robinson's volume is no exception to this rule. Such subjects as "a royal shoot" and "beside the covert" are, indeed, intercalated with chapters on "panics in bird-land," "the hawk's harvest," and the "birds of autumn," and throughout the portions devoted to the wild life of the county there will be found scattered many observations which cannot fail to be of interest to the field-naturalist and lover of the country. A feature of the work is the candid and straightforward manner in which the utility or harmfulness of the mammals and birds generally classed by keepers as "vermin" are discussed, no special pleading being used to afford any of these creatures exemption from destruction when, in the author's opinion, it is well merited. Among the mammals which, according to Mr. Robinson, rightly occupy a place in the "keeper's museum" are the stoat and the hedgehog, the indictment against the latter, from the keeper's point of view, being even heavier than the one in Bell's "British Quadrupeds."

To residents in Norfolk the book should prove specially welcome, but it is also one which can be taken up to while away an idle hour by every reader interested in sport and country life. R. L.

RELATION OF RAINFALL TO RUN OFF.

IN NATURE of January 7 (vol. lxix. p. 226) notice was directed to the attention paid by the Geological Department of the United States to the water resources of the country, and to the series of reports that had been issued relating to the supply available for domestic and business purposes, for power and for irrigation. We have recently received a further series of reports relating to the progress of the stream measurements for the year 1902 carried out on the northern and southern Atlantic coasts, Mississippi River, Great Lakes, Pacific coast and Hudson Bay drainage districts; the hydrography of California and the storage reservoir there; and an account of the irrigation of India.

With the exception of the last, these volumes consist almost entirely of statistical records of the flow of streams, and although of great value to American hydrologists, do not call for any special notice.

Paper No. 80 of the series of hydrographic investigations on the relation of rainfall to run off, compiled by Mr. George W. Rafter, contains information which is of value to those interested generally in the question of water supply.

The author of the paper commences by saying that, as the result of many years' study of the problem indicated by the title of the paper, he has come to the conclusion that no general formula is likely to be found expressing accurately the relation of rainfall to the run off of streams, for these vary so widely in their behaviour that every stream is a law unto itself.

Mr. Rafter directs attention to the desirability of the adoption of uniformity or standardisation of the units of measurement, and warns engineers to be very slow to add to the number of standards of measure

for flowing water already in use. In the United States, as in this country, the cubic foot is taken as the unit of volume and the second as the unit of time when measuring flowing water in streams, while here the gallon is generally adopted as the unit when dealing with supplies for domestic purposes. In the United States the million gallons in twenty-four hours appears to be recognised as a standard for city water supply, and an acre in area covered one inch or a foot deep in a month or a year is used for irrigation purposes. The unit of inches of rainfall per acre on the catchment area and the resulting run off in gallons for town supplies, or in cubic feet for drainage, is a measure of very general adoption. In India many irrigation engineers have adopted the term "cusecs" as representing cubic feet per second.

With regard to the proportion of rainfall that finds its way into a stream, the author deprecates the use of averages, and expresses the opinion that safe deductions can only be obtained from using the minimum rainfall and taking into account the longest period such minimums may be expected to occupy. The records of the United States show that this minimum period may be expected frequently to last more than three years.

In this country the general rule is to take the average of the longest period over which the rainfall records of the district extend, from this to deduct one-fifth to allow for the mean annual rainfall of the three consecutive driest years, and from the product further to deduct from eleven to fifteen inches for loss by evaporation, soakage, &c., according to the character of the ground, the remainder giving the quantity available for storing. If compensation water has to be provided, a further deduction of one-third of the available supply has to be made. Fourteen inches is commonly taken as the figure representing evaporation, &c., in this country. For example, with an average annual rainfall of thirty inches, ten inches would be available for run off or storage, or, where compensation water has to be given, 6·67 inches would be available for storage. Taking an inch of rainfall as 3630 cubic feet per acre, 10 inches would give 36,300 cubic feet or 226,300 gallons to the acre of gathering ground.

As a general statement, Mr. Rafter's investigations have led him to the conclusion that the minimum rainfall varies from half to one-fourth the maximum.

The late Mr. Symons's proportion for this country was that the rainfall for the wettest year was half as much more than the mean, and for the driest year one-third less, or, taking the average of three wettest years, one-fifth less than this average.

Mr. Rafter considers that averages derived from a shorter period than thirty-five years are not to be relied on within 2 per cent. The same conclusion was arrived at by Mr. H. R. Binnie in his paper on the average annual rainfall reported in the minutes of proceedings of the Institution of Civil Engineers, 1892. This figure was derived from an examination of rainfall statistics from 153 stations situated all over the world. While short periods like five years' average gave an error of 32 per cent., and thirty years 5·8 per cent., the error for thirty-five year periods was only 2½ per cent., and fifty years came no closer.

Although the annual quantity of rainfall varies very much in different localities and in different countries, the same law universally applies as to the relation of the wettest and driest years to the average fall if taken over a sufficiently long period.

As pointed out by the author of the report, caution is necessary in taking the average of the rainfall as a guide; for storage purposes, where the water has to be collected in a reservoir a minimum fall derived from an average of years may be a trustworthy guide, but where provision has to be made for carrying off the water in artificial channels for drainage purposes, or where the water has to be pumped, as in low-lying districts, the data to be ascertained is the maximum rainfall that has to be dealt with in a short period. Thus, while the rainfall of the year, or even of the winter months, may not have been excessive, yet floods may have ensued due to heavy rain falling for a few days on ground already saturated. In the Fen districts on the east coast of England, which depend entirely on artificial drainage, the rule is to allow for a discharge equal to a continuous fall of a quarter of an inch of rain during twenty-four hours. The mean daily fall of the rain which caused the twenty-one floods in the Witham district since 1852 was an average of 0·26 inch spread over seventeen days; the average annual fall of the district for the wet period was 32·39 inches, and over a period of seventy years 22·93 inches. The greatest fall during this period averaged 0·41 inch spread over fourteen days, in November, 1885, and also in October, 1883, when there was considerable flooding.[1]

The figures given in this paper show that in the eastern States of America with a maximum rainfall of from 20 to 60 inches half the rainfall runs off, and that with a minimum fall from a fourth to a sixth. In the western States, with a fall of about 12 inches, the run off varies from half an inch to an inch.

The total run off of a stream depends very largely on the run off of the storage period. Usually about 0·75 to 0·85 of the total rainfall of this period runs off in the stream, while for the summer, or growing period, not more than about 0·1 of the rainfall appears, this small quantity being due to evaporation and absorption by vegetation. The total run off for the year depends very largely on whether or not the rainfall from December to May is large or small. Whether any given stream is low during the summer months or has then a well sustained flow will depend very largely on the rainfall of the month of May. When the May rainfall is heavy enough to produce full ground water, the flow is likely to be well sustained.

The extent of afforestation seems to have a considerable effect on the run off of streams, catchments with dense forests showing a larger run off for the same rainfall than those which are deforested.

THE ARAPAHO SUN DANCE.[2]

THE scientific value of the anthropological series of the *Publications* of the Field Columbian Museum, Chicago, has been sustained by the important memoir on the Arapaho sun dance by Dr. G. A. Dorsey, the energetic curator of the Department of Anthropology. Although only very recently published, the work bears the date of June, 1903, which will cause superfluous trouble to bibliographers. Dr. Dorsey witnessed the sun dance in 1901 and 1902, and he has taken great pains to give a clear and minute account of this eight-day ceremony. The description is illustrated with a great wealth of illustrations, there being no fewer than 135 plates, many of which contain two figures; it is probably safe to say that no ceremony has hitherto been so amply illustrated. It is also a matter of congratulation that the description is so detailed, as the significance of a ceremony can only be adequately realised when all the details of the events

1 "The Fens of South Lincolnshire" (Simpkin, Marshall and Co., Ltd.) "The Drainage of Fens and Lowlands" (Spon, Ltd.).

2 "The Arapaho Sun Dance; the Ceremony of the Offerings-lodge. By G. A. Dorsey. Field Columbian Museum, Anthropological Series. Vol. iv. (Chicago, U.S.A., June, 1903.)

are carefully recorded. We can heartily congratulate the author and the museum authorities on the publication of this authoritative memoir. More information would, however, be welcome as to the precise part taken by the several social groups of the Arapaho in this national festival, as this is usually an important element in social ritual. Apparently the ceremony may take place at any time, but it is generally during the winter. It is performed in compliance with a vow.

Many ceremonies are performed in connection with a Rabbit-tipi (or tent), which is erected on the first day, and the men who perform the rites are known as Rabbit-men; the origin of the name is due to a myth. On the second day a sweat-lodge is built, not only as a means of bodily purification, but because they want to be cleansed from former sins, evil desires, and to be protected from all kinds of plagues. Next, a bison should be caught and killed; now they have to content

FIG. 1.—The straight-pipe being smoked by the Sun Dance priests and dancers.

themselves with any old buffalo robe that is available, and this skin has to be painted. On the fourth day the centre-pole for the Offerings'-lodge is cut down by two women, and brought into the camp and erected in its midst with great ceremony; as this new lodge is being completed, final rites are held within the Rabbit-tipi. In this very large lodge is the altar, and here dancing takes place, which is at the present day of a simple character. Near midnight of the second and fourth days a remarkable symbolic ceremony takes place between the grandfather and wife of the Lodge-Maker. The former personifies the sun and the latter the moon, and the ceremony brings strength to the people and increase to the tribe. The sixth day is known as "Medicine Day"; the dancers have now fasted for about forty hours, and it is supposed that by this time their minds are in a proper condition to be susceptible to the influence of the sun, and they are exhorted to be of a reverent frame of mind. The rising sun is greeted with a dance. During this most important day of the series new chiefs are inaugurated and names changed. There is a considerable amount of evidence that in former times unbridled license prevailed throughout the camp on this night, which was taken advantage of by all, as it was considered one of the rites of the ceremony; in more recent years this has been entirely given up, but the occasion is utilised for courting. The seventh day commences and ends with sun dances, and then takes place the ceremony with the symbolic sun-wheel. The dancing is particularly fatiguing, and finally, in the ceremony witnessed by Dr. Dorsey, a great shout was sent up by all, for the ceremony had come to a happy termination without anyone falling by the way and without a mishap. This impressive exhibition of endurance and faith is termed "gambling against the Sun." It expresses on the part of each dancer his earnest prayer and effort to conquer, to survive, and to complete his three days' fast without falling, in spite of the opposition of the intense heat of the sun; to survive means to win benefit. Then follow the bathing and purification of the dancers.

On the last day of the sun dance ceremony there takes place the final dancing out to meet the sun; the method of advancing by degrees outside the lodge is a form of asking the Man-Above and the Grandfather to listen to their prayers; it also typifies the going after something which is good. A shaking of blankets which takes place may be regarded as a purification rite whereby sickness and sorrow are shaken off. The smoking of the straight-pipe (Fig. 1) at this time, on the part of all, which forms the final performance in the ceremony, is to the effect that all might follow a straight road, that all might be protected, and that the families of those who have fasted and taken part in the ceremony might be guarded from harm, inasmuch as they have performed the ceremony according to the orders of the Man-Above.

Before dispersal, parents, often accompanied by their children, enter the Offerings'-lodge, and after praying, tie on to the centre-pole the clothes discarded by their children during the year. One of these prayers is as follows:—"White Man-Above, my Father, here are the clothes of my child. I am going to deposit them. They are no longer good for my child. By doing this I ask you to watch over him from day to day and keep him from temptation. May he grow up to be a man, to understand your teachings which we have just gone through! I hope you will hear our prayer for my child."

A. C. HADDON.

THE UNGULATE MOLAR.[1]

IN the course of his attempt to solve the puzzle of the homologies of the cusps in the more complicated types of ungulate molars, the author of this bulky memoir takes the opportunity of directing attention to certain points with regard to mammalian dentition in general, and also comments on the exceeding intricacy and difficulty of several of the problems presented thereby. The solution of one difficulty, he observes, not unfrequently gives rise to a whole crop of fresh problems, and, paradoxical as it may seem, every increase in our knowledge serves only to reveal the depth of our ignorance.

With the enormous amount of variation displayed

[1] "Recherches de Morphologie phylogénétique sur les Molaires supérieures des Ongulés." By F. Ameghino. *An. Mus. Buenos Aires*, ser. 2, vol. iii. Pp. 541, figures.

by the molars of the numerous types of ungulates peculiar to the Tertiary formations of South America, Dr. Ameghino has almost a superfluity of material upon which to work. So vast, indeed, is his subject, that it would be impossible, within the limits of our space, to follow him in his survey from one type to another, or, indeed, to discuss his general conclusions, and I shall therefore confine myself to directing the attention of my readers to certain points of special interest in the author's work.

In the first place, it may be noted that Dr. Ameghino reiterates his opinion as to the falsity of the tritubercular theory of molar development, tritubercular molars, instead of being the primitive type, having been derived, on his view, from those with four or six cusps. Whether this opinion is in any way biased by the author's contention that the earlier Patagonian mammals are of Cretaceous age may be worth consideration.

Of greater importance is the support given by Dr. Ameghino to the view that the molar formula of the placental and marsupial carnivores is numerically identical, that is to say, that there are three true molars in both (when the full series is developed) instead of three in the one and four in the other. He consequently regards the replacing marsupial premolar as the third instead of the fourth, and the tooth behind it as a persistent milk-molar. The numerical identity

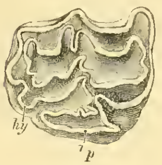

FIG. 1.—Right upper molar of horse. *p*, antero-internal pillar; *hy*, postero-internal pillar.

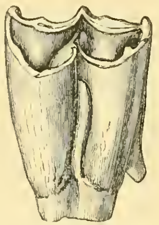

FIG. 2.—Left upper molar of Nilgai to show accessory pillar between the two main inner crescents.

of the marsupial and placental series was urged long ago by Prof. Gaudry, and this view was more fully developed a few years since by the present writer, when evidence in favour of the above-mentioned homology of the marsupial replacing tooth and the one behind it was likewise adduced. Although it has subsequently received the assent of Dr. Wortman, this view has not, however, yet been accepted by zoologists generally. It may be added that it is a question on which only those with a considerable amount of palæontological knowledge are competent to form an opinion.

Another point of great interest referred to in Dr. Ameghino's memoir is the alleged occurrence in Nesodon and certain other Patagonian Tertiary mammals of three distinct dentitions. Since the existence of this remarkable phenomenon is stated to have been accepted by Dr. Scott, it may apparently be taken as fully authentic. The "pre-lacteal" cheek-dentition, according to the figure given, consists of three very small teeth, differing somewhat in form from their successors of the milk-series. Dr. Ameghino, whose view is almost certainly in this instance influenced by his opinion as to the age of the Patagonian mammals, regards the "pre-lacteal" dentition as a direct inheritance from reptilian ancestors. In view, however, of the specialised characters of Nesodon and its allies, and the absence of a functional "pre-lacteal" series in any other mammals, it would seem much more probable that it is a superadded feature.

The last point to which we have space to allude relates to the homology of two of the cusps in the equine molar. To render this point clear, two figures have been introduced into this notice.

Since the date of publication of the first part of Gaudry's "Enchainements," the antero-pillar of the equine molar (*p* in Fig. 1) has been almost universally regarded as one of the primitive constituents of the tooth, corresponding to the inner extremity of the anterior transverse ridge (protocone) of the rhinoceros or anchitherium molar. From comparison with a large number of extinct forms, Dr. Ameghino comes, however, to the conclusion that this antero-internal pillar (which is detached in Hipparion but joined to the body of the tooth in Equus) is really a superadded element, derived from the cingulum, and corresponding to the "accessory pillar" of the molars of many ruminants (Fig. 2). Consequently, the protocone will be represented by a part of the anterior inner crescent of the horse's molar. Apparently Dr. Ameghino has made out a very strong, if not a conclusive, case for the new interpretation; I may add that the same opinion was independently arrived at and published by Dr. Forsyth-Major so long ago as 1873, but has been generally neglected in favour of the Gaudrian theory.

Without in any way endorsing all his views, it may be confidently stated that in this memoir Dr. Ameghino has made a very important contribution to mammalian odontology. R. L.

DR. ISAAC ROBERTS, F.R.S.

THERE is one class of scientific amateurs which seems to be the peculiar product of English society. Dealing with astronomy alone, and confining our attention to those who have passed away, we have such men as Lassell, Barclay, De La Rue, &c., all of whom, after amassing a considerable fortune in commercial pursuits, have devoted the evening of their lives to furthering the interests of their favourite science. The latest example of this earnest attachment to this particular branch of science was Dr. Isaac Roberts, whose death we record with profound regret. It is possible that he may be nearly the last of a distinguished series, for it is not unlikely that, as science tends to specialise in particular directions, such instances will become less and less frequent. The wealthy amateur, it may be, will continue to provide the means for others, but the requirements for the production of valuable work tend to become more and more severe, and the actual prosecution will soon be reserved to those who have been able to give up their whole life to special study. But Dr. Roberts was fortunate in finding a subject at which he could work with effect personally, and his own exertions were rewarded with valuable results.

For some years Dr. Roberts seems to have wavered between geology and astronomy as a congenial pursuit in his leisure hours. But possibly it was the application of some form of mechanical inquiry that attracted him in either direction. Among his early papers are the results of investigations affecting the circulation of underground water and the filtering and hygroscopic properties of Triassic sandstone. In studying the movements of underground waters, of which the observations were carried on with great regularity, he employed mechanical contrivances which he designed himself. Similarly, in practical questions such as the determination of the pressure of grain on the walls of lofty warehouses, when stored to great height, the mechanical side of the question seems to

have had the greatest attraction for him. Finally, when he settled down to the continuous study of astronomy and procured a powerful reflector suitable for his purpose, he introduced many small conveniences to assist the work, which no doubt contributed in a large measure to his ultimate success; for at the time he began his work astronomers had not recognised with the keenness they do now the necessity of controlled driving clocks to equatorials, and other happy suggestions for lightening the labour or the irksomeness of prolonged exposure in photographic work. This was the direction in which Dr. Roberts chose to work, and in which he earned a well merited reputation. It may be said of his early photographs that they were a revelation, and they are still worthy of profound study, though others working with more powerful instruments, and guided, it may be, by his early experience, have equalled and possibly surpassed them in the amount of detail shown. Two handsome volumes containing photographs of nebulæ and star clusters, which Dr. Roberts published at his own expense and widely distributed, speak to his industry and liberality, and his mechanical genius found another outlet by constructing a machine for the ready copying or transference of the positions of the stars photographed, to copper plates, from which they could be readily printed. How far this device has been used is uncertain; probably mechanical photographic processes have supplanted it.

Another feature in Dr. Roberts's methods which was eminently practical and worthy of imitation was the care he displayed in selecting a site for his observatory. His desire was to secure a good observing atmosphere and the greatest freedom from clouds, and many and minute were his inquiries, both at home and abroad, before he settled on Crowborough Hill, where his observatory was finally situated. Even shortly before his death he visited Las Palmas for the purpose of making some observations which required good observing conditions, and it will be to the regret of many friends that his activity and his energy are lost to us while he was still eager and capable of pursuing his favourite study.

The deceased astronomer, who had been elected a fellow of the Royal Society and many other learned bodies, was in his seventy-fifth year. He was twice married, on the second occasion to Miss Dorothea Klumpke, whose name and reputation are known throughout Europe, and to whom the deepest sympathy will be tendered.

NOTES.

We regret to have to record the death, at the age of eighty-two, of Sir John Simon, K.C.B., F.R.S., which took place on Saturday last.

The death is announced of Prof. Trasbot, formerly director of the Alfort School, at the age of seventy-two years. He had been a member of the Paris Academy of Medicine since 1886, and was the author of many works relating to pathology, epidemic diseases, and sanitary administration.

The death is announced also of Dr. J. Bell Hatcher, curator of vertebrate zoology at the Carnegie Museum, Pittsburg, at the age of forty-six years.

The Berlin correspondent of the *Lancet* states that Prof. Koch will vacate his position as chief of the Royal Institution for Infectious Diseases on October 1, in order that he may have more time for scientific research. He will, however, continue to be connected with the institution, and, by special order of the Government, will have on the premises a laboratory furnished at the public expense, and the clinical material of the institution will be placed at his disposal. We learn also from the same source that Prof. Koch is to succeed Prof. Virchow in the membership of the Royal Academy, Berlin, and that his successor as chief of the Institution for Infectious Diseases will be Prof. Gaffky, now of the University of Giessen. Prof. Gaffky's acceptance of Prof. Koch's chair in the University of Berlin was announced in our issue of July 14.

It is announced in *Science* that Mr. H. C. Russell, Government Astronomer of New South Wales, is to retire at the end of the present year, after forty-six years' service.

The seventy-second annual meeting of the British Medical Association was opened at Oxford on Tuesday last, when the president, Dr. Collier, delivered his address. In the evening a reception was held in the Sheldonian Theatre, and the Middlemore prize for the best original work on ophthalmology brought out during the past three years was awarded to Mr. J. Herbert Parsons.

The Lord Provost of Glasgow opened on Thursday last the health exhibition which has been organised in connection with the twenty-ninth autumn congress of the Sanitary Institute now in session at Glasgow. The exhibition is divided into colonial, municipal, and educational sections, and among the exhibits are a model hospital and a model one-house dwelling.

The congress of the Royal Institute of Public Health at Folkestone was opened on Thursday last and closed on Tuesday.

An intercolonial agricultural conference was opened in Pretoria on Monday last, and the delegates will discuss, among other subjects, the formation of a Central South African Agricultural Union, African coast fever, the native question, irrigation, and fruit and cotton growing.

The sixth centenary of the birth of Petrarch opened at Arezzo on July 20. The Count of Turin represented the King of Italy, and Signor Orlendo, Minister for Public Instruction, represented the Italian Government. An artistic tablet was unveiled at the house in the Via dell' Orto in which Petrarch was born, and later there was a memorial ceremony in the Politeama Aretino. The festivities lasted until July 25.

The new hall of the Royal Horticultural Society in Vincent Square, Westminster, was opened by His Majesty the King on Friday last. The building, which includes a library, offices, council chambers, and a lecture room, in addition to the large hall in which the society will hold its fortnightly exhibitions, has been built to celebrate the centenary of the society. In the address which Sir Trevor Lawrence read to the King and Queen the work of the Royal Horticultural Society was reviewed, and in regard to the efforts of the collectors sent out by the society in the nineteenth century, it was said, in the words of Mr. Andrew Murray, that "the results have affected the appearance of all England. Nowhere can a day's ride now be taken where the landscape is not beautified by some of the introductions of the Royal Horticultural Society." Perhaps nothing indicates more clearly the way in which the society has promoted the science and art of horticulture than the fact that whereas there were one thousand three hundred fellows in 1887, there are now eight thousand, one hundred and fifty. Baron Sir Henry Schroeder presented the report of the building and appeal committees, in which it was stated that twenty-six thousand pounds had been subscribed towards the cost of the hall, which will amount in the end to forty

thousand pounds. His Majesty received congratulatory addresses on behalf of the society. Dr. Maxwell Masters presented those from the Société Royale d'Agriculture et de Botanique de Gande and from the Horticultural Society of Prussia; Mr. Edwin Mawley that from the National Rose Society. His Majesty then declared the hall open. It is, we understand, the intention of the society to provide scientific instruction as well as practical training in connection with the gardens at Wisley.

Arrangements have been made which will make it unnecessary to close the Museum of Practical Geology, Jermyn Street, for a month in autumn as heretofore; the museum will therefore remain open to students and visitors daily.

The International Astronomical Congress will begin its meetings at Lund, Sweden, on September 5.

The tenth International Congress of Navigation is to be held at Milan from September 24 to 30, 1905. Applications for the local organising committee's letter of invitation to the congress, and for the programme of the arrangements made, should be addressed to the general secretary of the congress, Signor E. Sanjust di Teulada, 3 Via Sala, Milan, or to Prof. L. F. Vernon Harcourt, 6 Queen Anne's Gate, Westminster.

An interesting exhibition of about 700 incandescent electric lamps, including the first experimental lamps made by Mr. Edison, is about to take place at the St. Louis Exposition. The collection is stated to be complete and unique, and to include a specimen of every kind of filament lamp ever made in Europe or America.

According to the Indian correspondent of the *Lancet*, Mr. Tata left a will by which his heirs and trustees are required to carry out his intentions with reference to the research institute in which he took so great an interest.

The Paris Academy of Sciences has awarded the Lecomte prize of fifty thousand francs for the most interesting work in physical science to Prof. Blondlot for his researches on the *n*-rays.

A gold medal has been awarded to Commander Peary by the Société de Géographie, Paris, in recognition of his work in the North Polar regions.

The Elliott-Cresson medal is to be conferred on Dr. Hans Goldschmidt, of Essen (Ruhr), Germany, by the Franklin Institute, Philadelphia.

After an absence of a year and eight months the Scottish National Antarctic Expedition has returned to Scotland, leaving, however, Mr. R. C. Mossman, the meteorologist, in the South Orkney Islands to continue his research work. At the meeting held to welcome home the expedition, Sir John Murray, as president of the Royal Scottish Geographical Society, read the following message of congratulation which had been telegraphed to Mr. Bruce, the leader, by Lord Knollys:—"I am commanded by the King to congratulate you and the officers and crew of the *Scotia* on your and their safe return and on the completion of your addition to scientific knowledge and discovery in the south-eastern part of Weddell Sea.—Knollys." A number of other congratulatory messages were also read, the gold medal of the Royal Scottish Geographical Society was conferred on Mr. Bruce, and a gold watch-seal presented to Captain Robertson.

According to the *Electrical Review*, the United States Naval Wireless Telegraph Commission will shortly recommend the establishment of wireless telegraph stations at various strategical points on the sea coast. These stations will transmit all Government messages, including weather bureau information, and it is probable that commercial telegrams will also be accepted. The Treasury proposes to provide revenue cutters with wireless telegraph apparatus. It is also stated that a contract has been signed between the United States Government and the De Forrest Wireless Telegraph Co., by the terms of which it will ultimately be possible to send wireless messages between New York and Japan. The Government, which will defray the cost of the various equipments, will have the use of the various installations for naval and other purposes, and the company will be bound to maintain them in good working order with the right to transmit commercial messages.

We have received from the secretary a programme of the proceedings of the sixth International Zoological Congress to be held at Berne from August 14 to 19. Up to the present 250 persons have joined the congress, and a number of countries and scientific societies will be represented, while no less than seventy communications have been announced to be read at the various sections. These sections are six in number, and in them the study of geographical distribution is assigned an important position. The proceedings will commence by a meeting in the great market-hall on the evening of Sunday, August 14.

Mr. J. G. Millais is to be congratulated on his good fortune in having been able to add an entirely new mammal to the British fauna in the form of a vole (*Microtus orcadensis*), of which the description appears in the July number of the *Zoologist*. In a postscript by Mr. O. Thomas it is stated that the new species is totally distinct from all other known forms, differing from the common short-tailed field-mouse (*M. agrestis*) not only in external characters, but in the number of folds in the second molar, and being apparently equally distinct from the Continental field-mouse (*M. arvalis*) and the eastern *M. ratticeps* and their immediate relatives. It forms, in fact, a small zoological and geographical puzzle. In the same number Mr. R. J. Howard describes an instance of the long-eared owl nesting on the ground.

A note in the *Scientific American* directs attention to a communication which was recently addressed to the French National Society of Agriculture by M. Bignon on the efficacy of artificial clouds in preventing late frosts. M. Bignon has for many years successfully protected his vineyard by the method he describes. The vineyard is divided into five parts, separated from east to west by walks of from 12 to 15 feet wide, and is encircled by an avenue of equal width. These walks facilitate the placing of the fires, which are built in small basins sunk into the earth some 50 feet apart, and filled with 15 or 20 pounds of resinous matter and some pieces of pine and other vegetable débris. During 1903 (in one week of which the frosts were very heavy) the method saved, it is reported, 25 per cent. of the harvest, or some 125 to 150 barrels of wine. It is stated that any substance can be burnt which gives a thick and abundant smoke, such as green herbs, moss, damp straw, tufts of grass, &c., but best results have been obtained by the heavy oils which are the residues of gas.

M. Élisée Reclus is preparing for the Belgian Society of Astronomy, Meteorology and Physical Geography a monograph descriptive of the volcanoes of the world and maps showing their distribution. One map, in colours, will

be on a scale of 1 : 40,000,000, and this will be supplemented by others on a scale of 1 : 2,000,000. On the proposed maps all the areas the surface of which is formed of eruptive rocks will be shown, and the location of the various forms of volcanic phenomena will be marked. Volcanoes that are believed to have been extinct since the historic period, those that have been active since the beginning of human history, and those which have more recently been centres of eruption will all have their distinctive signs.

In the opinion of the town sanitary committee of St. Petersburg the town medical officers should be sent abroad periodically in order to become acquainted with the progress of the sanitary and medical departments of the large towns of western Europe, and so be able properly to organise medical and sanitary supervision.

Dr. R. Fulton, writing to us from Dunedin, New Zealand, suggests that polyandry among birds is connected with the parasitic habit of depositing the eggs in the nests of other species. After referring to the well known fact that the common cuckoo is very markedly polyandrous, Dr. Fulton proceeds to point out that the same feature exists, or is in course of being developed, among many other wholly or partially parasitic species, such as the American cow-birds and cuckoos, parasitism gradually creeping in *pari passu* with the development of parasitism. If our correspondent's theory is well founded, it would certainly seem worth the attention of ornithologists. The writer further states that, contrary to the usual opinion, there are numbers of instances known where cuckoos (species not stated) have supervised the forced adoption of their offspring by other species, have assisted in their feeding, and have finally reclaimed and taken them away from their foster-parents. In support of this statement he cites Campbell's "Australian Birds."

We have been favoured with a copy of a circular letter from Hofrath Dr. Franz Steindachner, director of the Royal Museum of Natural History, Vienna, in which attention is directed, in the first place, to the importance of Parà, at the mouth of the Amazons, as a zoological station, and, secondly, to the great value of the biological work which has been carried on there during the last few years by Dr. Emil Goeldi and his able staff of assistants at the "Museum Goeldi." Dr. Goeldi's "Album de Aves Amazonicas," which has been specially noticed in our columns, and Dr. Huber's "Arboretum" are, in Dr. Steindachner's opinion, works of the highest scientific value.

In the *Quarterly Review* for July, Prof. Ray Lankester in an article on sleeping sickness reviews our knowledge of the trypanosomata. He directs attention to the recent researches of Schaudinn, which seem to prove that two blood-parasites, the first a malaria-like one, the Halteridium of birds, the other a spirillum-like form or Spirochæte, are simply phases of trypanosomes. Similarly the parasitic bodies known as the Leishmann-Donovan bodies (Nature, vol. lxix. p. 495), are stated by Rogers to give rise to trypanosome forms. Incidentally Prof. Lankester takes the opportunity to indict the British Government for its supineness with regard to scientific research.

Parts i. and ii. of vol. lxxvii. of the *Zeitschrift für wissenschaftliche Zoologie* contain two long papers devoted to annelid morphology, the one, by Mr. A. Luther, on the "Eumesostomine" rhabdocœlous turbellarians, and the other, by Mr. E. Mattiesen, on the embryology of the fresh-water planarian, or dendrocœlous, turbellarians. Both are of far too technical a nature for detailed notice in our columns, but it may be pointed out that, according to modern principles of nomenclature, the title "Eumestominæ" for the subfamily typified by the genus Mesostoma is a misnomer, the proper term being "Mesostominæ."

The *Entomologist* for July opens with a coloured plate illustrative of three new species of butterflies described in the first article by Mr. W. Dannatt. Various writers record the capture during the present season in different parts of the country of no less than eight examples of the rare striped hawk-moth (*Deilephila livornica*).

The July number of *Nature Notes* contains an account of the annual meeting and conversazione of the Selborne Society held in May last in Burlington Gardens, when a large number of prizes were awarded for work connected with field natural history. The society continues to display its wonted activity in endeavouring to protect such natural and artificial features of the country as appear in danger.

No. 12 of the *Publications de Circonstance* of the International Council for the Exploration of the Sea contains a useful catalogue of the fishes of northern Europe with their names in the different languages of this region. In part xiii*a*. of the same is commenced a detailed account of the present condition of the Swedish and Danish sea-fisheries, illustrated with maps and diagrams.

The *Proceedings* of the Philadelphia Academy for April contain three papers dealing with descriptive zoology, namely, one by Mr. A. Gulick on the fossil land-shells of Bermuda, a second by Mr. J. A. G. Rehn on the bats of the genus Macrotus, and a third by Mr. H. C. Oberholser on the birds of the genus Dendrocincla. More general interest attaches to a communication by Mr. A. E. Brown on post-Glacial Nearctic centres of dispersal for reptiles, of which only the first page is included in the section before us.

The third part of Mr. G. M. Allen's list of the fauna of New England (in course of publication by the Boston Natural History Society) is devoted to the Mammalia, of which eighty-eight species and subspecies are recognised. Old-fashioned naturalists will be somewhat surprised to see well known species figuring under such unfamiliar titles as *Paralces americanus* and *Odocoileus virginianus borealis*.

The *Proceedings* of the Royal Physical Society of Edinburgh for June contain an abstract of the address of the retiring president, Prof. J. C. Ewart, which was devoted to the "making of the elephant," based on recent discoveries in Egypt. In addition to Mr. W. E. Clarke's account of the Færöe mouse, already noticed in our columns, the contents of this number include a paper by Drs. Hepburn and Waterston on the anatomy of the porpoise, and one on colour variation in the viper by Dr. G. Leighton.

In *Science* (July 1) Prof. Long, in an interesting paper, gives an able summary of the relation of modern chemistry to modern medicine. He deals briefly with the action of enzymes, with oxidation in the tissues, with toxins and Ehrlich's side-chain theory, and with the application of physical and mathematical chemistry in the exact study of problems which at one time were assumed to be essentially biological. He finally discusses what should be the proper course of chemistry for the medical student, and concludes that the young man commencing the study of medicine must bring with him a knowledge both of inorganic and organic chemistry sufficiently broad to enable him to grasp the new problems which medicine now presents.

The papers in the July number of the *Journal of Anatomy and Physiology* (xviii., part iv.) are almost all purely anatomical in character. Prof. Arthur Robinson's third Hunterian lecture on the early stages in the development of mammalian ova and an obituary notice of the late Prof. His are the only exceptions.

To commemorate the centenary of the birth of M. J. Schleiden, botanist and naturalist, a short account of his life and works has been prepared by Dr. Mobius, and is published by Engelmann, of Leipzig. Endowed with a controversial temperament and possessed of a ready wit, Schleiden's life was characterised by strenuous activity, but he practically sacrificed his scientific career at an early age in order to plunge into political matters. He is best known for his "Grundzuge der Botanik," which may be described as the first *scientific* text-book of botany. A collection of lectures entitled "Die Pflanze und ihr Leben" was even more successful, as it passed through six German editions, and was translated into English, French, and Dutch.

In addition to the general botanical surveys of a county or a division of a county, there is considerable scope for the investigation of ecological problems on a less extensive scale. In the account of the botanical survey of a pasture which appears in the *Naturalist* (April), Mr. R. C. Gaut describes the characteristic plants which were found, and discusses the causes which enabled the crested dogtail grass to dominate a wet field, while hard by it was replaced by tussock, Yorkshire fog, or foxtail grasses.

In the *West Indian Bulletin* (vol. v. part i.) Mr. Buttenshaw takes up the subject of West Indian starches, their origin and characters. The majority of them are obtained from roots and tubers, and the order Scitamineæ provides a number of plants which store up starch. The writer mentions that the bread-fruit yields a starch suitable for laundry work, and that farinaceous foods can be prepared from the yam-bean, *Pachyrhizus tuberosus*, and "cho-cho" root, *Sechium edule*. In the same number will be found a report on the fruit industry of Jamaica by Mr. W. E. Smith, and a list of the birds of St. Vincent prepared by Mr. A. H. Clarke.

A third report of the special chloroform committee of the British Medical Association has been published (*Brit. Med. Journ.*, July 23, p. 161). Prof. Sherrington and Miss Sowton have continued the perfusion experiments on the isolated mammalian heart (see NATURE, vol. lxviii. p. 351), and find that equal quantities of chloroform dissolved in physiological saline solution, in serum, and in blood respectively exert on the heart very different degrees of depression, chloroform in the salt solution depressing the heart much more powerfully than when administered in blood in the same percentage strength. Mr. Vernon Harcourt gives the results of further tests with his inhaler, and Messrs. Byles and Harcourt and Sir Victor Horsley discuss the estimation of chloroform dissolved in blood.

We have received a copy of the twenty-sixth annual report of the Deutsche Seewarte, for the year 1903. This report marks an important epoch in the history of the Seewarte, owing to the retirement of Geheimrath Dr. G. v. Neumayer, with the title of "Excellenz," after twenty-seven years of eminent service as director of the institution. Under his able guidance the Seewarte has become one of the best organised of the European services, especially in the domain of maritime meteorology and international weather telegraphy. Dr. Neumayer's successor is Rear-Admiral A. Herz, who has the aid of a very efficient staff of assistants. We observe from the report that, like the work of our own Meteorological Office, the useful operations of the Seewarte are constantly increasing. In the department of ocean meteorology, 1169 log-books of various classes were received in the year 1903 against 939 in the previous year, which gave the very substantial increase of 72,563 sets of observations in the year 1903. In the department of weather telegraphy and storm signals great activity has been shown in perfecting the system of 7h. a.m. reports, and in extending it over the whole of Europe. Experiments have also been made with the view of improving the system of signals for giving warning of storms at night, by means of white and red lanterns. Space prevents us from specially mentioning the work of several other departments, but we have frequently had occasion to refer to the valuable publications issued by them from time to time.

In view of the arrangements in progress for continuous temperature observations at the observatory on Monte Rosa, Dr. Emilio Oddone contributes to the *Atti dei Lincei*, xiii. (1), 8, a short note on the values of the mean temperature for the different months of the year, estimated for the Monte Rosa station from other observations. Three different methods have been adopted. The first is based on observations at lower levels combined with corrections based on the temperature gradient; the second is based on temperature observations made in balloon ascents, and the third on 800 temperature observations made in various Alpine ascents, and reduced to the altitude and latitude of the Monte Rosa station. In this way materials have been collected from which it will be possible to infer, in the light of future observations, to what extent the mean temperature of a mountain station can be predicted from observations made elsewhere.

We have received the "Year-book" of the Austrian Central Institute for Meteorology and Terrestrial Magnetism for 1902. A more valuable series of observations and carefully prepared results could not be imagined; the volume contains daily observations or results for 409 stations, including Jerusalem and two other foreign places. The rainfall observations of 2560 stations are separately dealt with by the hydrographic department, and the Philosophical Society of Brünn has also a separate system of some 200 temperature stations, while the observations for Hungary are published by the Hungarian Meteorological Office. The distribution, as regards altitude above sea-level, of the 409 stations contained in the "Year-book" in question is worthy of note:—from 0–500 metres, 252 stations; 500–1000 metres, 111 stations; 1000–1500 metres, 33 stations; 1500–2000 metres, and 2000–2500 metres, 6 stations each; 1 station (Sonnblick Observatory), 3100 metres. We have here all the necessary materials for determining the value of observations on mountain stations for the purpose of weather forecasting, and for discussing other interesting questions as to the effect of altitude on the behaviour of various meteorological elements. A report of an international expert conference as to the usefulness (or otherwise) of the practice of gun firing for the dispersion of hail-clouds ("weather-shooting") is published separately as an appendix to this volume. The director of the Austrian Meteorological Service is Dr. J. M. Pernter.

Although many attempts have been made to prepare mixed anhydrides of organic acids and nitrous or nitric acid, they have always hitherto been fruitless. In the June number of the *Gazzetta*, however, L. Francesconi and U. Cialdea describe the method by which they have succeeded in preparing the mixed anhydrides of nitrous acid and acetic, propionic, and benzoic acids. These

anhydrides, which have the general formula R.CO.O.NO, are obtained by the interaction, at the temperature of a mixture of ice and salt, of nitrosyl chloride with the silver salts of the acids named. They form yellowish oils which may be distilled in a current of carbon dioxide at temperatures not exceeding 70°. On being heated, the vaporised anhydrides explode with violence, so that especial methods had to be devised for their analysis. By water the anhydrides are decomposed into nitrous anhydride and the corresponding organic acid.

IN the same number of the *Gazzetta* L. Francesconi and N. Sciacca establish the remarkable result that, at the temperature of liquid air, nitric oxide cannot be made to combine with a larger proportion of oxygen than that corresponding with the production of nitrous anhydride. Only at temperatures above $-110°$ does nitrous anhydride combine with oxygen to form the peroxide N_2O_4. At $-150°$ nitric oxide readily reduces the peroxide to nitrous anhydride, whilst the latter is stable, under the ordinary atmospheric pressure, at all temperatures below $-21°$. The pure anhydride is, at $-185°$, a dark blue solid which on being melted forms a dark blue liquid.

TO part iii. of vol. i. of *Records* of the Albany Museum Dr. R. Broom contributes four short papers on reptilian and amphibian remains from the Karoo series. Special interest attaches to an anomodont hind foot on account of the mammalian affinities exhibited by the tarsus. A new genus of labyrinthodont (Cyclotosaurus) and one of an endothiodont anomodont (Chelyoposaurus) are described.

THE *Annual Report and Transactions* of the Manchester Microscopical Society for 1903 has just been issued, and is of an encouraging nature. The society has now 181 members as compared with 170 at the end of 1902, and the financial statement is of a satisfactory character. The address which was delivered in December by Prof. S. J. Hickson, F.R.S., as president, on "Variations" is printed in the volume.

IN the *Physikalische Zeitschrift* (No. 14) W. Seitz describes a method of measuring the intensity of the β rays given off by radio-active bodies, in which the converse principle to that adopted by Strutt and by Paschen is made use of. Instead of measuring the positive charge which accumulates on a radio-active body in a vacuum, the magnitude of the negative charge produced by the impact of the rays themselves on an insulated metallic disc suspended in an exhausted glass vessel is determined. The apparatus used lends itself particularly well to the study of the absorption of the rays caused by the interposition of thin sheets of various materials. It is shown that the law found by Lenard to govern the absorption of the kathode rays roughly applies also to the β radiations, namely, that for unit surface the same absorption is caused by equal "masses" of the different materials, these masses being measured by the product of thickness and density. But the law is only approximately true, and, in the case of the elements, there is an increase in the absorption, for equal masses per unit of area, with an increase in the atomic weight.

AMONG papers in the *Verhandlungen der k.k. geologischen Reichsanstalt* for 1904, we note a study by Father R. Handmann of the Congeria-fauna of Leobersdorf, near Vienna (p. 48). The author sustains the view of Dr. Brusina, that this fauna is a northern offshoot from a Croatian centre of development. Dr. O. Ampferer (p. 73) describes in detail the relics of great landslips from the mass of the Tschirgant above the valley of the Inn. These probably occurred in late Glacial times. Travellers by road in this district will know how to this day the hillsides are in a state of unrest and instability. Herr C. von John (p. 104) furnishes a paper of interest to chemists and engineers on the different deductions that may be arrived at as to the heating power of coals, according to the condition and treatment of the sulphur present. This element may exist in organic combination, or in iron pyrites, or in a sulphate, and the mode of calculation adopted may seriously affect the statement of the oxygen present.

IN the *Journal* of the Royal Microscopical Society for June, Dr. A. E. Wright discusses the following four methods of measuring the magnification of a microscope and its elements:—(1) use of a focusing lens placed above the ocular for bringing the emergent rays to a focus in the plane of a suitable measuring scale; (2) separate measurements of the magnifying powers of objective and ocular; (3) measurements depending on Helmholtz's formula; and (4) methods involving the production of a fiduciary phenomenon by means of a diffraction grating.

THE Royal Engineers' *Journal* for June contains the description of a new form of slide rule invented by Major F. J. Anderson. The advantages claimed for it appear, so far as can be judged from the description, to consist in the fact that it can be used with a ducdecimal instead of a decimal scale of notation, and that the numbering of the lines is made absolute, there being separate and parallel scales on the upper limb for numbers from 1 to $\sqrt{10}$, $\sqrt{10}$ to 10, and so forth, and on the lower limb for the square roots of these numbers. Those interested in slide rules will doubtless compare the present instrument with the circular slide rule and the form proposed some time ago, in which the graduations formed a spiral line on the surface of a cylindrical ruler.

IN the *Parents' Review* for July, Prof. J. Arthur Thomson gives a suggestive paper on "Nature and Nurture," in which he discusses some of the problems of inheritance and shows that much may be done to mould the young in spite of the factors of inheritance. Dr. Leslie Mackenzie discusses normal growth in the school ages, dealing with such subjects as work, play, sleep, and diet; Dr. Clouston gives some useful hints on nervous diseases and symptoms of the school age, and Mr. George Smith discusses developmental exercise at school. If parents and others in charge of the young would study such articles as these and put into practice what they teach, the race would grow up healthier and happier.

THE last three numbers of the *Bulletin* of the St. Petersburg Society of Naturalists (2, 3, 4, for 1904) contain a number of interesting communications:—"On the Respiration and the Biology of Enzymes," by I. Warschawsky, S. Kostytschew, N. Maximoff, and M. Lestsch; "On the Tertiary Formations of Crimea and Western Caucasus," by V. Bogatscheff and J. Mikhailovsky, both giving extensive lists of the fossils they have found; "On the Geology of Samara," by W. Lehmann; "On the Peat-bogs of Novgorod," by W. Sukatcheff; "On the Lichens in the Sayans," by A. Elenkin; "On the Volcanic Rocks of the Trialet Mountains in the Caucasus," by B. Kolenko; "On the Fossils Found in the Bolshezemelsk Tundra (North-eastern Russia)," by W. Chitrowo; "On the Survival of the Heart in Mammals," by Th. Thur; "On the Morphology of the Phagocyte Organs of Insects," by O. Dawydoff; "On the Influence of Quinine on the Respiration of Germinating Seeds," by J. Smirnoff; "On the Morphology of the Rust-fungi," by W. Tranzschel; and several smaller notes. All of them are summed up in French or in German.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN AUGUST:—

Aug. 7. Juno in opposition to the Sun (Juno, mag. 8·7).
10. 7h. Saturn in opposition to the Sun.
10–12. Epoch of the August meteors (Perseids, Radiant $45^\circ + 57^\circ$).
14. 11h. 20m. Minimum of Algol (β Persei).
15. Venus. Illuminated portion of disc = 0·983, of Mars = 0·986.
17. Saturn. Outer major axis of outer ring = 43″·43. Outer minor axis of outer ring = 11″·37.
19. 16h. Mercury at greatest elongation (27° 24′ E.).
23. 11h. 6m. to 12h. 33m. Transit of Jupiter's Sat. III. (Ganymede).
24. 8h. Moon in conjunction with Saturn (Saturn 4° 4′ S.).
30. 8h. Moon in conjunction with Jupiter (Jupiter 2° 7′ N.).
" 14h. 44m. to 16h. 8m. Transit of Jupiter's Sat. III. (Ganymede).
" 14h. 51m. to 16h. 13m. Moon occults ξ' Ceti (Mag. 4·5).

THE CENTENARY OF DOPPLER.—We have received from Dr. Karl Haas a copy of the address that he read on the occasion of the celebration of the centenary of the birth of Christian Doppler. It is strange to reflect that Doppler, in 1842, years before Kirchhoff and Bunsen had demonstrated the possibilities of the spectroscope, first announced the principle bearing his name which has since become so famous and so fruitful of application. He himself was not happy in his original suggestion, for he sought to employ the "principle" as a means of explaining the colour of double stars, and it may be that some of the controversy that at one time raged round this question originated in its faulty application, rather than in the generic principle underlying the suggestion. So far as acoustical waves were concerned the matter could be, and was, settled by experiment, and Dr. Haas not only referred to the various tests that had been made to prove the validity of the "principle," but exhibited some of the apparatus that had been employed, and repeated the experiments. Dr. Haas briefly referred to Doppler's strenuous life and work in other departments of natural science, showing that the enunciation of the principle was not a matter of accident, but that it was led up to by philosophical study, and put before the audience the grounds on which Doppler was entitled to their respect But the valuable work that had been accomplished in the realm of spectroscopy naturally made him linger on this part of the subject, and he gave a useful summary of what has been effected by those who saw how the principle could be applied in special directions; as, for example, Sir William Huggins in the measurement of the motion of stars in the line of sight, Sir Norman Lockyer in the matter of sun-spots and prominences, Dr. Langley and others in the determination of the time of rotation of sun and planets, Prof. Keeler in the spectroscopic observations of the ring of Saturn, and by Dr. Vogel in the department of spectroscopic binaries. M. Belopolsky's scheme for showing experimentally the validity of the principle when applied to light waves was mentioned, while in the department of theoretical physics one was reminded how the application of the same principle was rendering most efficient service. If the centenary served no other purpose, it at least had the effect of tracing the connection between the original thought and its manifold applications.

SATURN'S NINTH SATELLITE (PHŒBE).—The next volume of the "Harvard Annals" is to contain a discussion of Prof. W. H. Pickering's recent observatons of the satellite Phœbe from the photographs obtained at Arequipa.

Meanwhile, in order that other workers may be able to observe this satellite, Prof. E. C. Pickering publishes the following position angles and distances from Saturn on the dates named:—

1904	Position angle	Distance
July 14 ...	77°·4	17′·8
July 24 ...	79°·8	14′·3
August 3	84°·0	10′·5

(*Circular* No. 67, Kiel Centralstelle.)

PRINCIPAL PLANES OF THE STARS.—In the first of a series of papers entitled "Contributions to Stellar Statistics" (published by the Carnegie Institution), Prof. Newcomb discusses "the position of the galactic and other planes toward which the stars tend to crowd."

After demonstrating *in extenso* the formation of the general equation determining the planes, he considers several special cases, and arrives at the following important results, giving the positions of the poles of the respective planes determined:—

	R.A.	Dec.
Galactic plane (omitting branch) ...	192°·8	+27·2
" " (including ") ...	191·1	+26·8
Gould's belt (as determined from 36 stars, of small proper motion, near it) ...	179·6	+26·4
Plane of all stars to magnitude 2·5.	181·2	+17·4
" " " 3·5.	180·0	+21·5
Plane of fifth-type (Wolf-Rayet) stars ...	190·9	+26·7

A determination of the mean latitude of 42 points in the main stream of the galaxy shows that this stream is not, on the whole, a great circle, for the mean latitude obtained is $-1^\circ{\cdot}74$, showing a small but well marked displacement of our system from the central plane towards Coma Berenices, where the north galactic pole is situated.

Gould's values for the poles of his belt were R.A. = 171°·2, dec. = +30°; the value given in the above table reduces his value for the inclination of the belt to the galactic plane by nearly one half.

The above position of the plane containing the Wolf-Rayet stars was determined from the positions of seventy-one such stars (excluding those found in the Magellanic Clouds) communicated by Prof. Pickering, and deviates by only 15′ from the position obtained for the galaxy.

Prof. Newcomb has also investigated the law of "star-richness" of the galactic regions, and among other interesting results records the following numbers as the richness per square degree as determined from the Bonn and Cordoba Durchmusterungs:—

	Bonn DM.	Cordoba DM.
Near galactic pole ...	8·6	29·9
In rifts of the galaxy ...	19·8	45·7
In the galaxy generally ...	24·6	94·1

This result shows that, neglecting the agglomerations, the galactic density is more than double the other in the northern hemisphere, whilst in the southern it is not more than 50 per cent. greater. The general result indicates that, even neglecting the condensation of the Milky Way, the richness increases considerably from the galactic poles towards the equator.

THE PERSIMMON CREEK METEORITE. No. 1380, vol. xxvii., of the *Proceedings* of the U.S. National Museum contains an illustrated description of the physical and chemical characteristics of the meteorite found at Persimmon Creek, North Carolina, in the spring of 1893. The weight of the main mass of this meteorite was 9 lb. 6 oz., but a fragment weighing 1 lb. 13 oz. had been previously detached. The date of the fall is unknown, but the general appearance when found indicated that it had lain in the soil for a considerable period, whilst the inspection of a polished surface afforded evidence of its meteoritic origin, and showed that it was composed of a more or less continuous matrix of iron containing troilite, schreibersite, and carbon. Separate analyses of the various constituents were made, and the results are given in the paper.

ENHANCED LINES OF TITANIUM, IRON, AND NICKEL.—In No. 5, vol. xix., of the *Astrophysical Journal*, Mr. Herbert M. Reese, of Yerkes Observatory, gives a list of wave-lengths in the Ti, Fe, and Ni spark and arc spectra respectively, indicating a fair number of new enhanced lines. The majority of these, however, are only very slightly enhanced, and will require further confirmatory evidence before being finally accepted.

FURTHER EPHEMERIS FOR COMET 1904 *a*.—A supplement to No. 3961 of the *Astronomische Nachrichten* contains a continuation of the ephemeris published by Prof. Nijland in No. 3951 of that journal. This ephemeris gives the positions of the comet for every alternate day from July 18

to October 30, but, as the comet will be only 0·3 of its original magnitude on July 30, and is still decreasing, it is scarcely worth while reproducing it here.

The R.A. is varying but little, and on August 1 will be 12h. 16m. 40s., whilst the declination is slowly decreasing, and on the same date will be $+47° 34'·6$.

A MODIFIED FORM OF THE NEWTONIAN REFLECTOR.—In the *Monthly Notices* for May, 1895, the Rev. Chas. Davies described a modified form of Newtonian reflector in which the rays from celestial objects fell on a large plane mirror fixed at the open end of a horizontal tube, and were thereby reflected on to an ordinary parabolic mirror fixed at the other end, afterwards being brought to a focus through an aperture in the centre of the plane mirror to which was affixed the observing eye-piece. A movement of the plane mirror about the optical axis, and of the horizontal tube in azimuth, allowed any point in the sky to be reached.

By fixing the telescope in a fork at the upper end of a polar axis, M. E. Schaer, of Geneva, now proposes to modify this instrument so that, whilst retaining its original advantages, such as the unchanging position of the eye-piece, it may be used like an ordinary equatorial and cœlostat, and by the simple rotation of the polar axis by clockwork the object may be kept stationary in the centre of the field. In this arrangement the mirrors are so placed that they suffer very little from flexure caused by changes of position. Using a model instrument constructed on these lines M. Schaer found that the practical results were excellent (*Astronomische Nachrichten*, No. 3958).

SEISMOLOGICAL NOTES.

THE sixteenth number of the *Publications* of the Earthquake Investigation Committee in Foreign Languages (Tokyo) consists of 117 quarto pages of print and 9 full-page illustrations. The subject is on Milne horizontal pendulum seismograms obtained at Tokyo, the author of which is A. Imamura, assistant professor of seismology at the Imperial University of Tokyo.

While discussing amplitudes, it is pointed out that these quantities may be increased or decreased according to the relationship existing between the periods of earth movements and the period given to the pendulum, an objection, as has frequently been pointed out, to pendular apparatus in general. Out of a list of 298 records (July 24, 1899, to December 24, 1902), the more important are considered in relation to corresponding records obtained from other types of instruments in Japan, and from similar types of instruments in various parts of the world, the registers from which are issued biannually by the British Association. The more important results relate to the speeds with which different phases of earthquake motion have been propagated over paths of great length. By means of more than forty diagrams, each referring to a particular earthquake, speeds along arcual paths for several of the more important phases of motion are represented by straight lines, that is to say, the speeds are constant. For certain disturbances the evidence leads us to this conclusion, but this is not the case for all. For example, in Fig. 4, a diagram similar to publications by the British Association (Report, 1902, p. 66), we notice in connection with the preliminary tremors that the longer the wave path the greater are the divergencies among the observations which give the time interval to traverse the same. The time taken to travel 25° has apparently varied between 3·5 and 4 minutes, that is to say, the observations agree within 30 seconds. For 80°, however, the divergence is 5 minutes, while on still longer paths the intervals are still greater. When we look at these variations as shown on squared paper, we should certainly hesitate before representing their mean position by a straight line. If, however, it is a straight line, and we know the recording instruments to be similar, then one inference is that minute tremors which may be recorded at a station near to an origin may have failed to reach or to make themselves evident at stations which are very remote.

But why should earthquake vibrations fall in line with the vibrations of elastic bodies? If our world has a fluid or gaseous nucleus, Arrhenius, Fisher, and other physicists and geologists see in the same an explanation for many phenomena. Convection currents might explain slight changes in latitude (Fisher), and they certainly suggest variability of velocity along the same path.

Although we do not agree with all Mr. Imamura's conclusions, seismologists are indebted to him for a piece of valuable research.

In vol. ii., No. 6, of the reports of the Tokio Physico-mathematical Society Mr. K. Honda gives an account of the daily periodic changes in the level in an artesian well the depth of which is 380 m. with a water head within 3·2 m. of the surface of the ground. What he found was that there were two maxima and minima every twenty-four hours, the range of motion varying between 3 cm. and 1 cm. (For somewhat similar experiments made in a shallow well close to the bore-hole here considered, see Reports Brit. Assoc., 1895, p. 104.)

Near to the days of full and new moon the movements are marked and regular; the phases of maxima and minima agree with those of the tides in Tokyo Bay. The well sinks with a high barometer and rises with a low barometer. Rain does not affect the level. By experiment it was found that variation of pressure of 1 mm. of mercury produced a change in the level of the water of 13·5 mm. An equal natural pressure acting on the water head causing it to sink, and on the surrounding ground causing it to rise, only results in a level change of 4·35 mm. From this it is concluded that the earth's crust only transmits 68 per cent. of pressure on its surface to a depth of 380 m. Another conclusion is that the daily fluctuation of 1 to 3 cm. is more likely to be a tidal than a barometrical effect. The distance to the sea is 3 km. In a deep well in Yokohama 0·6 km. from the sea, the tidal effect results in a change of level of 16 cm. This extremely interesting paper concludes with references to the frequency of earthquakes in relationship to fluctuation in barometric and tidal loads. In No. 9 of the same reports Mr. Honda gives a continuation of similar researches carried on at three other deep wells, at the end of which he shows that earthquakes with a submarine origin are most frequent when tidal pressure is at maximum, a minimum, and when the rate of pressure is changing most rapidly. No. 8 of the *Journal* is from the pen of Dr. F. Omori, who shows, chiefly from the consideration of after shocks, that earthquake frequency is affected by changes in atmospheric pressure.

Consul G. Pára, of Uskub, gives (*Kaiserliche Akad. d. Wissenschaften in Wien*, April 21, No. 10) a few statistics relating to the destruction caused by the earthquake which on April 4 disturbed the Balkans. This is followed by further details of a more geological character by Prof. R. Hoernes. The phenomena described are of an ordinary character.

Under the title of "L'Eruzione dell' Etna in 1892," (vol. i.), in a large quarto volume, the director of the observatory in Catania, Prof. A. Ricco, and S. Arcidiacono give a detailed account of the phenomena which accompanied the eruption of Etna in 1892. As an assistance to the better understanding of the historical sequence in events, this is prefaced by accounts of the eruptions of 1883 and 1896, all of which took place on the line of a radial fracture at points from 1000 to 1500 m. lower than the main central crater. It is essentially a volume of observations of value to the vulcanologist, to be followed at a later date by deductions.

In the *Bollettino dell' Accad. Gioenia, Catania*, fas. lxxix., December, 1903, S. Arcidiacono gives a short account of earthquakes which recently disturbed Etna, and which were of local origin. From a tabular statement of these it appears that from 1898 seismic activity was fairly uniform and not pronounced, but after the eruption of 1902 it became three-fold.

The first paper in the *Bollettino della Società Sismologica Italiana* (vol. ix., No. 9, 1903–4), by M. Tito Alippi, relates to the possible relationship of *bonniti* and *bombiti* (mist poeffers, barisal guns, &c.) to seismic movements. From a list of seismic disturbances recorded in a district where *bonniti* were frequent, it does not appear that the two phenomena are connected. The multiplication of the seismograph was, however, only 12. Had it possessed ten times this sensibility it might have responded to minute

tremors propagated in the soil, and quickly afterwards to movements produced by air waves acting on the building, and then to the instrument. A second paper, by the late Dr. M. Contarini, is on the choice of earthquake recorders. Although the paper is short it contains good advice. We are told first to select our instrument according to the object we may have in view. If we wish to record earthquakes of local origin, a type of instrument may be used different to that which will record disturbances with their origins as distant as the antipodes. Again, an instrument which may record the times of arrival of certain phases of motion may not be able to analyse the same; in fact, for earthquakes of distant origin it is doubtful whether an instrument yet exists that gives a true record of the movements of the soil.

At the end of the number the Italian catalogue of shocks of local and of distant origin is brought up to the end of September, 1902.

In an interesting article of twenty-eight pages, M. Paul Choffat gives in *Communicações du Servia Geologique du Portugal* (Tome v., pp. 279–306) an account of "Les tremblements de terre de 1903 en Portugal," to which he adds notes relating to earthquakes which took place in previous years. From the conclusions we learn that there are two chief centres from which disturbances felt in Portugal originate, one of which is suboceanic off the mouth of the Tagus, from which the great Lisbon earthquake of 1755 radiated, and the other is in Andalusia, the shocks from which are comparatively feeble. There are also several local centres.

AGRICULTURAL NOTES.

THE officials in charge of the County Technical Laboratories at Chelmsford are engaged in an investigation that will commend itself to Londoners; they are trying to gain some information as to the natural causes bringing about variation in the composition of milk. Two reports dealing respectively with the winter and summer months of the past year have been issued. From the latter we learn that in Essex milk is poorest in the months of July and August. This is the common experience of dairy farmers. It is when the pastures begin to dry up that the quality of milk suffers most. In the Essex experiments four cows were kept under observation from May until September, and two others for a shorter period. The yield of milk fell off at the rapid rate of 10 per cent. per month; with this decline there was an increase in the proportion of fat, but no regular increase in the case of solids not fat. In the month of July the percentage of non-fatty solids decreased in the milk of every animal. The milk of four of the cows, and the mixed milk of the six animals, never fell below the standard in solids not fat, but two of the cows often failed in this respect. The mixed milk and the milk of one of the cows never contained less than the standard quantity of fat, but the milk of two of the cows frequently, and the milk of two others occasionally, contained less than the required 3 per cent. of fat.

In connection with the investigations on nutrition, which form an important part of the work of the Storrs Agricultural Experiment Station, Conn., analyses have recently been made of the flesh of many kinds of fowl. The analyses were published in the annual report of the station for 1902–3, and some account of them is also given in a recently issued bulletin on "Poultry as Food." The bulletin contains a table showing the composition of the digestible nutrients in the flesh of poultry; comparisons are made between young and mature birds, and also between poultry and other common articles of diet. The meat of light-fleshed birds is shown to be usually richer in albuminoids and poorer in fat than the meat of dark-fleshed; and among light-fleshed fowls chickens supply a more nitrogenous food than mature birds; on the other hand, in dark-fleshed fowls the flesh of the young appears to contain more fat and less albuminoids than the flesh of older birds. The following figures show that the breast, or breast and wings of poultry, usually contain more albuminoids and less fat than the legs or dark meat. The analyses were of raw meat. Cooking may materially alter the proportion of fat.

	Digestible nutrients	
	Albuminoids	Fat
	Per cent.	Per cent.
Chicken, light meat	21·2	7·0
,, dark ,, ...	20·2	7·8
Turkey, light meat	25·0	10·7
,, dark ,, ...	19·4	23·8
Duck, breast	21·6	2·2
,, other parts	16·9	24·8

An important paper containing a summary of Koch's investigation of Rhodesian red-water, or, as he prefers to call it, African coast fever, appears in the May number of the *Agricultural Journal* of the Cape of Good Hope. This disease of cattle, introduced from the coast, has recently worked havoc in Rhodesia, the mortality among the herds of certain districts having risen to 90 per cent. Like Texas fever, with which it was at first confounded, coast fever is due to the presence of a tick-conveyed parasite in the blood. An animal which has recovered becomes immune, and, according to Koch, a proportion of the progeny contract the disease in a mild form as calves and also become immune, so that an immune race will gradually form in the same way as a partially immune population is to be found in many of the most deadly malaria districts. In the absence of ticks, coast fever cannot spread. Unlike Texas fever, injection of the blood of a diseased animal will not produce the disease. But Koch has shown that repeated injections result in a mild fever which is sufficient to confer partial, and in his opinion a high degree of immunity. On this fact is based the treatment which he recommends for the disease, the injection of 5 c.c. of defibrinated blood from a sick or "salted" animal about seven times at intervals of a fortnight. This treatment he believes will in four or five months confer immunity. Inoculation is absolutely safe, for of 3115 "clean" animals treated not one died, and the treatment is so rapid that an operator can deal with 300 to 500 per day. Of the efficacy of the treatment it is clear that Koch has a high opinion, though he is careful to point out that his experimental evidence is not yet complete. Of 1688 animals that had been exposed to infection and were inoculated, 174 died. As in many of these cases inoculation must have been too late to benefit, Koch argues that the number dying because inoculation failed to protect must have been very small. In view of the very high death rate in unprotected herds it would appear that the proposed treatment is of high promise.

But Koch's views on the value of inoculation do not seem to be shared by all the experts who are now engaged in the study of African coast fever, and the Government entomologist, Mr. Lounsbury, who has made a careful study of the tick conveying the disease, appears to favour the use of arsenical dips, which, by destroying the tick, would put an end to the ravages of coast fever. Lounsbury speaks of these dips as an "effectual remedy," while Koch characterises their use as a "temporary" measure. Mr. Lounsbury publishes an interesting account of the experiments by which he proved that the infection was carried by the common brown cattle tick of South Africa (*Rhipicephalus appendiculatus*). He failed in ten experiments to convey it through the blue tick, which Koch says is partly responsible for transmission. In a preliminary experiment Lounsbury proved that brown ticks taken from sick cattle in Rhodesia produced coast fever in Cape Colony. Brown ticks were then collected in a region in the colony in which coast fever was unknown. From these ticks progeny were raised, the majority of which were fed throughout life on healthy cattle without causing any disturbance in health; others were taken to Rhodesia and placed on a sick cow; they were then taken back to Cape Colony and put, at intervals of a few days, on three cattle. "The results were most decisive. The three animals sickened each in turn about a fortnight after the infestation," and all died. This experiment was repeated, and it was found that a single tick could produce the disease. Lounsbury notes that one of the cattle which died in his experiments had previously been inoculated ten times from an animal pronounced by Koch to be suitable as a "bleeder."

While in South Africa Koch has studied horse-sickness, and in a recent report on his work he speaks of "encouraging results which . . . impress me with the conviction that a practical method of protective inoculation against Horse-sickness is within our reach." A serum has been prepared which has slight curative but high protective properties. Unfortunately, the immunity conferred by the serum lasts only for some fifteen days, so that a horse cannot be "salted" by inoculation, and to be safe from an attack the animal must have already had horse-sickness in some form. The "practical method" which Koch proposes consists in producing horse-sickness by an injection of virus, and then arresting its progress by injections of the protective serum before it becomes dangerous. The method has been practised successfully on more than a dozen animals. As the result of his experiments Koch recommends the following treatment:—Seven injections of virus at intervals of twelve days, the doses increasing from 0.01 c.c. to 5 c.c. Four days after each of the first three injections of virus, doses of 100 c.c., 50 c.c., and 50 c.c. of protective serum to be given. The injections of both virus and serum are made subcutaneously in the neck.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Frank Smart studentship in botany has been awarded to Mr. A. M. Smith, of Emmanuel College.

Mr. E. R. Burdon, of Sidney Sussex College, has been appointed assistant curator of the botanical museum.

Science announces the resignation of Prof. G. Trumbull Ladd as head of the department of mental philosophy and metaphysics of Yale University.

LORD STRATHCONA has given 4000*l.* to the scientific department of the Manitoba University. A block of land sufficient to yield a large annual income is also to be placed at the university's disposal.

THE chair of chemistry in University College, Sheffield, has been accepted by Dr. W. P. Wynne, F.R.S., at present professor of chemistry in the School of Pharmacy of the Pharmaceutical Society of Great Britain.

DR. C. SCHUCHERT, of the U.S. National Museum, has been appointed professor of historical geology in the Sheffield Scientific School of Yale University, and curator of the geological collections in succession to the late Prof. Beecher.

THE "Year-book" for the session 1904–5 of the Armour Institute of Technology, Chicago, a copy of which has reached us, contains full particulars of the course in fire protection engineering instituted last year. The course is arranged to furnish instruction in modern methods of fire prevention and extinction. Since fire insurance interests are closely connected with the work of the course, a portion of the time of senior students is devoted to the study of modern practice of fire underwriting. Prof. Taylor, who is in charge of this department of the institute, has rightly given great prominence in his syllabus to the scientific principles upon which successful work in fire extinction depends.

THE consultative committee to the Board of Education has submitted a number of suggestions to the board for a system of school certificates. The committee is of opinion that, with the object of diminishing the multiplicity of examinations affecting secondary schools, and of providing a test of adequate general education which may be widely accepted, a general system of school certificates is desirable. The committee does not think it is desirable that examinations for such certificates should be conducted by means of papers set for the whole country from a single central organisation. It suggests that such examinations should be controlled by a recognised examining body, which should be either a university or a combination of universities, or an examination board representative of a university or universities, and of the local authorities which are prepared to cooperate with them. It proposes that recognition of these examining bodies should mean recognition by the Board of Education, acting on the advice of the consultative committee. The establishment is suggested of a central board for England consisting of representatives from the Board of Education and from the different examining bodies, the duty of which should be to coordinate and control the standards of these examinations, to secure the interchangeability of certificates, and to consider and, as far as possible, to adjust the relations of the examining bodies and their spheres of external action. There can be little doubt that some such plan as the consultative committee proposes would enable schoolmasters to utilise in the better education of their boys much of the time now absorbed by the preparation for numerous special examinations.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 11.—M. Mascart in the chair.—Thermochemical investigation of the solution and polymerisation of cyanogen: M. **Berthelot.** Potassium cyanide has considerable thermal effect on a solution of cyanogen whether in water or alcohol.—Note on the heat of transformation of black crystalline sulphide of antimony into the orange coloured precipitate: M. **Berthelot.**—Condensation of glycol bromoacetate with acetoacetic and acetone dicarboxylic esters: A. **Haller** and F. **March.**—Origin in food of the arsenic normally found in man: Armand **Gautier** and P. **Clausmann.** Practically all food materials, particularly fish, contain traces of arsenic, the total arsenic received by an average man in a year being 7·66 mg.—The relation between external work and total expenditure of energy in a muscle in dynamic contraction, when the muscle is doing negative work, against the fall of a load, by gradually elongating as the load falls: A. **Chauveau.** It is concluded that the expenditure of energy is greater in negative work than in fixed contraction, but less than in positive work under the same conditions of load, stimulus, &c., and that in negative work the expenditure of energy increases more rapidly, when the work is increased by increase of load, than by increase of movement.—Note on a new method of observing *n*-rays: R. **Blondlot.**—Analysis of the ashes contained in the urns of Materpa (Thebes, eighteenth dynasty): MM. **Lortet** and **Hugoumenq.**—Regulation of watches at sea by wireless telegraphy: J. A. **Normand.**—The academy appointed MM. Mascart, Troost, Moissan, Guyon, and Lacroix to assist at the inauguration of the Pasteur monument in Paris.—Two problems on isothermic surfaces: L. **Raffy.**—Explosion waves: E. **Jonguet.**—Kathode rays and magnetofriction; reply to Villard: H. **Pellat.**—Note on the refractive indices of solutions: Edmond **Van Aubel.**—The relation between the pressure of a gas in a vacuous tube and the length of the spark produced: Gaston **Séguy.** As the pressure decreases in geometric progression the length of the spark increases in arithmetic progression.—The densities of sulphurous anhydride and of oxygen: Adrien **Jaquerod** and Alexandre **Pintza.** Morley's method of weighing the gas by the loss in weight of the generating apparatus was used with concordant results in the case of sulphurous anhydride.—The heat of combustion of organic sulphur compounds, and a note on that of compounds containing halogens: P. **Lemoult.** Results of experiments are compared with those obtained by calculation according to the position of the sulphur.—Reactions of the esters of 2:3-butanonic acid. (1) Action of phenyl hydrazine: L. **Bouveault** and A. **Wahl.** The phenyl hydrazone obtained in the cold is proved to be that in the 2-position by the formation of the paranitrophenyl hydrazone of methyl phenyl acetopyrazolone previously obtained by Bülow.—Researches in the pyrane series: E. **Blaise** and H. **Gault.**—On some phenolic ethers of the pseudo allyl chain $R—C(CH_3)=CH_2$: MM. **Behal** and **Tiffeneau.** These bodies are obtained by the magnesium methiodide reaction on the corresponding esters, using one or two molecules in excess of the magnesium methiodide, and are intermediate between the corresponding allyl and isoallyl compounds in boiling point, density, and refractive index.—Action of traces of some salts, and of caustic alkalis on diphenyl carbonic ester: R. **Fosse.**—Mechanism of the action of the cytoplasm in seeds during germination, and the synthetic realisation of this mechansm *in vitro*: Maurice **Nicloux.** The development of acid in oily seeds, when

germinating, is proved to be due to the hydrolytic action of the cytoplasm on the oil. The name *lipaséidine* is proposed for the active substance in the cytoplasm. The action requires some acid to start it, but CO_2 is proved by experiment *in vitro* to be sufficient, and CO_2 is produced in germination.—A new trypanosome in birds: M. **Thiroux.**—Some phenomena during ovogenesis among the cirripedes, particularly in *Scalpellum velutinum*: A. **Gruvel.**—On the structure of the heart in gasteropods and lamellibranchs: F. **Marceau.**—On the development of black rot (*Guignardia Bidwellii*): P. **Viala** and P. **Pacottet.** For rapid development black rot requires a warm temperature and a moist atmosphere, but at low temperatures growth proceeds slowly. It is, moreover, highly resistant towards acids and toxic substances generally.—Garéwaite, a new fibrous basic rock of the North Urals: L. **Duparc** and F. **Pearce.**—Stationary waves observed in the neighbourhood of the human body: Augustin **Charpentier.**—Localisation of iodine in the African turtle: MM. **Doyon** and **Chenu.** Action of salts of the alkaline earths on living substance: N. C. **Paulesco.**—Influence of sterilisation on food-stuffs: A. **Charrin.**—On the contractility of protoplasm, i., action of chlorhydrate of amyleine on ciliary movement: L. **Launoy.**—On the supposed chlorophyll of silk: Jules **Villard.**

July 18.—M. Mascart in the chair.—Experiments on the slow oxidation of cyanogen and cyanides by free oxygen: M. **Berthelot.** The absorption of oxygen from air by the following solutions is examined:—potassium cyanide, hydrocyanic acid, and cyanogen in water and in alcohol, alcohol alone, and alcoholic potash, also by these solutions in the presence of mercury. Absorption of oxygen is observed in every case, but becomes more rapid when the tube is heated or exposed to light. When mercury is present, the absorption of oxygen causes solution of some mercury, particularly with the cyanides.—The natural immunity of cynocephales towards trypanosomiases, and the activity of their serum towards trypanosomes: A. **Laveran.**—Hypsometric tables of Cretaceous strata in the north of France: J. **Gosselet.**—Pamphlets presented to the academy:—Considerations on the principles of arithmetic: L. **Gros.**—Researches on the quantity of citric acid in wines: Lucien **Robin.**—A work on tables of corrections of the times of the moon's rising and setting: S. **Abdullah.** A supplement to the general problems of flight: M. **Averly.**—The secretary read several telegrams concerning the earthquakes of July 12 and 13.—Steered balloons. Longitudinal stability: Ch. **Renard.**—On the anomalous propagation of light in the neighbourhood of a focal line, and on the interference of vibrations the amplitudes of which are different functions of the distance: G. **Sagnac.**—On the disappearance of some of the silicon lines in the spectra of certain stars: A. **de Gramont.**—Variation of the index of refraction of an electrolyte under the action of the current: H. **Bordier.** Chlorides of copper and of zinc were used. It was found that, when the current is constant, the reduction of index of refraction decreases with increase in the concentration of the electrolyte, whilst, when the concentration is constant, the decrease of refractive index plotted in a curve against the strength of the current forms a straight line.—The influence of the density of the current in electrolysis with alternating current: André **Brochet** and Joseph **Petit.** Nickel electrodes in a solution of potassium cyanide were used, and the relation between the amount of nickel dissolved and the density of the current investigated for different frequencies, when the time and total current were constant.—On the fundamental law of the phenomena of osmosis: E. **Ariès.**—On the constitution of dissolved salts: Albert **Colson.** The formula

$$HSO_4Zn—O—Zn—SO_4H$$

is assigned to zinc sulphate from considerations of the basic sulphates obtained by alkalis, and of the freezing point of solutions of zinc sulphate.—On some crystalline iodates of copper: A. **Granger** and A. **de Schulten.**—Dextrolactic acid and lævolactic acid are not alike in their reactions: E. **Jungfleisch.** *l*-Lactic is much more easily racemised than *d*-lactic, so much so that in separating *d*- and *l*- from *in*-lactic by the quinine salts, *d*-lactic is easily obtained, but the supposed *l*-lactic is mainly $d+l$.—Orthophosphoric anilide and its homologues; the non-existence of the compound $C_6H_5NH—P\equiv(NC_6H_5)_2$: P. **Lemoult.** Condensation of acetylene ketones with alcohols and phenols: Ch. **Moureu** and M. **Brachin.** Action of oxalacetic ester on benzaldehyde in the presence of primary amines: L. J. **Simon** and A. **Conduché.** The heat of neutralisation and acidity of monomethylarsenious acid: A. **Astruc** and E. **Baud.**—On a frequent source of error in the analysis of coal: Just **Alix** and Isidore **Bay.**—On some points in the anatomy of the cirripedes: A. **Gruvel.**—Antimeridian plants: Édouard **de Janczewski.**—Carpellised stamens of the wallflower: C. **Gerber.**—Bravais's law considered as a law of observation: G. **Friedel.**—A new theory of ouralitisation: L. **Duparc** and Th. **Hornung.**—On the terraces of the Carpathian rivers in Roumania: E. **de Martonne.**—Researches on the genital poisons of different animals: Gustave **Loisel.** The extract of an ovary is always more poisonous than that of a testis, and varies in different animals, that of the frog being most poisonous towards a rabbit. The toxic effect is nervous, producing tetanus and dyspnœa.—The influence of lactation on the resistance of the organism to morbid agencies: MM. **Charrin** and **Vitry.** A female in lactation is less resistant than the normal to alkaloids and bacteria.—The mechanical cleansing of the blood: Ch. **Répin.** To remove poisonous substances from the blood a method is used by which the plasma is removed, being replaced by artificial serum, but the corpuscles, being separated centrifugally, are immediately returned to the blood stream.—Researches on arsenic in some food-stuffs: V. **Bordas.**—A new contribution to the bacterial purification of spring and river waters by means of fine sand, which is not submerged: P. **Miquel** and H. **Mouchet.**—On the duration of the experiments in the treatment of arterial hypertension by d'Arsonvalisation: A. **Moutier.**—On a new type of piezometer: M. **Buchanan.**—The Hirondelle deep in the archipelago of the Azores: M. **Thoulet.**

"MUTATION" v. SELECTION.

Evolution and Adaptation. By Thomas Hunt Morgan, Ph.D. Pp. xiii+470. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1903.) Price 12*s.* 6*d.* net.

THE author of the present work is one of those biological theorists who, while accepting the doctrine of evolution, and apparently admitting that natural phenomena must be capable of rational explanation, yet think it necessary to adopt a severely critical attitude towards the only principle which seems able to account for the facts of organic development, the principle, namely, of selection, as first propounded and illustrated by Darwin and Wallace.

Among the difficulties which those who impugn the doctrine of selection have to face, the existence of adaptation in every department of organic nature is one of the most formidable. After every allowance has been made for hasty allegations which further knowledge has tended to disprove, there remains an immense body of facts relating to the adjustment of organisms to their surroundings that demands to be accounted for in accordance with the known laws of nature. What rational means of explanation are still open to those who would dispense with the Darwinian key to the puzzle of adaptation? This is, in brief, the question which Dr. Morgan asks and attempts to answer in the volume before us. It is true that his acceptance of the facts of special adjustment is somewhat grudging; even in the case of Kallima, which, as Weismann says, is "decisive for adaptation," he appears to question the utility of the very perfect concealment afforded by the underside. But whatever scepticism he may be justified in showing with regard to particular instances, neither he nor anyone else can deny with reason the general principle of adaptation. It must be set down to the author's credit that he does not seek refuge in the views of the Lamarckian school, whether new or old:—

"Despite the large number of cases that they (the Lamarckians) have collected, which appear to them to be most easily explained on the assumption of the inheritance of acquired characters, the proof that such inheritance is possible," he justly says, "is not forthcoming."

Where, then, are we to find a solution of the mystery? The answer, according to Dr. Morgan, lies in the "mutation theory" of De Vries. But here comes in a curious inconsistency of which the author himself seems to be partly, but only partly, aware. If he urges one point with greater insistence than another, it is that De Vries's theory "stands in sharp contrast to the selection theory." Yet the whole drift of his argument goes to show, though he seldom acknowledges it in so many words, that even if De Vries's account of "variations" and "mutations," and of the relation between them be accepted, selection must still be called in to explain the aspect of the world around us.

Let us for the moment lay aside the subject of the nature of variation, admitting that it is capable of a more minute analysis than Darwin gave it, and that much remains to be learned concerning different kinds of variation and their power of transmission by heredity. We are still face to face with the question, "How is it that the favourable variations form the majority of those that we see? What has become of the others?" The answer shall be given in Dr. Morgan's own words:—

"Over and beyond," he says, "the primary question of the *origin* of the adaptive, or non-adaptive, structure is the fact that we find that the great majority of animals and plants show distinct evidence of being suited or adapted to live in a special environment, *i.e.* their structure and their responses are such that they can live and leave descendants behind them. I can see but two ways in which to account for this condition, either (1) teleologically, by assuming that only adaptive variations arise, or (2) by the survival of only those mutations that are sufficiently adapted to get a foothold. Against the former view is to be urged that the evidence shows quite clearly that variations (mutations) arise that are not adaptive. On the latter view the dual nature of the problem that we have to deal with becomes evident, for we assume that, while the origin of the adaptive structures must be due to purely physical principles in the widest sense, yet whether an organism that arises in this way shall persist depends on whether it can find a suitable environment."

What is this but selection? The fineness of the distinction here drawn appears to have struck the author himself, for he immediately adds:—

"This latter is in one sense selection, although the word has come to have a different significance, and, therefore, I prefer to use the term *survival of species*."

We need not dispute over the term, provided that the principle, which is essentially Darwin's, be admitted.

The more we examine Dr. Morgan's argument as against Darwin, the greater difficulty do we experience in defining the precise point at issue between them. It is not the origin of variation; for if Darwin did not attempt to account for this, neither does De Vries. Nor is it the existence of the discontinuous variations called "mutations" by De Vries, for some of these were well known to Darwin. Nor, again, is it the principle of selection; for this, as we have seen, is virtually admitted on all hands. We might have been inclined to say that it was the question of the origin of species by large as against small variations, but for the fact that the author expressly states that "as De Vries has pointed out, each mutation may be different from the parent form in only a slight degree for each point." We are reluctantly impelled to the conclusion that the controversy is rather of a personal than of a material nature, and that at the root of it lies a kind of jealousy—no doubt unconscious—of Darwin's position and influence. It would

doubtless be unfair to say of the author that, so far as his treatment of Darwin is concerned—

> "Willing to wound, and yet afraid to strike,"

he would

> "Just hint a fault, and hesitate dislike;
> Damn with faint praise, assent with civil leer,
> And without sneering, teach the rest to sneer"—

but we cannot acquit him of a somewhat captious method of dealing with Darwin's clear and well considered utterances. We have seen of late a great deal of groundless objection to the Darwinian position, and many quite uncalled-for attempts to minimise the value of the Darwinian contribution to evolutionary theory. We may freely concede that the opinion expressed in the "Origin of Species" in favour of the transmission of acquired characters has not stood the test of investigation; but this is a negligible matter in comparison with the enormous impulse to evolutionary theory given by the doctrine of selection, which doctrine it was the peculiar merit of Darwin and Wallace to have presented in such a form as to command the attention of all scientific workers, and the assent of most. It cannot be said that the various attempts to dispense with selection have met with success, and in spite of the "carpers carping with their carps," we think that the Darwinian treatment of variation and selection still affords the only basis for a reasonable account not only of adaptation, but also of the origin of species.

F. A. D.

THE FAUNA AND FLORA OF ALASKA.

Harriman Alaska Expedition. Edited by Dr. C. H. Merriam. Vol. v. Cryptogamic Botany (pp. ix+424). Vols. viii. (pp. ix+238) and ix. (pp. 284). Insects. Vol. x. Crustaceans (pp. 337); illustrated. (New York: Doubleday, Page and Co., 1904.)

FROM time to time brief notices have appeared in our columns of various issues of "Papers from the Harriman Alaska Expedition," published in the *Proceedings* of the Washington Academy of Sciences. The whole of these papers, together with others hitherto unpublished, are now in course of re-issue in the form of a series of handsome and well illustrated volumes, with the title cited above, and under the editorship of Dr. C. Hart Merriam, the well known chief of the Biological Survey of North America. As the various papers are reprinted from the original electrotypes, and the original pagination is given in brackets, there is no likelihood of any confusion arising by quoting from the re-issue. Of these volumes, four are now before us.

Before going further, it may be well to state that the work does not attempt to give a complete account of the fauna and flora of the Alaskan peninsula. In the insect volumes, for example, many of the papers deal only with the material brought back by the expedition, although in a few instances the existing state of our knowledge of each group is given so far as Alaska is concerned. Even where no attempt is made to formulate complete lists, in many cases the material obtained was, however, so extensive as to include the greater part of the representatives of the group described. In every instance the description and identification of the specimens collected have been assigned to specialists.

The volume on cryptogamic botany contains not only the new information acquired as the result of the expedition, but an account of the previous state of knowledge of the subject. Special interest attaches to the general account of Alaskan vegetation given in the introduction. The southern districts of Alaska, it appears, are characterised by the grandeur of their forests and the brilliancy of the flowers beyond the forest tract, the usual alpine conditions prevailing above the timber belt. Closer examination even of the wooded area reveals, however, a wealth of flowerless vegetation which gives to the flora a character it would otherwise lack; while the flowers of the mountain tops and prairies are set in beds of moss and fern. In the forest, owing to the abundant rainfall, every mouldering log, as well as the standing stems, are clothed with moss, which carpets the ground, and hangs in festoons from the branches. Among the mosses and liverworts grow many of the more delicate flowering plants, while the many fleshy funguses make this carpet their special home. The open glades are occupied by peat-mosses (Sphagnum) in considerable variety, which afford a basis for cranberries, sundews, and butterworts. North of the forest zone appears a wet, boggy tract, passing into the frozen Arctic tundra, the mossy carpet of which is, however, spangled in summer with a perfect blaze of flowers. In these open areas ferns grow in great luxuriance, and on Kadiak Island the traveller may wade through beds of bady-fern nearly waist-deep.

No less than eight specialists have given their services to the determination and description of the cryptogams collected during the expedition.

Passing to the volumes on insects, we have to note, in the first place, that this department in the expedition was confided to Prof. Kincaid, of Washington University, who collected some 8000 specimens, representing about 1000 species, and, secondly, that under the general title of insects are included both myriapods and arachnids. In the first of the two volumes, special value attaches to the paper on myriapods by Mr. O. F. Cook, since it treats of all the known members of that little-worked group hitherto obtained from north-western North America. Previous to the Harriman Expedition, our knowledge of the Alaskan insect fauna was mainly restricted to the Coleoptera and Lepidoptera, and consequently special efforts were made to collect the other groups. The result has shown that Alaska possesses a rich entomological fauna which awaits other collectors to reveal fully. Out of the 1000 species collected, 344 have been regarded as new to science. Special attention was devoted to the study of the adaptation of Alaskan insects to their surroundings, more particularly in the Sitka district, where the annual rainfall attains the enormous total (for a non-tropical or subtropical zone) of 105 inches. As might have been expected, the Diptera were found to form the predominating element in the insect fauna, but of this group only a small percentage has hitherto been, in all probability,

collected. In addition to those on myriapods and arachnids, the first of the insect volumes includes papers on Alaskan Coleoptera, Lepidoptera, Neuroptera, Orthoptera, Homoptera, and various minor groups. Special interest attaches to the chapter by Prof. Kincaid on the metamorphoses of Alaskan Coleoptera, in the course of which the author points out that the prevalent idea as to the extreme difficulty of rearing adult beetles from their larval condition is to a great extent founded on error.

The second of the two volumes on insects (ix.) is devoted to the Diptera and Hymenoptera, the article on the former being written by Mr. W. Coquillett, and the one on the latter group by Mr. W. H. Ashmead. In addition to these are three minor papers on certain sections of the aforesaid groups. A sample of the excellent results of Prof. Kincaid's energetic collecting is afforded by the case of the Hymenoptera, in which group less than thirty species were known from Alaska previous to the expedition, while the number now recorded is no less than 335, 201 of these being regarded as new to science. Of Diptera, 2423 specimens, representing 276 species, were collected, out of which one genus and 63 species are described as new.

As regards the volume on crustaceans, the great bulk of this is occupied by Miss Rathbun's elaborate and exhaustive memoir on the decapod section, Miss Richardson contributing a short account of the isopods, while Messrs. Holmes and Cole are severally responsible for the amphipods and pycnogonids, or sea-spiders. Miss Rathbun has treated her portion of this extensive subject from a very broad standpoint, discussing the crabs and shrimps not only of the Alaskan seas, but of the western coast of America generally, from the Arctic Circle to southern California. The decapod fauna of the North Pacific has proved very rich in individuals, if not in species. Among the more abundant types are the hermit-crabs, of which many species have local centres of distribution, where they attain their maximum development, both as regards size and numbers. In certain localities this crowding of crustacean life has been specially favourable to the development of parasitism. The decapods form the staple food of many kinds of fishes, and certain species are commonly used by fishermen as bait, or caught for the table. In many cases the northern limits of the species are determined by the winter line of floating ice in Bering Sea.

As regards the other groups, it must suffice to say that while Mr. Holmes restricts himself to the amphipods collected during the expedition, the isopods and pycnogonids of the whole western coast, from Alaska to California, are discussed. It is perhaps this variation in the mode in which the different groups are treated that constitutes the main ground for criticism in regard to the general plan of this magnificent and valuable work. Both editor and contributors are to be congratulated upon the results of their labours, so far as these are at present before the public, while the thanks of the scientific world are especially due to Mr. Harriman, as the generous provider of the means whereby this important addition to knowledge has been rendered possible. R. L.

THE THEORY OF DETERMINANTS.

The Theory of Determinants. By R. F. Scott, M.A. Second edition. Revised by G. B. Mathews, M.A., F.R.S. Pp. xi+288. (Cambridge: University Press, 1904.) Price 9s. net.

THIS well known treatise has been revised and enlarged in several respects. For instance (chapter xi.), the theory of linear equations is more complete than in the first edition, and Bezout's method of elimination is explained, as well as Sylvester's.

An introductory chapter has been inserted, containing an elementary account of three-rowed determinants; this should prove a considerable help to beginners. As a whole, the new edition is probably easier reading than the first; but even now the style seems rather too condensed for the average reader, and illustrations of general theorems by special cases are somewhat scarce.

A chapter (x.) on infinite determinants has been added; this appears to be based on the work of von Koch and Cazzaniga, but as some investigations have been abbreviated, occasional difficulties may be encountered at a first reading. Thus von Koch's proof that a normal determinant converges (art. 5) would be clearer if reproduced in full, and the convergence-test employed here[1] might be explained at greater length. The investigations of arts. 6 and 10 assume that certain infinite sequences (α_{ik} and C_{ik}) have upper limits; von Koch establishes this property by comparison with infinite products.

Semi-normal determinants are defined, in art. 11, after Cazzaniga; von Koch's definition would give a more elegant form to the theory without loss of generality. The two rules for multiplying semi-normals are stated in art. 12; but C is not proved to be equal to AB, and the statement (p. 128) "the series c_{ik} is absolutely convergent" must not be taken to refer to Σc_{ik}. Some examples like Cazzaniga's would emphasise the contrast between these rules and the four rules of art. 10 (for multiplying normal determinants).

On several grounds it is regrettable that chapter x. is not more complete. No proof is given that the value of a normal determinant is the same, wherever the origin may be taken on the principal diagonal; and various analogies with finite determinants are omitted.

A new chapter (vii.) has been inserted, containing the simpler theorems on *Elementartheiler* of determinants; this term is translated literally *elementary divisors*, although several English writers have used *invariant-factors* as the equivalent. The treatment follows Dr. Muth's book very closely; we have explained elsewhere (*Bulletin* Amer. Math. Soc., vol. vii. p. 308) that some changes in Dr. Muth's order might make the work more readable. But, in default of any English text-book, we must welcome this chapter as a useful introduction to the subject.

Frobenius's calculus of bilinear forms is explained

[1] "A sequence A_n converges if $\lim_{n=\infty}(A_{n+p}-A_n)=0$, for all positive integral values of p." In this test, *p must be free to vary with n*; for instance, if A_n is log n, and p is *fixed*, the limit is zero, although the sequence diverges.

in arts. 1–9 of chapter xiv., but more use might have been made of the method. Applications may be found in the theory of orthogonal substitutions (xiv., 19, 24) and in "the equation of secular inequalities" (xi., 19). The expression given in xiv., 7, does not correctly represent the square-root of a bilinear form; in fact $[\chi(x)]^2 - x$ is not divisible by $\psi(x)$, the last equation on p. 185 being wrong. The right value will be found in Muth's book (pp. 37, 38); see also *Proc.* Camb. Phil. Soc., vol. xi. p. 81.

The reduction of a quadratic form to squares (xiv., 10) may prove misleading, for it is natural to suppose that the reducing substitution belongs to the same *unitary* type as those in the article quoted (vii., 10). But this inference is not usually correct; thus $2x^2 + 2xy + 2y^2$, which has the matrix $\begin{pmatrix} 2, & 1 \\ 1, & 2 \end{pmatrix}$, *cannot* be reduced to the form $\lambda(ax+by)^2 + \mu(cx+dy)^2$, where λ, μ, a, b, c, d are *integers*. It is remarkable that a corresponding reduction *is* possible for an *alternate* form; this contrast might be mentioned. We are surprised that Weierstrass's theorem on equivalence of bilinear forms is not stated, although Kronecker's theorem (xiv., 8, 9) is proved; the latter can hardly be appreciated without the former.

Instead of the bibliographical list which closed the first edition, Mr. Mathews has given a brief historical note. It would have been better to add some references in the course of the text, for, even with a bibliography at hand, it is often difficult to identify the original sources from which extracts have been taken.

T. J. I'A. B.

A MANUAL OF MEDICINE.

A Manual of Medicine. Edited by W. H. Allchin, M.D., London, F.R.C.P. Vol. v. Pp. xii+687. Plates ii.; charts and diagrams. (London: Macmillan and Co., Ltd., 1903.) Price 10*s.* net.

THE volume before us is the fifth of Dr. Allchin's manual of medicine, and is devoted to diseases of the digestive system, the liver, the peritoneum, the vessels of the abdomen, the kidneys, and the ductless glands.

The volume begins with two short articles by the editor upon the normal anatomy of the alimentary canal and the physiology of digestion. These articles seem to be well up to date, and in the former due importance is attached to the surface anatomy of the parts, so important to the clinician. It is, however, rather to be regretted that in the physiology of digestion no mention is made of the recent work upon pancreatic secretion. These articles are immediately followed by one on food and diet by Dr. R. Hutchinson. In twenty pages, only the merest outlines of this subject could be discussed, and the value of articles so condensed is open to question; the principles, however, of dietetics and the chemical composition of the most important food-stuffs and food preparations are given. A useful note upon the bacteria of the alimentary canal, with some suggestions concerning the therapeutic use and actions of so-called intestinal antiseptics, is written by Dr. Lazarus Barlow.

The following eighty pages are devoted to diseases of the mouth, tongue, pharynx and œsophagus, an account of these being supplied by Dr. Bertram Abrahams. These diseases are treated in a comprehensive and systematic manner. We would draw special attention in this connection to the parts of the article devoted to throat complications of acute infectious diseases and the differential diagnosis of acute sore throat. The practitioner will find these sections exceedingly useful. The next section of the work treats of diseases of the stomach and intestines, this section occupying practically 200 pages and being written by the editor. Interpolated in the above is a short account by Dr. Bertrand Dawson of the physical examination of the stomach and intestines. This includes the ordinary clinical methods and the examination by the Röntgen rays and by so-called gastro-diaphany, and also directions for the chemical examination of the gastric contents after the administration of test meals. The reviewer cannot, however, find any directions for the chemical or microscopic examination of the fæces, which might well have been incorporated. In view of recent work upon the subject, a short article by the editor upon diseases of the pancreas will be of interest.

A hundred odd pages are devoted to diseases of the liver, this subject being introduced by a general article upon the morbid anatomy of the liver by Dr. Barlow. Hepatic abscess and perihepatitis are dealt with by Dr. Crombie; degenerations, new growths and gall-stones by Dr. Hebb.

The next section of the book treats of diseases of the peritoneum, and it is also introduced by a short note on the general anatomy of the peritoneum. The consideration of retro-peritoneal suppuration and tumours and sub-phrenic abscess concludes this monograph, for which Dr. Hale White is responsible. Dr. Bryant writes a short account of the diseases of the abdominal blood-vessels, and the volume concludes by an article by Dr. Bradford upon diseases of the kidneys, and one by Drs. Sydney Coupland and Bertram Abrahams upon diseases of the ductless glands.

It will be seen from the above remarks, which amount to little more than an elaborated table of contents, that the volume before us deals very fully with the diseases of the abdominal organs. In conclusion, we may add that this last addition to Dr. Allchin's manual of medicine maintains the standard of its predecessors, and is likely to be of much value to the professional reader. Its usefulness is enhanced by a complete and accurate index.

F. W. T.

OUR BOOK SHELF.

The Racing World and its Inhabitants. Edited by A. E. T. Watson. Pp. vii+309; illustrated. (London: Macmillan and Co., Ltd., 1904.) Price 12*s.* 6*d.* net.

THIS volume, which consists of a reprint of a series of articles contributed by various writers to the *Badminton Magazine*, is essentially a work written by racing men for racing men, and as such seems admirably adapted for its purpose. An important feature is that each article is written by one who has

made the subject of that article his particular pursuit, relaxation, or study; a trainer writing on training, a breeder on breeding, and so on. Under Mr. Watson's able editing, all these diverse factors have been woven into one harmonious and continuous whole.

To the naturalist the most interesting chapter is perhaps the one on breeders and breeding, in which the writer strongly advocates the advisability of plenty of fresh air and exercise for young horses of all kinds, as well as change of pasture. Contrary to the opinion of some of his fellows, the author firmly believes in heredity, and therefore advises the selection for breeding purposes of mares which have made a name on the turf.

As regards shape, he prefers long, low, and broad animals, but it is somewhat curious to notice that in the chapter on trainers and training the writer considers this an old-fashioned view, pointing out that "St. Simon," who was anything but a long and low horse, has done much to modify opinion on this point. It is satisfactory to learn that, according to the last mentioned writer, there is much less viciousness prevalent among racehorses than was formerly the case, this being attributed to gentler and more humane methods of training and treatment.

One other point and we must take leave of this brightly written and well illustrated volume. The point in question relates to the proper manner of drawing a racehorse at full speed. As the frontispiece of Mr. Watson's work we have a picture of a race in which the horses are represented as seen in a photograph, one of them having all four legs off the ground, and looking as though it were about to fall on its nose. In contrast to this, we have, facing p. 103, a reproduction of Herring's well known picture of "Flying Dutchman," in which the horse is represented as galloping *ventre à terre*, with the fore and hind limbs stretched out to their full extent. Obviously it is an inconsistency to have these two types of representing a galloping horse in the same work, as one must obviously be wrong. From the fact that when we draw the wheels of a carriage in rapid motion we represent the spokes as forming a continuous blur, and not as seen in a photograph, our own opinion inclines to the advisability of drawing racehorses somewhat after the old conventional manner, and not as they appear in photographs, when the postures are quite unlike the appearances presented to our eyes.

R. L.

Geologie von Deutschland und den angrenzenden Gebieten. Zweiter Teil. Lieferung i. By Dr. Richard Lepsius. Pp. 246. (Leipzig: Engelmann; London: Williams and Norgate, 1903.) Price 8s. net.

THIS part of the text elucidating Dr. Lepsius's well known geological map of Germany maintains a high level, and secures the acceptance of the book as a permanent work of reference. It is not so redolent of the country itself as is the great work on Austria-Hungary recently noticed in these columns (May 19, p. 49), but it embodies the results of extensive researches, and the individuality of the author is agreeably seen when he marshals and reviews the conclusions of those who have gone before him. The present section is of especial interest to students of metamorphic areas. The amphibolites and marbles of the "kristalline Grundlage im Erzgebirge" will recall many occurrences in our Scotch and Irish highlands. The description of the saturation of a schistose area by invading granite (p. 104), and the consequent origin of the gneissic *massif* of the Erzgebirge, will appeal to those who have sought to show that our own "Archæan" gneisses may often be of composite origin, and in places of post-Silurian age. The famous area of granulite in Saxony is dealt with from the point of view so long maintained, in other regions, by French geologists, to whom personal recognition is accorded (p. 172). Dynamic metamorphism is relegated to a relatively unimportant place, and the granulite is treated as a part of the Carboniferous granitic intrusion, making its way, under pressure of superincumbent layers, into a great dome of schists. The pyroxene-granulites and other variations arise from the absorption of diabases, quartzites, and so forth, into the invading mass. The observations of Callaway in Galway and Barrois in Brittany thus receive confirmation from the stronghold of the dynamometamorphic school.

The present part also includes a description of the sandstone area of the Elbe, with lists of Cretaceous fossils, and of the post-Cretaceous overthrust (p. 182) of granite and syenite on the right bank of the river at Hohnstein.

G. A. J. C.

Traité Élémentaire des Enroulements des Dynamos à Courant Continu. By F. Loppé. Pp. vi+78. (Paris: Gauthier-Villars, 1904.) Price 2 f. 75 c.

Étude sur les Résonances. By G. Chevrier. Pp. 76 (Paris: L'Éclairage Électrique, 1904.)

M. LOPPÉ'S little book is an elementary treatise on dynamo windings which we have no doubt will prove useful to many students of this subject. The treatment is quite simple, and the mathematics required are of the most elementary nature. The book is divided into two chapters, the first dealing with bipolar and the second with multipolar machines; only ring and drum windings are discussed. There are a number of good diagrams and winding tables.

The subject of resonance in electric cables carrying alternating currents has already become of considerable importance in electrical engineering, and is likely to come still more to the front as the development of power distribution at high voltages proceeds. M. Chevrier's book is a welcome essay on the subject, as the author has endeavoured to coordinate the existing knowledge and to present the elements of both the theoretical and practical aspects in a clear manner. After a general discussion of oscillating motion, electric circuits are considered in detail, and the various cases of resonance or possible resonance in distributing mains are treated at some length.

Lehrbuch der experimental Physik in elementarer Darstellung. By Dr. Arnold Berliner. Pp. xvi+857; with plates and illustrations. (Jena: Gustav Fischer, 1903.) Price 14 marks.

THIS is an elementary but not a rudimentary treatise. The aim of the author has evidently been to present as completely as possible the fundamental principles and facts which form the groundwork of physics (including mechanics). It can be confidently recommended to any second or third year student of experimental physics who is familiar with German. The mathematics in it is of a very elementary character; the author relies, in fact, not on mathematical demonstrations, but on general descriptions aided by diagrams. Many of these diagrams are very well conceived, and materially assist the description in the text. The author is fond of the use of analogies, and we think him very successful in employing them. We were rather surprised to find the Boer war figuring as one of these analogues.

The book will be found most useful to those students whose mathematical knowledge is only slight. The medical student has, in fact, been kept in view in its elaboration.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Octopolarity and Valence.

OF the elements and their compounds there is a general property which is related to the peculiarities of their periodicity in a remarkable manner. This property is that of crystallisation, and in the isometric system is seen in its least complicated form. Among the conceivable causes which might act to produce the regular arrangement of particles evidenced in crystals, the view that considers the atom as having eight fields of polarity radiating from it, corresponding to the eight corners of a cube or the eight faces of an octahedron, agrees well with a wide range of facts. When an isometric crystal is heated and cooled under suitable conditions, polarity is developed in this manner. Four of the centres of polarity are positive and four are negative; the angle between the direction of like poles is 109° 28′.

Consider the bonds of chemical affinity or valence in the first two series of the elements. Helium, the first element of the periodic table proper, is devoid of affinity to combine; the valence of lithium, the first member of the first series, is one, of beryllium two, of boron three, and of carbon four. From stereochemical considerations it is believed that the four bonds of affinity in carbon are alike, and are disposed about the centre of the atom at angles of 109° 28′ apart, as are the four portions of the isometric crystal that have the same polarity. In the first four members of the series there is a regular increase of one bond of affinity to each succeeding element, and all are of the same character. In the next member, nitrogen, the valence is five, but one is of a different character, while four are alike in all respects as in compounds of the type NH_4Cl. Nitrogen forms compounds also on another type of valence, as in NH_3, where it is trivalent. These three bonds of affinity are of the same character. Two bonds of opposite character, one positive and one negative, are rendered latent, a self-balanced pair. Oxygen, the next member, has only two active bonds and also latent pairs, but these are more difficult to render manifest than those of nitrogen. Fluorine has one active bond of affinity, and gives some evidence of possessing latent pairs also. The valence of neon, the last member of the series, is zero, being similar to helium. The next series of eight, Na, Mg, Al, Si, P, S, Cl, and A, corresponds perfectly in regard to the number of active bonds of affinity with the preceding series, while the latent pairs are more easily rendered manifest in combination, with the exception of argon, which has not been made to enter into chemical union. The series exhibits these valencies:—

Na_1	Mg_2	Al_3	Si_4	P_5	S_6	Cl_7	—
				P_3	S_4	Cl_5	—
					S_2	Cl_3	—
						Cl_1	—
							A_0

Thus the arrangement of the pyroelectric poles of an isometric crystal may serve to illustrate the changes of valence of the elements with increment of atomic weight. It would seem that when all eight polar faces have received the increment there is perfect balance, and the structure is no longer chemically active, as in helium, neon, and argon. Each of the first four members, Na, Mg, Al, and Si, has a definite valence which does not change, while P, S, and Cl have, beside the maximum valence, 1, 2, and 3 pairs respectively which can be rendered latent in pairs, as a positive field of force neutralising the effect of a negative field.

With this clue as to the nature of the increment of atomic weight, a conception of the structure of the atom can be formed which presents many remarkable and unexpected points of agreement with the system of the elements. If the increment of atomic weight or the principal factor of increment is due to addition of a ring, and no other structure be found to adapt itself, the original atom form will consist of eight rings arranged like the eight circles inscribed on the faces of an octahedron. That rings will unite to form this as a structure of maximum stability will depend on their possessing the following properties. The material of the ring is a conductor of electric current, and a field of magnetic force permeates the space about the ring. The magnetic field on one side of the ring plane is of opposite polarity to that of the other side. The ring is elastic, and in vibrating would have a number of equidistant non-vibrating nodes about its circumference, separated by internodes of vibration. Briefly it is an elastic, current-bearing ring in rapid motion. After examining all conceivable combinations of this ring, it became apparent that the structure of maximum stability resulting from combination of these rings is that of eight rings arranged like the eight circles inscribed on the faces of an octahedron. The essential condition of stability is that contact of rings should be at non-vibrating nodes, otherwise the energy of vibration would drive them apart, also that the flow of electric current in contiguous rings should be in the same direction in each ring at the point of contact, otherwise there would be magnetic repulsion.

Rings may be added to the eight-ring structure in the order indicated above from study of the crystal and the change of valence in the series, and the stability of the structure retained or even increased. As the external arrangement remains the same, the first rings are forced inward, and as more are added the further in these first rings become, but they will not be strongly vibrating like the outer rings, and so can come in stable contact at any point of the circumference.

As there would very evidently be a limit to the number of series possible, a wire model was made of rings to determine this. When eighty rings were used, forming nine series of eight members each, after the original eight-ring form, no more rings could be added. The four innermost rings had come in contact and would go no further in, being arranged like the four circles inscribed on the faces of a tetrahedron. If a free ring was laid on the surface of the eighty-ring structure, it would be first attracted strongly by the magnetic field, and instead of being held in stable combination would be driven off by vibration of the internodes of the ring where it was laid. Such a structure would spontaneously lose rings, and these liberated rings, in accordance with their properties, would form the original eight-ring structure corresponding to helium.

Botanical Nomenclature.

AN event of considerable importance to botanists is the publication of a new code of botanical nomenclature, prepared by a commission appointed by the Botanical Club of the American Association for the Advancement of Science. This document, which has the approval of a large number of the leading botanists of America, appears in the *Bulletin* of the Torrey Botanical Club for May, being printed in three languages. The commission proposes to move in the Vienna Botanical Congress of 1905 that the code now offered be adopted bodily, and all other articles abandoned.

In these circumstances, it must be admitted that discussion is opportune. The authors state that they have found the Paris code of 1867 unsatisfactory, because "many important principles are either not recognised, or else given altogether too meagre consideration, and that there is a want of definite and exact statement, which leads to ambiguity." While there is very much in the new code to approve and admire, it seems to me that upon certain points these very words are exactly applicable to it. Without attempting to cover the whole ground, I desire to refer to a few special points.

(1) "Names published for primary subdivisions of species are treated as subspecific names, however designated by their authors." One example given is *Zizia aurea*, var. Bebbii, Coult. and Rose. No example is given of a plant designated a form, or of mutation; are these intended to be excluded? It seems evident that many plants designated varieties are not in any sense subspecies, and so to consider

them is improper. A nomenclatural technicality should not be allowed to obscure the facts.

(2) "A subspecies elevated to specific rank retains the same name, unless the resulting binomial has been previously published." However, *Juncus acuminatus robustus*, Engelm., 1868, though a valid species, does not become *Juncus robustus*, because of *Juncus robustus*, S. Wats., 1879. Further on, we read, "A specific or subspecific name is a homonym when it has been published for another species under the same generic name. Two subspecies of the same genus shall not retain the same name." If two subspecies in a genus may not retain the same subspecific name, as I suppose is intended, though not clearly stated,[1] may a species and a subspecies do so? It appears logically to follow, though again it is not stated, that they may not. Hence in the above case of Juncus, the Watsonian *Juncus robustus* is invalid from the first, because of the Engelmannian subspecies, and there would result from the combination of these rules the dropping of the name "*robustus*" altogether, which seems absurd.

(3) "A generic or subgeneric name is a homonym when previously published, or proposed in print, for another genus." But we are not told whether the publication of a subgeneric name precludes its use in another sense for a genus, or whether when a subgenus is elevated to generic rank it is obligatory to use the subgeneric name, if it is not a homonym. These things are recognised by zoologists, and it does not seem proper for the botanists to ignore them in their code, and then do as they individually please.

(4) Names are considered identical when "mere variations in the spelling of the same word." This seems to me a dangerous rule, and illogical since it ignores the fact that names belong to the objects they designate, independent of derivation. By considering derivation, one can prove that crab and crayfish are "mere variations" of one word,[2] and most assuredly Theodore and Dorothy are one! The examples cited in the code expressly exclude differences of gender in generic names as valid distinctions, and while the specific names Greenei and Greenii (after Greene and Green) are admitted, we are not allowed *virginianus* and *virginiensis*. In this last case, I think a difference in the sense of the adjective may be detected, apart from its application to the plant. It is the same difference that is found between the statements that a man is English, and that he lives in England. One refers to quality, the other to place.

(5) Hybrids may be named like species, with the sign × before, as × *Salix capreola*. I should prefer to write *Salix* × *capreola*. The naming of hybrids in this manner seems necessary, on account of the possible instability of the combination-names. Thus *Castilleia confusa* × *acuminata*, Ckll., *Bot. Gazette*, April, 1900, p. 280, is better called *Castilleia* × *Portcrae* (a name I have long had in MS.), because the plant formerly known as *acuminata* is now called by a different name. T. D. A. Cockerell.

Colorado Springs, Colorado, May 21.

[1] It is, however, clearly indicated by an example given.

[2] Krebis, krebs, crab; krebis, ecrevisse, crayfish, and American, crawfish!

The Formation of Coral Reefs.

Seeing (Nature, April 21, p. 581) that this delicious bone of contention has once more been clawed from its resting place, I would beg editorial permission to join in discussing it.

That dead coral is soluble in warm seas is indisputable, but that solution in coral regions exceeds deposition is an issue to be tried not in a European laboratory, but on a coral reef. It is claimed that the lagoon of an atoll was excavated by solution, and that the matter removed was poured into the open sea through the reef channels. In opposition to this I reply that the central floor of a lagoon in process of excavation should present a bare surface of eroded rock like the basin excavated by a waterfall; but the middle of a lagoon floor has been shown by many observers, and especially by Mr. G. H. Halligan's boring, to consist of weed, mud, sand, and shingle. These are indications of an area of accumulation, not erosion. Let those who believe that the lagoon floor is dissolved away produce water from the seat of action heavily charged with solution!

Again, it is contended that the water flowing from the lagoon through the exit channels bears away in suspension and solution both matter excavated from the lagoon floor and matter washed by the waves into the lagoon. In denying that either is so drained away to any considerable extent, I would point out that water unarmed with sediment has no cutting power; but if the exit channels conveyed heavily charged water, the sand blast thus produced would cut to pieces every living thing in the passage. By my observations these passages are well carpeted with luxuriant life. To elucidate this important point the next biologist to report on coral fauna might be instructed to survey a main lagoon passage in detail.

If, as I maintain, the lagoon is an area of rapid accumulation from both growth and deposition, then, if no subsidence of the atoll occurs, the lagoon must in time be filled in. Every phase from a chain of islets to an atoll filled in solid is represented in the Pacific.

The destiny of every lake and pool on the earth's surface is to be obliterated by alluvium. It is here contended that the inevitable fate of a stationary atoll is the same, the only difference being that matter is poured from above into the terrestrial lake, whereas it is washed up from below into the atoll lagoon; but, as Darwin observed, while subsidence continues it will preserve to the atoll its lagoon.

Charles Hedley.

Australian Museum, Sydney, N.S.W., June 20.

The Traction of Carriages.

In reference to a letter on the above subject in your issue of July 21, the draught of a vehicle depends largely, though not entirely, upon the ratio that exists between the distance from wheel to wheel and the height of the centre of gravity from the ground. If the wheels are far apart and the centre of gravity low, the carriage is hard to draw; if the wheels are closer or the load higher, the draught is lighter.

The reason for this fact may, I think, be readily seen by the following illustration:—Let us suppose a bicycle and rider, the centre of gravity four feet above the road, and vertically mid-way between the wheels. For the present purpose we will disregard the effect of springs and of speed. If the front wheel goes over a stone, say, two inches high, the centre of gravity, or load, is partly lifted vertically and partly thrown back over the hind wheel, describing, with relation to the machine, part of a circle having its centre at the point where the hind wheel touches the ground; and if the wheels are four feet apart, centre to centre, the load is raised about half an inch and moved backward to a much greater extent.

But we can imagine a bicycle of the same weight and having the same load with wheels, say, forty feet apart, and if this machine meets the same obstacle the load will be lifted nearly a full inch, the back-throw being scarcely perceptible; or, on the other hand, we may conceive of a bicycle with wheels four feet apart and the centre of gravity forty feet high, in which case the two-inch stone will scarcely lift the load at all, but only send it (dangerously, no doubt) back over the hind wheel.

Heavy draught depends upon, or is caused by, having to lift the centre of gravity rapidly, and may be lightened by easy springs, large wheels, putting the load high, or putting the wheels near together. Cecil G. Saunders.

Tower House, Canonbie Road, Forest Hill, S.E., July 25.

The Word Cingalese.

On p. 131 of the current volume of Nature, the expression "Cingalese fishes," and on p. 78 of the same volume the expression "Cingalese outlier" are found. The word Cingalese is also used in the "Cambridge Natural History" (Mollusca) to denote a subregion. In the first place the word should be spelt Sinhalese, the form above quoted being a quite incorrect transliteration. In the second place, the adjective corresponding to Ceylon is Ceylonese, the word Sinhalese meaning "of or belonging to the Sinhalese race."

Ceylon, July 6. A. K. Coomaraswamy.

Residual Affinity.

If Mr. Pickering has imagined that fractions of a charge are necessary, and has not discriminated between fractions of a charge and fractions of a bond, it is not surprising that his contribution of thirteen years ago failed in impressiveness. Oliver Lodge.

AMERICAN EXTINCT VERTEBRATE ANIMALS.[1]

SINCE the foundation of a department of vertebrate palæontology in the American Museum of Natural History in 1891, the curator, Prof. H. F. Osborn, and his assistants have made some most remarkable contributions to our knowledge of the extinct vertebrate animals of North America. The published work of the first six years was collected in one volume at the end of 1897, and the still more numerous papers contained in the museum *Bulletin* during the last six years have just been bound together in a second volume, which is now issued for sale or exchange. Since 1897, five large quarto memoirs on extinct Reptilia and Mammalia have also appeared under the same auspices. All these publications are illustrated both by photographs and by excellent drawings, which not only explain the technical points of the descriptive letterpress, but are also in many cases beautiful works of art.

The pioneer explorations of Leidy, Marsh, and Cope in the arid regions of the west, where the rocks are not obscured by vegetation, revealed more or less in-

FIG. 1.—Restoration of Four-toed Horse (Protorohippus) from the Lower Eocene of Wyoming.

complete evidence of the evolution of several groups of land mammals. Their work is now ably continued by the American Museum in the more favourable circumstances which result from the spread of civilisation and railroads in the remote territories where the fossils occur. Instead of making hurried forays with an armed escort, the explorers are now able to collect at leisure and make detailed observations of the rocks. Photographs are taken of all the important sections and diggings, and notes are made to determine the exact geological position and relative age of all the skeletons collected. The succession of extinct animals in western North America is thus being gradually determined with certainty, and rests less on inference than formerly. The fossiliferous deposits themselves are also better understood, and some of the earlier conclusions as to their origin have been considerably modified by these later researches. For instance, it appears from Dr. W. D. Matthew's work in connection with the American Museum that many of the famous bone-beds in the west are not contained in the sediments of old lakes of immense extent, but are largely wind-borne, and have accumulated on plains where there were varying swamps, pools, and wandering streams.

While adopting these careful methods of collecting, the American Museum has recently, with the aid of a generous donation from Mr. William C. Whitney, devoted special attention to the ancestry of the horses. Since 1899 expeditions have been sent out each year into the various Tertiary regions to collect fossil horses, and the result is that the volume now before us contains some of the most important contributions to this test-case of evolution that have hitherto been published. It is curious that although remains of horses were dug up and recognised in America so long

FIG. 2.—Rear view of Skeleton of Three-toed Horse (Hypohippus) from the Middle Miocene of Colorado.

ago as 1826, no complete fossil skeleton had been found until Mr. J. W. Gidley quite lately discovered that of the *Equus scotti* in the Lower Pleistocene of Texas. His collection now in the American Museum comprises satisfactory remains of many individuals, and makes it possible for the first time to realise the exact nature of the true horses which were once so abundant on the North American continent, and strangely became extinct before the dawn of history. A complete skeleton of a three-toed horse (*Neohipparion whitneyi*) is also described by Mr. Gidley from the Upper Miocene of South Dakota, and another nearly similar complete skeleton (Fig. 2) was discovered by Mr. Barnum Brown in 1901 in the Middle Miocene of Colorado. These remarkable fossils are mounted in the American

[1] "Fossil Vertebrates in the American Museum of Natural History Department of Vertebrate Palæontology." Vol. ii. Articles collected from the American Museum *Bulletins* of the years 1898–1903. With a preface by Henry Fairfield Osborn, Curator.

Museum with the older ancestral skeletons and feet obtained from the Cope collection and other sources, and the whole series is described in a popular manner by Dr. W. D. Matthew in an admirable small handbook which can be purchased by the visitor. The interest of the general public in the "dry bones" is also roused by some attempted "restorations" of the various animals as they appeared when alive, Prof. Osborn having secured the services of a skilful artist, Mr. Charles R. Knight. As an example of this popularisation, we reproduce the life-like drawing of the ancestral four-toed horse, Protorohippus (Fig. 1).

Prof. Cope's well known researches on the ancestry of the camels and llamas, which were originally North American animals, have been extended by Dr. Wortman, and he devotes one of the most important papers in the volume now before us to this subject. He and Dr. Matthew also treat of the ancestry of the dogs, while Prof. Osborn himself not only deals with the evolution of the rhinoceroses, but likewise with that of the Amblypoda—the small-brained herbivores of the Eocene period which eventually became bulky and developed fantastic horns when on the verge of extinction. It is curious that the extinct rhinoceroses of North America never developed a horn, except, perhaps, an incipient trace in one species. It is also remarkable that in some of the earliest normal and hornless Amblypoda (Coryphodon) Prof. Osborn is able to discover slight indications of a bony thickening where the horn-cores were destined to grow in the later members of the race.

Numerous primitive small-brained carnivores (Creodonta) are described and discussed by Drs. Wortman and Matthew, and a new classification by the latter author advances far beyond any scheme previously published. These animals are very important, because they are not only to be regarded as the ancestors of the higher Carnivora, but are also closely related to the marsupials of the Australian region and South America. The North American specimens appear to be abundant, and many are especially well preserved. Collections like those made by the American Museum are thus of more scientific value than the fragmentary remains with which palæontologists have hitherto been obliged to remain content in the Old World.

Among the remains of true Carnivora discovered by the American Museum expeditions, one of the most interesting is a gigantic skull, 18 inches in length, found with a few other bones of the skeleton in the Upper Miocene of Texas. This specimen evidently belongs to a massive animal which is neither a bear nor a dog, but something intermediate between the two. Dr. Matthew compares it with Dinocyon from the Upper Miocene of France, and describes various fragments of allied genera. It now appears that the late Prof. Cope was referring to a jaw of one of these animals when he made the announcement some years ago of the discovery of a fossil hyæna in North America. There is still no evidence of hyænas in the New World.

The ancient American lemurs form the subject of an elaborate technical paper by Prof. Osborn. The possible earliest ancestors of the rodents, from the basal Eocene, are also discussed by him. A horned rodent—the first known horned member of its order—is described by Dr. Matthew from the Upper Miocene of Colorado. This animal (*Ceratogaulus rhinocerus*) seems to have been related to the beaver, and bears a pair of bony horn-cores on the nose. There is also a paper by Dr. Matthew on the first remains of a true hedgehog discovered in North America.

The perfection of the modern methods of collecting and preparing fossils is well seen in the wonderful carapace of an extinct armadillo, *Glyptotherium texanum*, from the Lower Pleistocene of Texas. It has been known for many years that the typical South American Glyptodonts ranged northwards over the Isthmus of Panama into the southern United States before their final extinction, but no example so nearly complete as that now mounted in the American Museum (Fig. 3) had previously been obtained.

Besides Mammalia, the American Museum has collected many Reptilia, notably Dinosauria from the Jurassic of Wyoming. Since 1898 a party has been sent each year to the so-called Bone Cabin Quarry, which has proved especially rich in megalosaurian and dinosaurian remains. During the first season alone, no less than six nearly complete limbs and three fore-feet were disentombed from this spot. Since then a nearly complete skull of the megalosaurian Creosaurus, and the greater part of a skeleton of a new small and slender Dinosaur (*Ornitholestes hermanni*) have been obtained, besides less important fossils. All these are described by Prof. Osborn, and add valuable facts to our knowledge of the animals to which they belong. A well preserved skull of the horned Cretaceous Dinosaur *Triceratops serratus* is also described in much greater detail than heretofore by Prof. R. S. Lull.

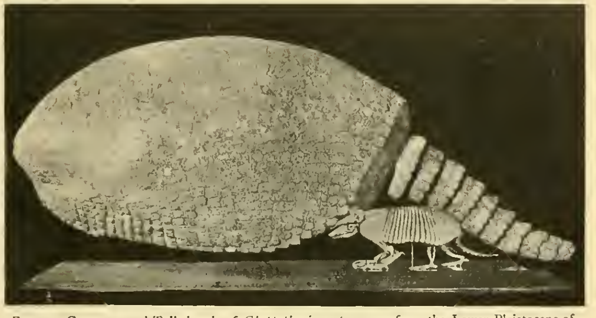

FIG. 3.—Carapace and Tail-sheath of *Glyptotherium texanum* from the Lower Pleistocene of Texas; with a modern Armadillo for comparison.

It only remains to add that the lower vertebrates are by no means neglected by the American Museum. In the present volume there are two valuable papers on Cretaceous fishes by Dr. O. P. Hay, the one dealing with American specimens in the Cope collection, the other with well preserved fishes from the fissile chalk of the Lebanon, Syria. The latter is particularly interesting as making known much new evidence of the forerunners of the saw-fishes and eels, which were almost completely developed in the Cretaceous period.

In conclusion, it must be remembered that the American Museum of Natural History is only in part a public institution. It receives only limited support from the municipality of New York and the State Board of Education. The department of vertebrate

palæontology depends almost entirely upon private munificence for the means of research. The staff is thus to be congratulated all the more on its remarkable achievements in advancing this branch of science. The collection it has mounted for public exhibition is unique as an illustration of the facts of organic evolution, and the specimens themselves have never been surpassed as examples of skilled collecting and preparation. A. S. W.

MANCHURIA UNDER RUSSIAN RULE.[1]

THIS book, dedicated to the "Gallant Japanese Nation," is a reprint of letters from Manchuria written during the autumn of 1903 for some Far Eastern publications. The narrative of events is brought down to the outbreak of war between Russia and Japan, and a "prologue" has been added to serve as a sketch of the history of Manchuria from the earliest times of which there is any record to the present day. The author is well versed in his subject, has travelled extensively in all three provinces of Manchuria, is a careful observer, and shows a sound judgment. His style is easy, and the book well worth reading from beginning to end. Indeed, we may say that it should be read by everyone who wishes to form a true opinion of the remarkable events now taking place in the Far East. For remote as Manchuria is from western Europe, its occupation by Russia, coupled with the lease from China of the peninsula of Kwan-tung, the construction of the "Chinese Eastern Railway," and the war are of great importance to the whole civilised world.

The story of this extraordinary leap in the dark of a great Power whose policy had been hitherto not wanting in prudence and foresight is well told by the author in his opening chapters. The idea, it seems, first occurred to Prince Uktomsky while accompanying the present Tsar, then Tsarevitch, in a tour round the world ten years ago. He was astonished at the success which had "attended the spread of Anglo-Saxon trade and ideas under the ægis of England's undisputed naval might," and he thought the time had come for Russia to establish an empire in the Far East. To carry out such a gigantic undertaking it was necessary to secure the services and collaboration of men of genius and untiring industry. Such a man was found in Count Cassini, the Russian Minister at Peking, whose name is associated with that of Prince Uktomsky in this vast project. "These two men," says our author, "did more than any others to set the snowball rolling down from bitter Siberia on to China."

The next step was to organise the Russo-Chinese Bank, for without this Russia could not have gained even a temporary success. M. Pokotiloff, the agent of this bank, and Mr. Victor von Grot, one of Sir Richard Hart's most valued colleagues, were entrusted with the measures necessary to ensure the credit of the Russian Government. Success at first crowned the labours of these men, and the possibilities of the future grew more and more attractive, the ultimate destruction of China and the reduction of Japan to the rank of a secondary Power being not the least important. The first blow to Russian supremacy occurred in 1895, when Japan defeated China and obtained the cession of Liau-tung. This, however, was neutralised by skilful diplomacy, and China retained possession of the forfeited territory at the price of the concession for building the trans-Manchurian Railway. By 1900 the Russo-Chinese Bank had attained the high-water mark of prosperity. But even then there were symptoms of something not being quite right, and when the following year the Russian railway administration decreed that henceforth passenger fares and freight charges must be paid for in rouble notes the whole edifice of Russian Empire in Manchuria began to totter. The defeat of the "travelling rouble" is well told by Mr. Weale—how the dollar-loving Chinaman resented the threatened loss of what he considered his birthright by the arbitrary decrees of the Russian bureaucrats, how he prepared for battle, and how finally the rouble notes, tons of which had been imported into China, were discredited and disappeared.

FIG. 1.—The Entrance to Port Arthur. From "Manchu and Muscovite."

The three chief instruments of Russia in her policy of expansion in Manchuria were the rouble, the Russo-Chinese Bank, and the railway. These three were so intimately associated and so well planned to work together that you cannot explain one without mentioning the others. In the words of our author, "they are a three-headed Medusa that turn their threatening faces on poor China and either enchant or quell her with their looks." It was becoming evident that the task Russia had so lightly undertaken was beyond her powers. She had misjudged the resistance she would encounter from the yellow race; great as her own resources were, she had over-rated these. Too confident of her strength, and relying on her successes

[1] "Manchu and Muscovite." By B. L. Putnam Weale. Pp. xx+552. (London: Macmillan and Co., Ltd., 1904.) Price 10s. net.

in overawing the native races of Central Asia, with a great faith in her destiny, she had embarked on these projects of expansion without due preparation and almost in a reckless spirit. Russia urgently requires peace, reform and retrenchment, and all these grand schemes of expansion, whether eastward to the Pacific or south to the Persian Gulf, must be abandoned. The whole system of administration is corrupt, and as long as it remains so she cannot expect to prosper, however well her soldiers fight. The lessons of this war will, it is to be hoped, turn her attention to other matters than conquest.

In the course of three years our author visited the principal towns of Manchuria—Port Arthur and its docks; Dalny, the future commercial port, upon which millions have been wasted; Newchwang; Harbin, the great railway city; Mukden, the old capital; Tsitsihar, on the Nonni; Petuna; Ninguta; and Kirin, the centre of the lumber trade. All these places are admirably described, and the incidents of the journey, whether by road, rail, or river, are amusingly told. One of the most entertaining chapters of the book is that entitled "Russia's Great Manchurian General *alias* the Chinese Eastern Railway." What this railway has cost the Russian Government will probably never be known. The author estimates it at forty-five millions sterling, though others regard this as too moderate a sum, for many accidental charges have to be added to the original cost. There were the re-laying of the rails, for these at first were far too light to resist the train weights, the changing of the sleepers, the re-building of many miles of road destroyed during the Boxer troubles, new steel-bridge work, new feeder lines, the enormous administration buildings, and stone towers for guarding the line. There were the railway, sea-going and river-steamer services, the railway barracks, the railway mines, and many other offshoots belonging to the Chinese Eastern Railway Co. The railway managed as it is can never be a commercial success, yet so rich is the country through which it passes that if properly administered and in English hands it would pay a fair return on the outlay. At present it is a frightful failure, and the best thing that could happen would be for Russia to sell the whole undertaking to Englishmen—"the only men who have been able so far to handle the Chinese with real success in trade and industry."

We learn a good deal concerning the productions of Manchuria from this book—"the greatest wheat producer in the East, the greatest lumber-field and the greatest gold mining centre." Beans constitute at present the agricultural wealth of the country, but this will not remain so for long. Manchuria is a wheat country, and flour will in a few years have taken the place of beans in the export list. The climate is described as excessively cold in winter and hot in summer, but otherwise very healthy.

BRITISH ASSOCIATION MEETING AT CAMBRIDGE.

Sectional Arrangements.

In an article published in Nature, July 21, p. 277, a general account was given of the local arrangements for the forthcoming meeting. As the main items in the sectional programmes have now been settled, it may be of interest to give a short list of papers, lectures and discussions. A new feature in the sectional arrangements this year is the increased prominence given to discussions and afternoon lectures of a semi-popular character. The number of favourable replies to the usual invitation circular received from leading men of science in Britain justifies the hope that the meeting will be a thoroughly representative one. Invitations have been issued to an unusually large number of American and foreign men of science, and in spite of the St. Louis Exhibition and other counter attractions the committee hopes to have the pleasure of entertaining about 140 guests.

Section A (Physics).

The guests include Prof. Abraham, Göttingen; Prof. Burkhardt, Zürich; Prof. Birkeland, Christiania; Prof. Dieterici, Hanover; Prof. Kayser, Bonn; Prof. Korteweg, Amsterdam; Prof. Lummer, Charlottenburg; Prof. Langevin, Paris; Prof. Leduc, Paris; Prof. MacLennan, Toronto; Prof. Pockels, Heidelberg; A. L. Rotch, Director of the Blue Hill Observatory, U.S.A.; Prof. Rubens, Charlottenburg; Prof. Sommerfeld, Aix-la-Chapelle; Prof. Voigt, Göttingen; Prof. Volterra, Rome; Prof. Wood, Baltimore; Prof. Wien, Würzburg.

The most important items will be a discussion on the radio-activity of ordinary matter, opened by Prof. J. J. Thomson, a discussion on standard wave-lengths of light by Prof. Kayser, and one on the units used in meteorological measurements. Prof. Larmor will make a communication relating to the laws of radiation; Prof. Rubens promises a paper on "Reststrahlen" and the optical qualities of metals, and Prof. Wood will contribute papers on anomalous dispersion and colour photography. Prof. Poynting will deliver a popular afternoon address on radiation in the solar system, and on the last day of the meeting Prof. Fleming will give an address dealing with some recent advances in connection with wireless telegraphy. Dr. Glazebrook is expected to give an account of some recent work at the National Physical Laboratory, and Prof. Birkeland will make a communication on the connection between solar physics and meteorology.

Section A (Mathematics).

The guests include Prof. Bendixson, of Stockholm, and Prof. Meyer, of Königsberg.

The following papers have been arranged:—Prof. Franz Meyer, die Ziele der Geometrie; Sir Robert Ball, note on a special homographic transformation of screw-systems; Major MacMahon, the theory of linear partial differential equations; Prof. A. R. Forsyth, notes on the theory of groups; Prof. F. Y. Edgeworth, the law of error; Prof. F. Morley, geometry of the complex variable; Prof. Bromwich, on the roots of the characteristic equation of linear substitutions; A. N. Whitehead, Peano's symbolic method; Harold Hilton, notes on plane curves; G. H. Hardy, Taylor's series.

There will be an exhibition of geometrical models in the large room of the Cavendish Laboratory.

Section A (Astronomy and Cosmical Physics).

Dr. H. R. Mill, on the unsymmetrical distribution of rainfall about the track of a barometric depression; Miss F. E. Carr, the application to meteorology of the theory of correlation; H. N. Russell, on the masses of the stars. Papers are promised also by Father Cortie, S.J., Dr. Lockyer, H. F. Newall, and A. R. Hinks.

Section B.

The following have accepted the invitation to attend the meeting:—Prof. Aschan, Helsingfors; Prof. Brühl, Heildeberg; Prof. Busch, Erlangen; Prof. Cohen, Utrecht; Dr. Etard, Paris; Prof. Feist, Kiel; Prof. Franchimont, Leyden; Prof. Freund, Frankfort; Prof. Guye, Geneva; Prof. Gabriel, Berlin; Comte de Gramont, Paris; Prof. Haller, Paris; Prof. Knoevenagel, Heidelberg; Prof. Meyer, Brunswick; Prof. Meyerhoffer, Berlin; Prof. Michael, Tufts College, U.S.A.; Dr. Noelting, Mülhausen; Prof. van Romburgh, Utrecht; Prof. Thiele, Strassburg; Prof. Thierfelder, Berlin; Prof. Traube, Berlin; Prof.

Tschirch, Berne; Prof. Wegscheider, Vienna; Prof. Walden, Riga; and Prof. Wollenstein, Berlin.

It is expected that the following communications will be made:—Dr. T. M. Lowry, dynamic isomerism; H. O. Jones, the stereochemistry of nitrogen; Prof. Paul Groth, on crystal structure and its relations to chemical constitution; Prof. Isidor Traube, on the velocity of osmosis and on solubility; Dr. E. A. Perman, the decomposition and synthesis of ammonia; Prof. C. Dieterici, on the energy of water and steam at high temperatures; D. L. Chapman, on the active variety of chlorine; R. S. Morrell and A. E. Bellars, the oxidation of carbohydrates by hydrogen peroxide in the presence of ferrous sulphate; R. S. Morrell and E. K. Hanson, studies in the dynamic isomerism of the α- and β-crotonic acids; F. G. Donnan, a suggested explanation of the phenomena of opalescence observed in the neighbourhood of critical series; M. le Comte Arnaud de Gramont, sur le spectre du soufre dans la photographie de l'etincelle des minéraux; H. J. H. Fenton, mesoxalic semialdehyde; note on the influence of radium radiations on atmospheric oxidation in presence of iron; a reaction for ketohexoses; H. J. H. Fenton and J. P. Millington, a colour reaction for methylfurfural and its derivatives; Prof. Ossian Aschan, on the pentavalent nitrogen atom; G. Barger, saponarin, a glucoside coloured blue by iodide; Dr. W. A. Bone and R. V. Wheeler, the union of hydrogen and oxygen in contact with a hot surface; Prof. Richard Meyer, the constitution of phthalein salts; G. T. Beilby, the intensification of chemical action in the neighbourhood of hot metals and other surfaces; reactions between solid salts.

Section C.

The guests include Dr. Ami, Ottawa; Prof. Brögger, Christiania; Prof. Bächström, Stockholm; Prof. Busz, Münster; Prof. van Calker, Groningen; Prof. Groth, Munich; Prof. Goldschmidt, Heidelberg; Dr. Rothpletz, Munich; Prof. Sjögren, Stockholm; Dr. Seligmann, Coblenz.

It is expected that the following communications will be made to the section:—B. N. Peach and G. Horne, the base line of the Carboniferous system round Edinburgh; G. W. Lamplugh, note on Lower Cretaceous phosphatic beds and their fauna; H. B. Woodward, note on a small anticline in the Great Oolite series north of Bedford; P. F. Kendall, evidence in the Secondary rocks of persistent movement in the Charnian Range; Dr. Ami, the geological resources of Canada; E. Greenly, the lava domes of the Eifel; A. Harker, exhibition of Tertiary plutonic rocks from the Isle of Rum; Prof. Busz, notes on some Cornish rocks; Prof. Bäckström, origin of the great iron-ore deposits of Lapland; L. J. Spencer, on the different modifications of zircon; F. W. Harmer, the Great Eastern Glacier; Rev. W. Lower Carter, glaciation of the Don and Dearne valleys; E. Greenly, notes on the glaciation of Holyhead Mountain; W. Whitaker, on a great depth of drift in the valley of the Stour, Suffolk, and some Cambridgeshire wells; Rev. W. Lower Carter, river captures in the Don system; Rev. O. Fisher, on the elephant trench at Dewlish, Dorset; Prof. W. J. Sollas, on the structure of the Silurian Ophiurid, *Lapworthura miltoni*; E. A. Newell Arber, on the fossil plants of the Upper Culm Measures of Devon and on derived plant petrifications from Devonshire.

There will be a discussion on the nature and origin of earth movements, opened by the president (A. Strahan), Dr. Teall, Prof. Sollas and G. Horne. Dr. Marr will give a lecture on the geology of Cambridgeshire.

Section D.

Acceptances have been received from the following zoologists:—Prof. Boveri, Würzburg; Dr. Calkins, New York; Prof. Hubrecht, Utrecht; Prof. Keibel, Freiburg; Prof. Minot, Cambridge, U.S.A.; Prof. Osborn, New York; Dr. Przibram, Vienna; Prof. W. B. Scott, Princetown; Prof. Max Weber, Amsterdam; Prof. Ramsay Wright, Toronto; and Prof. E. B. Wilson, New York.

On Thursday afternoon Prof. Osborn, of New York, will open a discussion on recent contributions to the evolution of the horse. The discussion will be continued by Prof. Cossar Ewart and Prof. Ridgeway. On Friday there will be a discussion on heredity, in which the following have promised to take part:—The president (W. Bateson), Miss Saunders, and Messrs. A. D. Darbishire, Hurst, Biffen, Doncaster, Lock and Staples-Browne. In connection with this discussion there will be an exhibition of animals and plants in illustration of the several contributions. Monday morning will be devoted to a joint discussion with Section K on the significance of the reduction division of the nucleus, in which Profs. Calkins, E. B. Wilson and others are expected to take part. In the afternoon of Monday Prof. Przibram and Mr. Brindley will open a discussion on regeneration and asymmetry. Mr. Keeble will deliver a popular lecture on the coloration of marine Crustacea. On Tuesday afternoon Dr. C. W. Andrews will give a lecture on Egyptian Eocene vertebrates and their relationships, particularly with regard to the geographical distribution of allied forms.

The sectional programme includes also papers by Prof. Keibel and Prof. Calkins on the Cytoryctes, the protozoan said to be the organism of small-pox; G. H. F. Nuttall, on the precipitation tests in the study of animal relationships; Prof. Graham Kerr, on the African collections of the late J. S. Budgett; J. W. Jenkinson, on the origin of the cleavage centrosomes in the axolotl egg; J. H. Bryce, on the histogenesis of the blood of the lepidosiren larva; Prof. Elliot Smith, on Loos's researches on Ankylostoma (the miner's worm), which he has studied in Egypt.

Section E.

The foreign visitors include M. de Déchy, Odessa; Prof. Hettner, Heidelberg; and Dr. Wind, Utrecht.

Popular afternoon lectures will be delivered by Mr. A. Silva White on scenes and sketches of life in the Nile Valley, and by Dr. Tempest Anderson on the Lipari Islands and their volcanoes. The list of papers includes the following:—(*a*) *Travel*: Major Burden, people and places in Nigeria; A. W. Hill, a journey round Lake Titicaca; Colonel Delmé Radcliffe, surveying in Western Uganda; Dr. von Drygalski, the German Antarctic Expedition. It is hoped that Mr. Bruce, of the Scottish Antarctic Expedition, may be able to attend the meeting. (*b*) *Historical Geography*: Rev. H. S. Cronin, Ptolemy's map of Asia Minor, methods of construction; D. G. Hogarth, Cyrene—an illustration of the bearing of geography on history; C. R. Beazley, the first true maps (Portolani of the early fourteenth century); Rev. A. Hunt, the site of the battle of Brunanbush (Lincolnshire) in the tenth century; H. Yule Oldham, changes in the features of the Fen district. *Physical Geography*: M. Déchy, the glaciers of the Caucasus; M. C. Rabot, glacier-bursts; Dr. H. R. Mill, a new physical map of Great Britain; Prof. Yapp, vegetative features of the Fen district; F. J. Lewis, botanical survey of parts of Westmorland; R. T. Günther, changes in the coast-line in the Bay of Naples. There will also be a paper by Major Close, R.E., on recent improvements in survey methods.

Section F.

The following have signified their intention of being present:—Prof. Dietzel, Bonn; M. Yves Guyot, Paris; Dr. Körösi, Budapest; Prof. Lotz, Munich; Prof. Mahaim, Liège; Dr. Mandello, Budapest; Dr. Pierson, the Hague.

The following papers have been arranged in connection with this section:—Prof. Flux, on improvements in agriculture and their effect on economic rent; Prof. Edgeworth, a moot point in the theory of international trade. Friday, August 19, will be devoted to a discussion on the theory and practice of foreign trade at home and abroad. Contributions will be made by Prof. Dietzel, Prof. Lotz, M. Yves Guyot, and L. L. Price. It is hoped that most of the leading English economists will be present. On Monday Mrs. Bosanquet will read a paper on the economic importance of the family, and there will possibly be a communication on cotton-growing in the Empire. In the afternoon of Friday, August 19, some members of the section will visit the Garden City near Hitchin. Among other papers may be mentioned those by J. A. Baines, distribution of rural population in India; T. C. Horsfall and Mrs. Fisher, on the housing question, and possibly a communication on some allied questions by His Excellency Dr. Pierson. It is expected that the programme will include the following additional items:—Prof. Mahaim, changes in Belgian wages; A. L. Bowley, measurement of national progress; C. J. Hamilton, trade unions in the United States of America; H. A. Roberts, employment of graduates; and W. G. Adams, modification of the income tax.

Section G.

Prof. Schröter, of Munich, is expected to attend the meeting. After the presidential address the most important items of the programme are a discussion on internal combustion engines, opened by Mr. C. Dugald Clark and Prof. B. Hopkinson. On Thursday afternoon Mrs. Ayrton will give a lecture on the origin of sand-ripples, illustrated by experiments which were recently shown at a conversazione at the Royal Society. On Monday, August 22, papers will be read by C. H. Merz on the use of electricity on the North-Eastern Railway and on Tyneside; A. A. Campbell Swinton, electricity from water-power; W. M. Morley and A. G. Hansard, energy losses in magnetising iron; Prof. J. A. Fleming, large bulb incandescent lamps as secondary standards of light. The following communications have been arranged for Tuesday, August 23:—Major Sir Hanbury Brown, K.C.M.G., on the Nile irrigation problem; J. H. Wicksteed, a universal testing-machine of 300 tons for full-sized members of structures; S. Cowper Coles, a new process for applying zinc to metallic surfaces; J. W. Hayward, the effects of receiver drop in a compound engine.

Section H.

The guests who have accepted the invitation to attend connected with this section include Prof. Deussen, of Kiel; Mr. Howitt, Australia; Prof. Kabbadies, Athens; Prof. Montelius, Stockholm; Prof. Schmidt, Copenhagen; and Dr. R. Livi, Rome.

The address of the president (Mr. Henry Balfour) will be delivered on Thursday at 10.30, and will deal with the theory of evolution in the material arts, as expounded by the late General Pitt-Rivers, and illustrated in the Pitt-Rivers Museum at Oxford. The same subject will be pursued by Prof. Montelius, of Stockholm, in a study of the evolution of the lotus-ornament, by Prof. Flinders Petrie in regard to the series of Roman lamps discovered in this season's excavations at Ekhnasya, in Egypt, and by Mr. R. T. Günther in a paper on the *Timaruta* charms from Naples.

Friday's session will be devoted to papers on anthropological surveys, actual and projected, in various parts of the world. Special stress will be laid by Prof. D. J. Cunningham, Mr. J. Gray, Mr. F. C. Shrubsall, and others on the practical value of such surveys of the physical characters of a complex modern population in providing data for inquiries of hygienic, economic, and even political nature; and a discussion is arranged on the best means of organising such surveys, with special reference to the work of the committee on physical deterioration, the report of which is, fortunately, now available for consideration.

Another important discussion, also set down provisionally for Friday, deals with the report of the committee on the present state of anthropological teaching.

Monday will be devoted to papers on social and religious institutions, and on folklore, and to a discussion of Sir Richard Temple's method of recording the languages of savages.

Tuesday's programme deals with recent work in Greek lands, with papers by Dr. Arthur Evans, Miss Boyd, and Messrs. Bosanquet and Dawkins, on their respective excavations in Crete; and with a demonstration by Prof. Montelius on the geometrical period in Greece. Other archæological papers deal with recent excavations on prehistoric sites in Denmark, Scotland, and elsewhere.

The papers hitherto received on points of human anatomy are of less popular interest and will probably be discussed by a subsection on one of the days of the meeting, to be announced later.

Section I.

The following American and foreign physiologists hope to be present at the meeting:—Prof. Atwater, Middletown, U.S.A.; Dr. Asher, Berne; Prof. Adamkiewicz, Cracow; Prof. Boruttau, Göttingen; Prof. Biedl, Vienna; Fräulein Bienenfeld, Vienna; Dr. Barbieri, Paris; Dr. Camus, Paris; Prof. Cavazzani, Ferrara; Prof. Dupuy, Paris; Prof. Donaldson, Chicago; Prof. Fröhlich, Vienna; Prof. Gley, Paris; Prof. van Gehuchten, Louvain; Prof. Johannson, Stockholm; Prof. Kossel, Heidelberg; Prof. Munk, Berlin; Prof. Magnus, Heidelberg; Prof. Mareš, Prague; Prof. Macallum, Toronto; Prof. Nicloux, Paris; Prof. Porter, Cambridge, U.S.A.; Prof. Stewart, Chicago; Dr. Veress, Würzburg; Prof. Verworn, Göttingen; Dr. Vaschide, Paris; Prof. Wedenskii, St. Petersburg.

The organising committee has introduced two items which it is hoped will prove of considerable interest. Prof. Atwater will give a lecture entitled "Nutrition Experiments on Man in the United States." The lecture will include an account of the laborious researches carried on at Middletown, U.S.A., under the auspices of the United States Government. The lecture will be of an entirely popular character, and Prof. Atwater will deal not only with the strictly physiological, but also with the economic aspect of the subject. He will treat of such problems as the feeding of the very poor in large cities. The second new feature will be a couple of discussions of a highly technical nature—oxidation and functional activity, and conduction and structure in the nerve-cell and nerve-arc. The discussions will be opened by Sir John Burdon-Sanderson and Prof. Langley respectively. There will also be a number of papers on physiological subjects, and on Saturday morning two sittings will take place simultaneously, one being devoted to pathology and the other to experimental psychology and the special senses.

Section K (Botany and Agriculture).

The following botanical guests are expected:—Prof. Bertrand, Lille; Prof. Borzi, Palermo; Prof. Chodat, Geneva; Prof. Czapek, Prague; M. de Candolle,

Geneva; Prof. Engler, Berlin; Prof. Errara, Brussels; Prof. Eriksson, Stockholm; Prof Fujii, Tokio; Mlle. Goldflus; Prof. Klebs, Halle; Dr. Lotsy, Leyden; Prof. Macfarlane, Philadelphia; Dr. Overton, Würzburg; Prof. Pierce, Stanford University, California; Prof. Reinke, Kiel; Prof. Schröter, Zurich; Dr. Schoute, Wageningen; Prof. de Toni, Modena; Prof. Vöchting, Tubingen; Mme. Weber van Bosse, Amsterdam; Prof. Zacharias, Hamburg.

Mr. Francis Darwin's presidential address will deal with the statolith theory of geotropism, being a discussion of the recent work on the means by which plants "perceive" the force of gravity. The semi-popular lecture, which in recent years has become one of the features of the section, will be given on Monday afternoon, at 2.30 p.m., by Dr. D. H. Scott. Prof. H. Marshall Ward and Prof. Jakob Eriksson, of Stockholm, will discuss their recent important researches on the biology of the fungi, especially the Uredineæ. The structure of the Cyanophyceæ will be dealt with by Prof. Zacharias, of Hamburg, Prof. Chodat, of Geneva, and others. Dr. J. P. Lotsy, of Leyden, has promised to give an account of the virgin woods of Java, and Prof. S. H. Vines will read a paper on the proteases of plants. Dr. F. F. Blackman will give an account, illustrated by experiments, of his important researches on assimilation and respiration; Prof. A. G. Tansley will give an address on some problems of ecology, followed by papers on various aspects of ecological botany by Prof. Engler, of Berlin, Dr. W. G. Smith, and Messrs. T. W. Woodhead and F. T. Lewis. Papers will be contributed to this section also by Profs. Czapek, Vöchting, G. Pierce, C. E. Bertrand, Dr. Margaret Stopes, Miss Sibille Ford, Prof. Hartog, Dr. W. G. Lang, E. A. Newell Arber, J. Parkin, Dr. A. Reginald Buller, Alfred P. Maudslay, Harold A. Wager, G. Barger and others.

For the first time in the history of the Association there will be a subsection devoted to agriculture, presided over by Dr. W. Somerville.

The following communications have been promised:—A. D. Hall (Rothamsted Experimental Station), the probable error of agricultural field experiments, and analysis of the soil by means of the plant; T. S. Dymond (County Laboratories, Chelmsford), the influence of sulphate as manure upon the yield and feeding value of crops, and the determination of the availability of insoluble phosphate in manures; R. H. Biffen, the improvement of wheats and Mendel's laws; R. H. Elliot, the clover mystery—a probable solution of it; Prof. Middleton, improvement of clay pastures through the agency of clovers; T. B. Wood and R. A. Berry, chemical composition of root crops.

Section L.

The visitors to this section include Dr. Anderssen, Christiania; M. Demolins, La Guichardière; Prof. Dewey, Chicago; Dr. Gallander, Orebro; Miss Laura Drake Gill, Barnard College, Columbia University, New York; M. A. Gobert, Brussels; M. Hovelaque, Paris; Dr. Hausknecht, Kiel; Miss Hazard, president of Wellesley College, U.S.A.; Miss Irwin, Dean of Radcliffe College, Cambridge, U.S.A.; Fräulein Knittel, Breslau; Prof. Mangold, Berlin; Prof. Münch, Berlin; Mme. Dick May, Paris; Miss Oakley, Montreal; Director Trüper, Jena; Fröken Whitlock, Djursholm, Sweden; Miss M. A. Willcox, professor at Bryn Mawr, U.S.A.

One of the chief debates in Section L will be on the subject of school-leaving certificates, with special reference to the scheme proposed by the consultative committee of the Board of Education. Other important subjects selected for discussion are the national and local provision for the training of teachers, and manual instruction in its broadest sense. Afternoon semi-popular talks will probably be given by A. D. Hall, director of the Lawes Agricultural Trust, on the need of scientific method in elementary rural instruction, and by Prof. Armstrong on the research method applied to experimental teaching.

The above summary is based on the facts supplied by the recorders of the several sections.

Tickets and programmes of local arrangements may now be obtained on application to the local secretaries, Emmanuel College, Cambridge.

SIR JOHN SIMON, K.C.B., F.R.S.

BY the death of Sir John Simon, which occurred on July 23, in his eighty-eighth year, this country has lost one of the leaders in sanitary science who with Chadwick and others made the Victorian period a memorable one. Simon commenced the study of medicine in 1833, when he was seventeen years old, and attended both St. Thomas's Hospital and the recently established King's College. Here he studied under Joseph Henry Green, the first professor of surgery at the last-named college, and acted as assistant to Todd in preparation for his physiological lectures. On the foundation of King's College Hospital in 1840, Simon became senior assistant surgeon, being associated with men so well known as Fergusson, Partridge and Bowman. It was in 1848 that he turned his attention to that branch of medicine in which his name became famous. The Corporation of the City of London applied to Parliament for powers to improve the sanitary administration of the City, and as the result of the passing of the City Sewers Act he was appointed Medical Officer of Health. About this time the epidemic recurrence of cholera in this and other countries began to attract attention, and in 1855 it was decided to create a Central Board of Health, for the medical officership of which Simon was selected. In 1858 the functions of the Board were transferred to the Privy Council. This position made him adviser to the Government on all sanitary and medical matters, and he continued to act until 1876, when he resigned his appointment, and on his retirement the decoration of C.B. was conferred on him. On the occasion of Queen Victoria's Jubilee in 1887 he was created a K.C.B. In 1867 he was appointed a Crown member of the General Medical Council, and took an active part in the work of that body until 1895.

The effect of Simon's work as Medical Officer of Health was far more than local; his annual reports, which cover the years 1848 to 1855, form a landmark in the history of English sanitation; they survey the sanitary condition of the City, review the risks arising from cholera and other infective diseases, detail the evils of overcrowding, and direct attention to a condition of affairs which until then had escaped notice. In 1853 he was appointed one of the commissioners to inquire into the outbreak of cholera at Gateshead and Newcastle, and in 1856 submitted a report on the outbreaks of that disease in London in 1848–49 and in 1853–54, conclusively demonstrating the dependence of these epidemics on a polluted water supply. In 1857 he published a volume entitled "Papers on the History and Practice of Vaccination," which was followed in 1858 by the "Report on the Sanitary State of the People of England," which demonstrated for the first time the wide variations which exist in the local incidence of certain diseases and emphasised the need for skilled inquiry. During his term of office under the Privy Council the results of a number of

classical investigations were embodied in his reports, *e.g.* into diphtheria, diseases of the cotton famine, pulmonary diseases, &c. In 1862–63 an important inquiry was undertaken into dangerous industries, in 1863 a survey of the hospitals of the United Kingdom. In 1865–66 he had to establish the organisation to deal with cholera, in 1871 that to deal with the great epidemic of small-pox, and in 1870 he initiated a scheme for laboratory work in public health. He was an uncompromising opponent of the useless practice of quarantine.

Simon's resignation in 1876 was brought about by the Local Government Board Act of 1871 creating the Local Government Board. In Simon's opinion large questions of medical policy affecting the whole country could only be adequately dealt with by a Ministry of Health, a view which is widely held by the medical profession at present, and, having allowed time to see how the new Acts would work, he retired discouraged and disheartened. It is true that the Medical Officer of the Local Government Board and its staff now have duties and responsibilities far wider and more numerous than they were at the date of the creation of the Board, but still a great opportunity was missed. In 1890 he published his great work on "English Sanitary Institutions."

Simon numbered among his friends many of the greatest men of the nineteenth century—Darwin, Buckle, G. H. Lewes, Kingsley, Renan, Tennyson, Rossetti, Burne-Jones and many others. He was in 1878 president of the Royal College of Surgeons, and was the recipient of numerous other honours. He has gone to his rest honoured of all men, and his name will ever live in the annals of sanitary science.

R. T. HEWLETT.

A BANKER NATURALIST.

BY the sudden death of Mr. Henry Evans on July 23 the Midlands have lost a well-known and wealthy banker, and the West Highlands of Scotland an equally well-known deer-stalker, yachtsman and naturalist. Born in 1831, he was educated at Trinity College, Cambridge, graduated there, and was a member of the Senate of the University to the end of his life, coming up from time to time to record his vote on matters of importance. Early in his career he appears to have developed a love of natural history pursuits, for while an undergraduate he became an associate of the Ray Club, of which there are only six at a time, chosen on account of some proved zeal in these studies. He took at that time to entomology, and made a collection of British Lepidoptera. Even up to the end of his life, when he had long abandoned these early predilections, he was still proud of his insect cabinet, and especially of the numerous and fine specimens which it included of the now extinct English large copper butterfly. Being the youngest son of a banker, he naturally became a partner in his father's bank, that of Messrs. W. and S. Evans and Co., of Derby, and on its amalgamation with another firm he was made a director of the new company, Crompton Evans Union Bank. But though a shrewd and capable man of business, he never mingled in public affairs. The leisure of his younger years was largely given to rifle-shooting, in which he grew to be one of the best shots in the country. He competed at the Wimbledon meetings of the National Rifle Association until a lamentable accident occurred to him at one of the practices, when the rifle of a companion was unwittingly discharged against his leg. Three successive amputations were necessitated, and he had to go up on crutches to receive a prize which he had won. This disaster, however, was not allowed to deprive him of his favourite sport. He had become an expert shot among the red deer of the Scottish forests and the seals of the coast of Connemara, and with indomitable courage he now availed himself of the help of a pony and continued his campaigns among the mountains with more success than ever. In one season he fired fifty-two shots and killed fifty deer. After renting various tracts of ground in the Highlands, he finally, in 1875, leased the forest which comprises the extensive mountain ground in the centre of the island of Jura. Choosing a tract of bare moorland that sloped down to the sea, he built there a comfortable mansion-house, surrounding it with trees and shrubs and flowers, covering it with roses, and ingeniously devising expedients that baffled the Atlantic blasts and enabled his vegetation to bloom and spread. This charming Highland retreat became his home for some months every season for nearly thirty years, and he lingered longer there as time went on until eventually he spent more than half of each year in Jura. But though deer-stalking was the original and predominant motive for these prolonged northern sojourns, he was far more than a mere sportsman. His early love of natural history pursuits found an ample field for development in his island home, but it was to the birds that he now gave his attention. Gifted with excellent eyesight, Mr. Evans was an acute and accurate observer. The rapidity and exactness of his recognition of birds on the wing were so remarkable that to friends who accompanied him it almost seemed as if he were the happy possessor of another sense beyond the number allotted to ordinary mortals. He made his mountains and moors in Jura a perfect paradise for wild birds. No gun or trap was ever allowed to be used against them, and everything was done that would induce them to frequent the district.

But it was not only in his own forest that Mr. Evans watched the habits of wild birds. He fitted out a steam yacht, the *Aster*, of 250 tons, on which he usually spent a month or two every year, cruising around the coasts and islands of the west and north of Scotland. He was thus able to gratify his passionate love of cliff scenery and his delight in the crowded breeding haunts of the northern sea-fowl. There are few precipices and inlets in the west and north of Scotland which he had not visited and about which he had not some natural history record to tell. He used to keep jottings of these observations. But he had no ambition to be an author. The retiring disposition which kept him from taking part in public affairs prevented him also from publishing any account of what he saw. All that he observed, however, was freely communicated to those whom it would interest. Some of his observations have thus been made generally known, but his numerous unpublished notes on the distribution of birds all over the west of Scotland would doubtless furnish valuable material to zoologists interested in this subject. Besides shooting his red deer in Jura, he studied them as a four-footed community living isolated under special conditions. He embodied his observations and statistics in a little pamphlet printed some years ago, but only for private distribution, and entitled "Jura Red Deer." Before surrendering his forest to the landlord he brought the records of deer-life up to the end of his tenancy and embodied them in an interleaved copy of the pamphlet. His experience had enabled him to gather together a good number of valuable facts. It is much to be desired that the completed pamphlet should be carefully revised by a competent editor and published as a

contribution to the discussion of the struggle for life among a single species on a small island.

Three years ago Mr. Evans was stricken down by what with most men would have been a fatal illness. But his strength of constitution and marvellous determination of character enabled him to recover sufficiently to be once more able to resume his voyaging in the *Aster*. Deer-stalking, however, with all its joys among the corries of Jura was no longer possible for him. Accordingly he gave up his deer-forest and purchased the beautiful estate of Ascog, in Bute, which he immediately set about to alter and improve. At the end of June last he started with a few friends on what proved to be his longest and last cruise. Under pleasant conditions of weather he visited all his favourite haunts—the cliffs of Mingulay and Barra Head, the sea-lochs of the chain of the Outer Hebrides, the precipices of St. Kilda with their vast swarms of sea-fowl, the fjords of western Sutherland, the cliffs and inlets of Orkney, and the voes and furthest islets of Shetland. In many of these places the *Aster* was a familiar visitor, and was received with blowing of horns and other signs of welcome. At St. Kilda the villagers ran up their flag, and half the population came out in a couple of boats to see their old friend and benefactor, who never failed to bring them some token of his thoughtful interest in their welfare. The cruise was successfully completed by the return of the yacht to Oban, but before the final day, which was to include the rounding of the Mull of Cantyre and the passage up the Firth of Clyde to Bute, it was resolved to anchor opposite the old Jura home and to spend there the following Sunday (July 24). Mr. Evans had been remarkably well all the voyage, and was delighted to have successfully accomplished all that he had wished to do. On reaching Jura he went ashore for a short walk along the coast-road. He had hardly landed, however, and was in the act of conversing with an old gamekeeper who had come down to greet him when he dropped dead as he sat. His retiring modesty kept him from making many friends, but his frank and kindly nature and his vein of quaint humour endeared him to the restricted circle that was privileged with his friendship. He will be mourned by many a lowly family in the west of Scotland that has good reason to remember his cheery greeting and his generous help. He has left a benefaction to the museum of Cambridge University, which has already been enriched by valuable contributions from him in his life-time.

A. G.

NOTES.

CAPTAIN ARTHUR MOSTYN FIELD, R.N., has been appointed successor to Rear-Admiral Sir W. J. L. Wharton, K.C.B., F.R.S., as hydrographer to the Navy, the retirement of Sir William Wharton having taken place on Monday last.

THE next annual meeting of the British Medical Association will take place in Leicester, the president-elect being Mr. G. C. Franklin, senior surgeon to the Leicester Infirmary. The council of the association will recommend that the meeting in 1906 be held in Toronto.

THE next session of the American Medical Association will take place from July 11 to 14, 1905, at Portland, Oregon, under the presidency of Dr. Louis S. McMurtry, of Louisville, Kentucky.

THE Board of Estimate of the City of New York has voted the sum of 2000*l.* towards an investigation by a commission of medical experts as to the contagious nature or otherwise of pneumonia.

THE FitzPatrick lectures at the Royal College of Physicians for the present year will be delivered by Dr. J. Frank Payne on November 8 and 11, the titles being respectively "Gilbertus Anglicus and Medicine in the Anglo-Norman Period," and "Ricardus Anglicus and the History of Anatomy in the Middle Ages." The Bradshaw lecture will be delivered on November 15, the lecturer—Dr. F. F. Caiger—taking as his subject "The Treatment of Enteric Fever."

THE following lecture arrangements for 1905 have been made in connection with the Royal College of Physicians:—The Goulstonian lecturer will be Dr. W. C. Bosanquet; the Milroy, Dr. T. M. Legge; the Lumleian, Dr. W. H. Allchin; the Oliver Sharpey, Dr. L. E. Hill; the FitzPatrick, Dr. Norman Moore

AN American Society of Tropical Medicine has been started in Philadelphia. Dr. T. H. Fenton is the first president, and a number of men of science who have made researches in the prevention of tropical diseases have been elected honorary members. Among the latter we notice the names of Sir Patrick Manson, F.R.S., Dr. C. J. Martin, F.R.S., and Prof. R. Koch.

JOHNS HOPKINS UNIVERSITY is, it is reported, about to undertake systematic work on the subject of tuberculosis. Mr. Henry Phipps, of Pittsburg, has given the sum of 4000*l.*, by the help of which a dispensary building is to be erected so arranged that the treatment of patients may be attended to and the disease investigated.

A REUTER telegram published in the *Times* states that according to a private telegram published by the *Verdens Gang* from Finaes, in Finland, the captain of a vessel from Tromsö reports having found a bottle containing a letter sent off from M. Andrée's Polar balloon expedition. The bottle, which was picked up on a small island north of Spitsbergen, contains a letter bearing a date in 1898. Particulars as to the contents of the letter will not be available for another month. A private telegram from Finaes published by the *Landsblad* says that the bottle was found on the island of Moffen, to the north of Spitsbergen.

A BOARD of Agriculture has recently been established in the Bahamas, and a botanic station is to be started in connection with it for which a curator will be required. Applications for the post should be made in the first instance to the Imperial Commissioner of Agriculture for the West Indies, Barbados.

THE Barker anatomical prize of thirty guineas has been awarded to Mr. Charles Cooper, a student in the Royal College of Surgeons, Dublin. The prize is offered annually, and is open to all students in any medical school in the United Kingdom. This is the fifth successive year the prize has been conferred on a student of a Dublin college.

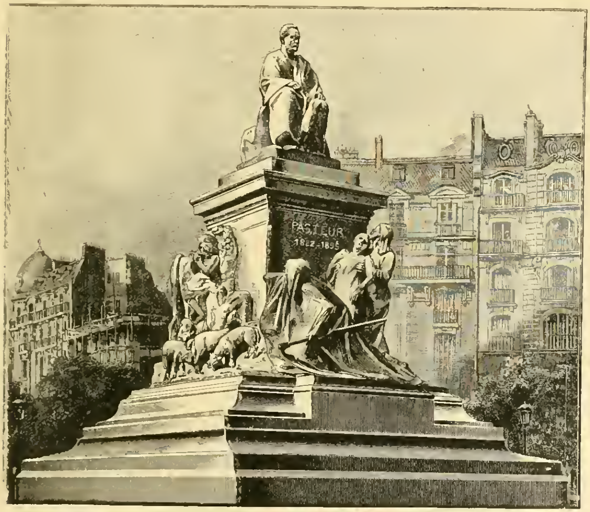
THE St. Bartholomew's Hospital testimonial to Mr. Alfred Willett will, says the *Lancet*, take the form of a silver medal to be known as the "Willett medal," which will be awarded each year to the candidate obtaining the highest marks in operative surgery in the Brackenbury surgical scholarship. A gold medal of the same design will be presented to Mr. Willett.

THE death is announced of Prof. Simonds, formerly principal of the Royal Veterinary College, and consulting

veterinary surgeon to the Royal Agricultural Society. Prof. Simonds made many researches into the diseases of animals, and became professional adviser to the Privy Council in all matters relating to the regulations and supervision of the cattle trade.

According to the *Scientific American*, the patents of the De Forest and Maskelyne wireless telegraphy systems have been amalgamated. The object of the combination is the employment of wireless telegraphy as a feeder for cable telegraphic systems. In cooperation with the cable companies, it is proposed to link isolated islands with the nearest cable stations, and to develop wireless communication between ships and shore, and between vessels at sea. This combination will, it is thought, strengthen both systems. The De Forest apparatus is a sound recorder, the messages being received on the principle of a telephone, while the Maskelyne system is a tape recorder. By this amalgamation, therefore, either system will be available according to requirements.

Falguière's monument to the memory of Pasteur was, as announced in Nature of July 21, unveiled in Paris by President Loubet on July 16. The monument is the result of an international subscription, and may be regarded as a world-wide tribute to the memory of a great man of science. The illustration, reproduced from *La Nature*, serves to convey an excellent idea of the memorial. The whole monument is about seven metres in height, of which a little more than four metres form the pedestal. Pasteur is shown seated and in deep thought. Beneath the statue round the pedestal are grouped allegorical figures which recall very naturally the successive discoveries made by Pasteur. On the front face of the pedestal occur the words "Pasteur 1822–1895," and underneath the inscription "Ce monument est dû à une souscription internationale."



A statue to Jan Pieter Minckelers, the reputed discoverer of coal gas, was unveiled last month in Maastricht, Holland. Minckelers was born in 1748, and became in 1772 professor of physics in the University of Louvain, where in 1784, in endeavouring to discover a substitute for hydrogen, he succeeded in obtaining from the distillation of powdered coal a gas which he called "inflammable air." It was in 1785 that he first utilised the gas for lighting purposes, when a class-room in the Louvain University was illuminated by his method. He died in 1824 at the age of seventy-six years.

The first annual convention of the British Foundrymen's Association was begun on Tuesday last at Manchester, when the president, Mr. Buchanan, delivered his inaugural address. Papers on the structure of metal and alloys, illustrated by photomicrographs of types of cast iron, steel, brass, and bronze, used in foundry practice, by Mr. Percy Longmuir (Carnegie medallist), and strength tests of cast metals, by Mr. W. T. MacCall, were read and discussed, and on Wednesday visits were paid to some industrial centres.

Several parts of Paris being so infested with mosquitoes, the matter of their suppression has been considered by the Conseil d'Hygiène et de Salubrité de la Seine, which, according to the Paris correspondent of the *Lancet*, recently adopted certain conclusions of which the following is a summary:—In the first place stagnant water where their eggs are hatched and localities where the insects collect, such as cellars, sewers, and dark places, ought to be kept under observation. Drains and sewers of all kinds, and the openings of the pipes which supply water in the streets, should be regularly inspected to avoid collections of stagnant water, and insects assembling in numbers should be destroyed either by a burning torch or by lime-washing. Roofs and rain-water gutters ought to be examined, and water ought not to be allowed to lodge in the gutters. Nothing capable of holding water should be placed in front of windows, and places which are the haunts of mosquitoes should be well ventilated. Stagnant water should not be allowed to remain in gardens and courtyards. Fountains and basins in public places should be emptied and cleansed at least once a week, and plenty of fish should be kept in large sheets of water. In basins and casks standing on private ground there should be a layer of petroleum oil on the surface of the water (about a gram per square metre), or if the water contains fish a layer of salad oil. The public should be advised to use mosquito curtains. Mosquito bites should be treated with a drop of tincture of iodine or with a drop of a solution of guaiacol of 1 per cent. strength.

According to the *Lancet*, Dr. W. H. Symons, medical officer of health, Bath, has completed a geological model of the City of Bath and the surrounding district covering an area of 36 square miles. The horizontal scale is six inches to the mile, and the vertical scale is six inches to 1000 feet. The model has been placed in the museum of the Royal Literary and Philosophical Institution of the city.

Prof. Schäfer, F.R.S., describes a simple and efficient method of performing artificial respiration in the human

subject, especially in cases of drowning (*Med. Chirurg. Trans.*, vol. lxxxvii.). Immediately the patient is recovered from the water he is placed face downwards, the head being turned sideways so that the mouth and nose are unobstructed, with a folded coat under the lower part of the chest; if respiration has ceased every instant of delay is serious. The operator then places himself athwart, or on one side of, the patient's body in a kneeling posture and facing the head. He places his hands flat over the lower part of the back (on the lowest ribs), one on each side, and gradually throws the weight of his body on to them so as to produce firm pressure—which must not be violent—on the patient's chest. This compresses the chest, and air (and water if there be any) is driven out of the patient's lungs. He then raises his body slowly so as to remove the pressure, still keeping his hands in position. This process of applying pressure and of relaxation of pressure by the forward and backward movement of the operator's body is repeated every four or five seconds without any marked pause between the movements. This course must be pursued for at least half an hour, or until the natural respirations are resumed. If the respirations after being established tend to fail, the process of artificial respiration must again be resorted to. If there be means, others may remove the wet clothing by cutting it off, and may apply hot flannels to the body and limbs and hot bottles to the feet, but nothing should be allowed to interfere with the regular and systematic application of artificial respiration. No attempt should be made to give restoratives by the mouth until natural breathing has re-commenced. In another paper Prof. Schäfer gives the results of the experiments he has performed, showing the efficiency of his system of treatment (*Proc.* Roy. Soc. Edin., xxv., part i.).

IT has always been more or less tacitly assumed that the difficulties which attend respiration at great altitudes are due solely to the diminished tension of the atmospheric oxygen. Two papers by A. Mosso in the *Atti dei Lincei* for June 19 would tend to disprove this assumption. It is shown, in the first place, that when the barometric pressure of a mixture of oxygen and nitrogen is diminished to one-third of an atmosphere, whilst the proportion of oxygen is increased so that its partial pressure is the same as in ordinary circumstances, severe inconvenience is incurred by breathing the mixture, and an abnormal respiration and pulse frequency are produced. That this is due not merely to the increased proportion of oxygen is shown by a study of the effects produced by breathing pure oxygen on the summit of Monte Rosa. Analyses of the blood indicate that a diminution in the proportion of carbon dioxide, caused by the low pressure, is probably responsible for the result, and this view is upheld by the fact that a mixture of oxygen and carbon dioxide, containing 20 per cent. of the latter, which on being inhaled in Turin caused giddiness and vomiting was breathed with ease and a sense of pleasure on Monte Rosa.

IN a paper by G. Gallo in the same number of the *Atti* an account is given of the conditions under which tellurium can be estimated electrolytically. Previous attempts to effect the electrolytic deposition of the element have been unsatisfactory because of the powdery nature of the product. It is now shown that the presence of sodium pyrophosphate in the electrolysed solution causes the tellurium to be deposited as a firmly adherent film; when, by saturating the solution with carbon dioxide, this film is protected from oxidation, its weight corresponds with a quantitative separation.

IN the same journal for July 3 appear two papers of considerable physiological interest. In the first, by A. Mosso and G. Galeotti, it is shown that when alcohol is ingested at great altitudes, for instance at the summit of Monte Rosa, it fails altogether to produce its usual characteristic effects. There is no indication of either excitement or intoxication, and it appears that at such a height the nerve cells are no longer responsive to alcoholic stimulus. The second paper, by A. Herlitzka, deals with the self-digestion of pepsin. From the experiments described it is concluded that, as a proteid, pepsin is capable of being digested by itself to form peptone, and that this change always occurs in a warm aqueous solution of pepsin containing hydrochloric acid. A falling-off of the digestive activity with regard to other proteids is a measure of the gradual change.

IN the *Memorie* of the R. Ist. Bologna (series vi., vol. i.) Prof. Augusto Righi describes a number of measurements he has made on the radio-activity of common metals. The rate of discharge, in dry carbon dioxide gas, of an especially constructed single-leaf electroscope of small capacity was observed when the leaf was hanging immediately above a disc of the metal in question. It was found that nearly all the common metals had practically the same ionising effect as glass; lead and bismuth were exceptions, their power of rendering a gas conducting being abnormally great. The observation is of significance because particularly active modifications of lead and bismuth have already been obtained by other workers.

A FURTHER contribution to the subject of Mendelian laws by Mr. C. C. Hurst appears in the *Journal* of the Royal Horticultural Society (May), wherein he describes his experiments upon heredity in peas, undertaken with the object of repeating Mendel's original observations; an important point is the consideration of the histological difference between races, as, for instance, between *round* and *wrinkled* peas. In the same volume will be found two papers devoted to the iris. In the first Miss Armitage treats of bulbous irises for the rock garden, and of rhizomatous species for the water garden, and appends a list of phenological observations which shows that by judicious selection of species it is possible to have iris flowers continuously for eight months; the variability of the flower, and the distinction between *bearded* and *beardless* irises is the subject of an article by Mr. W. J. Caparne.

IT has been stated on good authority that more than half of the waste lands in Ireland are suitable for forest plantations, and Dr. Henry, in the course of a lecture on "Forests, Wild and Cultivated," delivered before the Royal Society of Dublin in February, advanced further arguments in favour of afforestation. He pointed out that Ireland possesses an ideal forest climate on account of the heavy rainfall, the mild climate, and the absence of cold winds in winter. To illustrate his remarks on forest management, the author took his descriptions from French practice, including plantations in the districts of the Jura and the Vosges, and in the Landes, where successful results have been obtained with a strict regard for economy.

THE Natural History Museum recently received from Osborne House two mounted heads and one skull of Spanish draught oxen, sent by command of His Majesty the King. They have remarkably fine horns, and serve to illustrate the difference between this handsome breed and the Spanish fighting bull, of which an entire specimen has been exhibited for the past few years.

To *Naturen* for June and July Dr. L. Stejneger, of the U.S. National Museum, communicates an interesting paper on the "Celtic pony" recently described by Prof. J. C. Ewart and its relation to the now extinct tarpan of the Russian steppes, and to a Norwegian breed termed the "fjordhest." All appear to be closely related, if not, indeed, identical, the tarpan and the "fjordhest," at any rate, frequently lacking the callosity on the hind limb.

Judging from the fact that the one on the brain of the sheep has reached a third edition, Dr. B. G. Wilder's "Physiology Practicums," published by the author at Ithaca, U.S.A., appear to have attained the success they deserve. Seven plates illustrate the part before us.

No interruption to the steady pursuit of science in Japan appears to be caused by the war, three parts (one of them of exceptional thickness) of the *Journal* of the College of Science of Tokyo having reached us by last mail. The first of these (vol. xviii., art. 7), which comprises no less than 307 pages of text, illustrated by 23 plates, is devoted to the fourth instalment of Dr. I. Ijima's studies on the hexactinellid sponges. In this section the author treats of the family Rossellidæ, which he divides into three sub-families. Of the other two parts to hand, one (vol. xix., art. 14) contains a study by Mr. K. Yendo of the genicula of the calcareous algas of the group Corallinæ, while the other (vol. xix., arts. 18 and 19) is devoted to descriptions of certain low plant-organisms by Mr. K. Saito.

The *Entomologists' Monthly Magazine* for August contains notes by Mr. J. R. Tomlin on Manx beetles, which are said to be of interest in respect to island faunas, while Mr. J. J. Walker, who has recently visited Melbourne, contributes a notice of his inspection of the Curtis collection of British insects preserved in the museum of that city. This collection, it appears, was purchased about 1864 from the widow of Mr. J. Curtis. According to Mr. Walker, it contains the types of several of Curtis's species or varieties—it is a pity that these should be in Australia.

The *Biologisches Centralblatt* for July 15 contains the third instalment of an article by Mr. G. Klebs on the problem of development, the author in this instance discussing the evidence afforded by the lower plants. Dr. W. Petersen concludes his essay on the value of "indifferent" characters as species distinctions, and Dr. W. Volz communicates a note on the distribution of the two species of gibbon inhabiting Sumatra.

In the *Bulletin de la Classe des Sciences* (Brussels), 1904, No. 3, M. P. Mansion directs attention to the new international language proposed by Prof. Peano in the form of "Latin without inflexions." The attempts at building up a universal language in the forms of the Volapük of Schleyer and the Esperanto of Dr. Zamenhof have both met with considerable success, but it was left for the mathematician of Turin to reduce the problem to what may be regarded as the limit of simplicity by proposing, in 1903, a modification of Latin, in which not only genders, persons, cases, and numbers are abolished, as previously suggested by Leibnitz, but even tenses and moods are no longer retained. This system would not only have the advantage of making Latin the language of the learned world, as it used to be in the middle ages, but it could be very easily introduced owing to the extent to which Latin is taught in schools all the world over.

M. E. S. London has carried out a number of experiments on the physiological and pathological actions of the radium emanations derived from 10 milligrams of radium bromide dissolved in 10 cubic centimetres of water (*Arch. d'Électricité méd.*, No. 142, 1904). Frogs and mice exposed to the emanations for 5–6 days became ill and died, hæmolysis occurred in defibrinated blood exposed for two or three days, and the vitality of bacterial cultures was destroyed after an exposure of two days. The gastric and pancreatic ferments were, however, unaffected by the emanations.

The commission consisting of Colonel Bruce, F.R.S. (chairman), Major Horrocks, Staff-Surgeon Shaw, R.N., Dr. Zammit, chemical analyst and bacteriologist to the Government of Malta, and Dr. R. Johnstone, of the Local Government Board, has begun its work of investigating the etiology and pathology of Mediterranean or Malta fever. The experimental work is being carried on at the laboratories of the Naval Hospital, of the Army Station Hospital, and at the offices of the Board of Health, Malta. The disease, says the *British Medical Journal*, is the cause not only of many deaths among sailors and soldiers, but also of much invaliding, which is all the greater owing to the prolonged course which the disease commonly runs even in cases which ultimately recover. While it is known that the disease is due to a specific microbe, the *Micrococcus melitensis*, very little has yet been certainly ascertained as to the mode in which the specific agent maintains its existence and how infection is contracted. A knowledge of these points in etiology is an essential preliminary to devising and enforcing effective prophylactic measures.

The Röntgen Society will in future publish its proceedings in its own journal, which will appear as a bi-monthly "during the working session." The first part of the *Journal*, dated July, has just reached us, and is a well produced periodical which should be of service to radiographers. In addition to four full-page process plates, a separate photogravure portrait of Prof. Silvanus P. Thompson, F.R.S. (the first president of the Röntgen Society), is issued with the number.

Messrs. Newton and Co.'s new list of X-ray and high frequency apparatus has reached us. It contains particulars of the latest forms of apparatus made by this firm, and should be seen by all workers in this branch of science.

The summer number of the *Chemist and Druggist* (dated July 30) contains an article on Sir William Ramsay and his work. The paper contains a full-page illustration showing Sir William Ramsay in his laboratory experimenting with radium. The *Scientific American* for July 23 also has a page illustration of Sir William Ramsay in his laboratory, the original photograph of which was specially taken for our American contemporary.

Several of the August issues of the monthly magazines that have reached us contain articles dealing with subjects of a more or less scientific character. Thus *Chambers's Journal* has a contribution entitled "A Visit to a Wild-Animal Farm," the farm in question being that belonging to Mr. R. Leadbetter in Buckinghamshire, and known as Hazlemere Park; *Good Words* contains an appreciation of Stanley and a summary of the results of his work by Sir Harry Johnston; and in *Pearson's Magazine*, under the title of "Two Thousand Photographs a Second," the electro-stereo-chromophotographic camera invented by M. Lucien Bull for the photography of insects in flight is described and graphically illustrated.

OUR ASTRONOMICAL COLUMN.

THE RED SPOT ON JUPITER.—This object exhibited a slackening motion during the years from 1878 to 1900. It then became decidedly accelerated, so that the rotation period, which in 1899 and 1900 was 9h. 55m. 41·7s., decreased in 1901 to 9h. 55m. 40·6s., and in 1902 to 9h. 55m. 39·0s. In 1903 the spot again became retarded, and the rotation period increased to 9h. 55m. 41·0s. This retardation has now in turn given way to another acceleration of speed. In January last the longitude of the spot was 35°, whereas at the present time it is only 30°, so that the rotation period during the first six months of 1904 has been about 9h. 55m. 39·5s. It is difficult to explain these curious oscillations in velocity. Some extensive disturbances have, however, affected the south temperate region of the planet in recent years, and a large dusky patch has been visible since 1901 rotating with a rate of 9h. 55m. 18·7s., or about 22 seconds less than that of the red spot. The motion of the latter may possibly have been affected by disturbances occurring in the same latitude, but this can only be fully determined by further observations. In the meantime, both the red spot and the south temperate spot are being attentively watched as to their motions and appearances. The two objects were in conjunction in July, 1902, and June, 1904, and in the spring of 1906 the event will be repeated if the south temperate spot should remain visible until that time. As to the red spot and its surroundings, they appear to form features of remarkable permanency, and are likely to continue perceptible for an indefinite period.

VARIABLE RADIAL VELOCITY OF α ANDROMEDÆ AND FOUR OTHER STARS.—Whilst engaged in line-of-sight work with the Lowell spectrograph Mr. V. M. Slipher discovered the variable radial velocities of α Andromedæ, α Libræ, σ Scorpii, X Sagittarii, and ϵ Capricorni.

The velocities of α Andromedæ were obtained from measurements of the $H\gamma$ and 4481 magnesium lines, the helium 4472 line also being measurable. They range from +20 (February 11) to −45 km. (March 4), but are uncertain to a few kilometres. The observations indicate a period of about 100 days and a very eccentric orbit.

The measurements of the α Libræ spectrograms give a range between −60 km. on May 24 and +20 km. on July 6, and suggest that both components are bright. The velocities of σ Scorpii range between +25 (June 25) and −25 km. (June 18). Only two plates were measured for X Sagittarii, which is a visual variable having a period of seven days, and these gave +1 and −22 km. on June 19 and 22 respectively. A range of from −45 km. (September 7, 1903) to +6 km. (July 6) was obtained for the radial velocity of ϵ Capricorni (Lowell Observatory *Bulletin*. No. 11).

VARIOUS CLASSES OF SILICIUM LINES AND THEIR OCCURRENCE IN STELLAR SPECTRA.—In a communication to l'Académie des Sciences (Paris), M. de Gramont describes some results he has obtained during a series of experiments on the effects of various amounts of self-induction in the spark spectrum of silicium. His observations led him to form two main classes of silicium lines:—(1) those which are not affected or are strengthened by self-induction amounting to 0·03 henry; (2) those of which the intensities are reduced by self-induction and which disappear entirely with 0·006 henry.

He further divides them into eight groups (α–η), and, in a table showing their individual characteristics in the spark and in various stellar spectra, he shows their connections with the four temperature groups (silicium i.–iv.) named by Sir Norman Lockyer in his temperature classification of the stars. From this table he draws the following conclusions:—(1) Only the spectra of the first class, *i.e.* hydrogen and helium stars, show the lines which disappear under the action of self-induction, those of helium, *e.g.* the Orion stars, exhibiting as strong lines those which are first to disappear (Lockyer's silicium iii.), whilst the hydrogen stars, *e.g.* Sirius, present the lines which are the last to disappear (silicium ii.). Stellar spectra of the second class (solar type) and the "flash spectrum" contain the lines which appear in both arc and spark, and resist self-induction, *e.g.* λ 3905·7 (silicium i.). As the lines belonging to Sir Norman Lockyer's group iv. are near oxygen and nitrogen lines, and always disappeared from the spectra with the air lines, and as oxygen and nitrogen have been shown to exist in the absorbing atmospheres of the stars the spectra of which show this group (*e.g.* β Crucis), M. Gramont suggests that these lines are attributable to air (*Comptes rendus*, No. 3, vol. cxxxix.).

LINE OF SIGHT CONSTANTS FOR SOME ORION TYPE STARS.—In No. 3, vol. xix., of the *Astrophysical Journal*, Miss E. E. Dobbin gives a list of line-of-sight constants for 112 stars of the Orion type, computed for the reduction of the Bruce spectrograph observations.

Dr. Schlesinger's formulæ, as employed in his "Line-of-Sight Constants for the Principal Stars," were used, and the name, magnitude, position, and constants are given for each star. The longitude is given for 1900, and therefore requires the 50″ precession correction for each year since then.

THE TAILS OF BORRELLY'S COMET (1903) AND LIGHT-PRESSURE.—Mr. S. A. Mitchell, of Columbia University, has calculated the value of the repulsive force due to light-pressure which acted on the several tails of Borrelly's comet. Using the values for the angle between the radius vector of the comet's path and the tail, as determined by Prof. Albrecht, he found somewhat discordant values for the principal tail, which gave, in the mean, the value for the light pressure as 18·47 times gravity. For the secondary tail the values were much more consistent, and gave a mean of 1·824 times gravity; the last four lines given in this table, which were derived from measures of the angle on August 13, 14, 15, and 18, give a mean for the repulsive force of 1·460 times gravity, and therefore appear to indicate the existence of a third tail, which the photographs obtained on August 12 and 15 corroborated.

In a second table Mr. Mitchell compares the values of the angles between the tails and the radii vectores as obtained (1) by calculation from the repulsive forces given above, (2) by direct measurement. The results agree fairly well considering the uncertainty of the measures of such ill-defined objects as the tails. The differences between the observed and calculated values for the principal tail as the comet approached the sun indicate the presence of some other repulsive force in addition to that caused by light pressure, and Mr. Mitchell believes that part of this, at least, is real. The size of the particles forming each of the three tails, as determined from the above repulsive forces, was $0·1\mu$, μ, and $1·33\mu$ respectively (*Astrophysical Journal*, No. 1, vol. xx.).

SURVEY OF INDIA, 1901–2.—A volume of "Extracts from Narrative Reports of the Survey of India, 1901–2," published at Calcutta (1904), contains accounts of the work done by several parties of surveyors in connection with the triangulation of Upper Burma, latitude operations, the magnetic survey of India, tidal and levelling operations, and the topography of Upper Burma, Sind, and the Punjab.

During the latitude operations some puzzling anomalies were discovered between the observed and calculated values, the difference O–C preserving its positive character to a point much further north than might be expected.

The latitude results obtained, using stars from Newcomb's catalogue and from the Greenwich ten-year catalogue for 1880, show the same probable errors, but there is a noteworthy consistency of sign and amount (about +0·3″) in the value Newcomb-Greenwich.

An interesting account of the practical details of the magnetic survey, and of the instrumental equipments at Dehra Dun, Kodaikanal, Calcutta, and Rangoon are given in part iii., where the principles of several new and modified instruments are also fully described.

THE BRITISH MEDICAL ASSOCIATION IN OXFORD.

THE seventy-second annual meeting of the British Medical Association, which was held in Oxford last week (July 26 to 29), was beyond question one of the most successful meetings in the memory of members of the association, as it was in point of numbers much the largest yet recorded.

It was remarkable also for the persistence and enthusiasm with which, in spite of all the counter-attractions of that ancient and glorious seat of learning, and of the diversions, entertainments, and receptions arranged both by the

members of the university and by the citizens, a quite unusually large proportion of the members who were visiting Oxford steadily pursued the actual business of the meeting in the various sections.

Not only was the occasion distinguished by the presence and participation in the sectional meetings of a considerable number of eminent foreign visitors, and of an exceptionally numerous gathering of the recognised leaders of thought and investigation in medical science in our own country and the colonies, but it was also rendered memorable by the great importance and originality of the new work brought forward in many of the sections. Indeed, both in the science and the art of medicine in its widest sense, notable results of signal interest were recorded; and more than one sectional meeting witnessed the initiation of far-reaching advances, the significance of which it would be difficult to overestimate.

An academic interest was lent to the occasion by the presence of the Vice-Chancellor at a number of the meetings, and by the holding of a special convocation of the university, at which the doctorate in science, *honoris causa*, was conferred upon the following distinguished members of the association :—

Dr. T. Clifford Allbutt, F.R.S., regius professor of physic in the University of Cambridge; Mr. Andrew Clark, chairman of council, British Medical Association; Dr. T. D. Griffiths, late president of the British Medical Association; Mr. Jonathan Hutchinson, F.R.S., late president of the Royal College of Surgeons of England; Sir William Macewen, F.R.S., regius professor of surgery in the University of Glasgow; Sir Patrick Manson, F.R.S., of the London School of Tropical Medicine; Sir John W. Moore, formerly president of the Royal College of Physicians of Ireland; Prof. Osler, of Johns Hopkins University.

At the annual general meeting of the association the Vice-Chancellor of the university, Dr. Monro; the Dean of Christ Church, the Very Rev. T. B. Strong; the master of University College, Dr. Bright; and Mr. A. G. Vernon Harcourt, F.R.S., of Christ Church, were elected honorary members of the association.

The president, Dr. William Collier, took as the subject of his address "The Growth and Development of the Oxford Medical School." Starting from the period when the study of science and medicine in Oxford was at such an ebb that the school had been justly spoken of as "a lost medical school," he showed how large a part the association had played in its re-establishment.

By the action which it took in 1879 in memorialising the House of Commons, the university commissioners, and the hebdomadal council, it had afforded most material assistance to the late Sir Henry Acland and his colleagues at a critical period in the struggle which they were carrying on in Oxford. The work of Acland had been nobly carried on by his successors. Under their guidance there had gradually again grown up in Oxford a school of natural science and medicine which was already taking a prominent place among the leading schools of science in the country.

After emphasising the advantages which had thus accrued both to the profession of medicine and to the university, Dr. Collier drew a vivid picture of the brilliant past of Oxford medicine at the time when, in the sixteenth and seventeenth centuries, the university formed the centre of English scientific thought, and numbered on her roll such names as those of Willis, Boyle, Wilkins, Lower, Wren, and Harvey. To-day, he said, Oxford was again alive to the importance of science and the scientific method. Nothing save the bitter need for necessary endowments hampered her and held her back from bearing once again a noble part in the advancement of natural knowledge, and rivalling the scientific glories of her past.

Continuing, Dr. Collier said we all of us realised that the provision which has to be made for a modern scientific education is of necessity a costly undertaking. He wished more particularly to emphasise this point, because the amount of work done in the way of instruction in the scientific departments of the university for a totally inadequate remuneration was well recognised and much deplored. He would quote the words spoken recently by His Majesty the King at Cambridge :—"the older universities must receive new endowments, if education within my realms is to be kept at its proper standard of efficiency."

One could but hope that these new endowments of which the university stood in such urgent need would speedily be forthcoming; and one found a difficulty in understanding how it was that a university such as that of Oxford, with its noble traditions and its long roll of illustrious dead—a university which for many centuries had been, with the sister University of Cambridge, the acknowledged training school of the leaders of thought and action in the country—failed to appeal to those fortunate individuals who were in a position to do their country and education a service, and to enrol their names on that imperishable record of benefactors whose memories we honour and extol.

The addresses in medicine and surgery delivered by Sir William Selby Church and Sir William Macewen were of great importance, and a valuable popular lecture on disease germs, open to the public, was delivered by Dr. Bagot Ferguson.

Sir William Church dealt with the relation of medicine to the State, and with the pressing questions in public health. The national health, he urged, was a matter "of supreme importance far transcending the ordinary political issues of the day." But at the present time the administration, even of the Acts which had been secured, was ineffective.

He was afraid, from the nature of the report of the Treasury Committee appointed to consider the position and duties of the Board of Trade and the Local Government Board, that there was not much prospect of the Public Health Department of the Board receiving any increase either of power or payment. The health of the nation, on which its success and prosperity depend, was thrust into the background with the remark that the president of the board "has the advantage not only of the professional opinion of the Medical Officer of the Board, but also of the general administrative experience of the Permanent Secretary."

He thought that in pressing the necessity for the reform of the Local Government Board upon the attention of the president and the Government, three points should be especially emphasised :—first, that the central authority should act as an advisory as well as a supervising authority; secondly, that both in the Local Government Board and in the local authorities the medical element should have greater weight; and, thirdly, that the medical officers of these authorities should exercise further supervision and control over the purity and wholesomeness of articles sold for food.

In the section of anatomy Prof. D. J. Cunningham introduced a discussion upon giants and dwarfs. He regarded gigantism and acromegaly as morbid processes having many points of similarity, and stated that of the cases of gigantism on record thirteen were certainly acromegalic. Dr. Gibson and Prof. Symington also supported the view that gigantism is a pathological condition, and is associated with disease or abnormality of the pituitary body. Dr. Hastings Gilford held that giants and dwarfs may be either natural or pathological. He described three forms of dwarfism, which he illustrated by a number of living cases. He also exhibited a beautiful series of photographs bearing on ateleiosis and progeria.

In connection with this section Dr. Keith exhibited a series of hearts to demonstrate the arrangement of the auricular musculature forming the valves described by him as closing the venous orifices during normal auricular contraction. The observations which he has made have also led to the elucidation of the mechanism by which the right crus of the diaphragm, acting upon the heart, produces what is termed by physiologists "the respiratory pump." They also explain the means by which a number of the changes in the circulation taking place at birth are brought about.

Dr. Keith also had specimens proving the existence of a sphincter muscle at the ileo-cæcal valve in man.

Dr. Keibel, of Leipzig, showed an instructive series of models of the development of the urogenital system of Echidna, and Dr. Bryce detailed his observations into the origin of embryonic leucocytes, derived from a study of the histogenesis of the blood of larvæ lepidosiren.

The section of physiology held a discussion on the thalamic region in conjunction with the anatomists. The discussion was opened by Dr. Gustav Mann, who divided the central nervous system into an anterior part limited

behind by the posterior commissure, and a posterior portion which he termed collectively the cord. He described several new nuclei in the thalamus, and illustrated his conclusions by a series of models, microscopic sections, and stereoscopic photographs of the thalamus in monkeys and rabbits.

Sir Victor Horsley dwelt on the necessity for making both horizontal and sagittal sections of the thalamus, and for directing attention to cell-systems rather than to tracts of fibres. The current system of dividing the thalamus into tracts of fibres is quite untrustworthy unless checked by the degeneration method. His excitation experiments, so far as they had gone, confirmed Dr. Mann's results.

Dr. F. Griffiths and Dr. W. B. Warrington read an interesting paper on the varieties of the cells of the spinal ganglia and their relationship to axons of different distribution, and showed a useful series of illustrative microscopical sections.

Among many other valuable papers and discussions may be mentioned the important debate on chloroform anæsthesia and the demonstration given by Mr. Vernon Harcourt of his apparatus for the administration of known percentages of chloroform vapour. The apparatus is convenient and compact, and guarantees that the amount of chloroform administered is never in excess of 2 per cent. of the inspired air. An apparatus of a similar purpose by Dubois was also shown by Dr. Chapman.

In the section of pathology an unusual amount of valuable new work was published. The discussion on immunity was opened by the president, Dr. Ritchie, who began by pointing out what definite conclusions were now firmly established, and what were the problems which awaited solution. He then discussed the relation of the processes concerned in the immunity reaction to normal physiological events, and the general bearing on the question of the more important recent work. Dr. Bulloch followed, dealing in a masterly fashion with the cellular aspects of the problem of immunity, and Dr. Dreyer, of Copenhagen, read an important paper on agglutinins.

Dr. Madsen, of Copenhagen, then described the steps by which, in association with Prof. Arrhenius, he had shown that the relation of toxin and antitoxin in the living body, exemplified in what is known as "Ehrlich's phenomenon," cannot be explained, as Ehrlich holds, as being due to the presence of degenerated toxins in the crude bouillon from diphtheria or tetanus cultures. While not denying the existence of such degenerated toxins in the bouillon cultures, they maintain that the phenomenon is due to the fact that toxin possesses only a weak affinity for its corresponding antitoxin. It thus results that dissociation phenomena occur between the toxin, antitoxin, and the toxin-antitoxin molecules. In support of this view new evidence was submitted from investigations carried out upon ricin and anti-ricin, snake venom and antivenene, and saponin and its anti-body, cholesterin.

Further contributions to the study of snake venoms were communicated by Dr. C. J. Martin and Dr. Noguchi.

Dr. Wright described the experiments which led to his discovery of the bodies which he terms opsinines. These bodies have the property of enabling phagocytes to attack bacteria. They are present in the blood serum, but not in the phagocytes themselves, and they can, like anti-bodies, be transferred to foreign phagocytes, upon which they then confer a like bacteriolytic power.

At a later period of the meeting Dr. Wright gave a most lucid demonstration of the numerous brilliant modifications and new methods which he has introduced, and which have simplified and much increased the accuracy of all kinds of blood investigation and research into the mechanism of bacteriolysis.

A discussion was also held upon the *rôle* of the lymphocyte. This was opened by Dr. Lovell Gulland and Prof. Muir, and many valuable communications were contributed, notably a paper by Dr. Beattie, of Edinburgh, in which he concluded in favour of the endothelial origin of many of the mononuclear cells in inflammation. The discussion revealed the fact that a considerably greater uniformity of opinion as to the origin of the various kinds of leucocytes is coming into existence among pathologists.

The subject of the third discussion was the chemical pathology of gout. This was opened with a most able paper from Prof. von Noorden, and in the course of the discussion Dr. Walker Hall gave a demonstration of his simple apparatus for the rapid determination of the urinary purins.

In the section of tropical diseases Colonel Bruce opened the discussion on trypanosomiasis with a suggestive paper, in the course of which he stated that trypanosomal fever is in all probability the first stage of sleeping sickness, and that the *Glossina palpalis* is the medium of transmission.

A discussion was also held on the significance of the Leishman-Donovan bodies. This was introduced by Major Leishman, who pointed out the occurrence of these bodies in kala-azar, and maintained that they probably represent a stage in the life-history of a flagellate organism closely resembling a trypanosome. Dr. G. C. Low exhibited sections of the spleen from a case of kala-azar, showing these bodies *in situ*. He also exhibited a number of specimens showing the perivascular infiltration in the brain and cord in sleeping sickness.

Very instructive exhibits illustrating the conditions in ankylostomiasis and bilharzia infection were shown by Dr. Armand Ruffer and by Dr. Sandwith; and Dr. Nabarro showed specimens of trypanosoma from Uganda.

In the section of State medicine the president, Dr. J. S. Haldane, opened a discussion on standards of ventilation, discussing the effect upon the human system of poisonous gases and dust. The dust nuisances he considered could be better prevented by special measures, such as water sprays, than by a general increase of the ventilation. Subsequently he dealt with the effects of breathing air contaminated with an excess of carbonic acid gas, or containing a deficiency of oxygen or an increase of organic matter. The real pathological effects of such conditions, he held, were slight. The discussion was continued by Dr. Jones, Dr. Oliver, Dr. Hay, and others.

Dr. Newman opened a discussion on the control of the milk supply. Having reviewed the dangers to the nation which spring from the present inadequate and contaminated milk supply, he urged that the initiative for reform must come in the first place from the consumer. So far as legislation is concerned, he thought that all that could be expected was a systematic and universal enforcement of the Dairies Order. Dr. Henri de Rothschild agreed with Dr. Newman that the demand for reform must come from the consumer. The chief difficulty appeared to him to lie in the fact that the consumer wanted good milk at a price for which only bad milk could be purchased.

GEOLOGICAL NOTES.

"THE Stone Reefs of Brazil, their Geological and Geographical Relations, with a Chapter on the Coral Reefs," is the title of a memoir by Mr. J. C. Branner (*Bull. Mus. Comp. Zool. Harvard Coll.*, vol. xliv., geological series, vol. vii.). These stone reefs form striking features along the Brazilian coast from near Ceará to Porto Seguro; they are formed of sandstone, in places almost a quartzite, and stand flush with the water at high tide, while at low tide they are left exposed like long, low, flat-topped walls. The ports and towns behind these reefs owe their existence to them, as they form natural breakwaters, usually standing across the mouths of streams and estuaries.

In origin they are due to the solidification of beach sands. Coral reefs are now growing over and upon the stone reefs in some places, while at other places there are stone reefs overlying dead coral reefs.

Evidences of great depression and subsequent elevation occurred in late geologic times, and the sandstone reefs were formed when the land had finally risen. The author points out that in a region of concentrated rainfall and long droughts the river mouths had become temporarily closed, and the abundant aquatic and other life in the lagoons thus formed contributed to the organic acids of the waters. These waters, upon penetrating the dam of beach sand, first dissolved the carbonate of lime in it, and re-deposited this as cement when in contact with the dense sea-water on the ocean side. In this manner some portions of the beaches have been hardened, while others have remained incoherent.

In an able article on the modes of occurrence of intrusive rocks, Mr. J. G. Goodchild discusses the question whether they displace or replace the rocks which they invade (*Proc. Roy. Soc. Edin.*, xxv., No. 3). He cites and figures

numerous examples which support his views that in the main the process has been one of replacement, the intrusive rock eating its way into sedimentary rock which remains undisturbed above and below, and shows no sign of having increased the thickness of the strata. In certain cases where there is evidence of some displacement or mechanical rupture in the rocks affected by igneous intrusions, he finds that the extent of the displacement is, as a rule, by no means commensurate with the volume of the rock intruded. The subject was dealt with many years ago in an article on the Whin Sill by Mr. C. T. Clough, and that author, in referring to the fact that the dolerite maintained a uniform composition, although it replaced beds of diverse mineral constitution, pointed out that these difficulties disappeared when we regarded the molten rock as having a general circulation in its mass which would lead to a uniformity in its composition. Other observers, mentioned by Mr. Goodchild, have dealt with this interesting subject, but it has not before been so forcibly presented by an array of facts to which the author has himself largely contributed.

Figures of some notable crinoids are given in the quarterly issue of the *Smithsonian Miscellaneous Collections* (vol. xlv., June 15). These illustrate some notes made by Mr. Charles Schuchert, assistant curator of stratigraphic palæontology in the National Museum at Washington, who spent four months in Europe studying fossil faunas and their stratigraphic sequence in the field and in museums. He returned with "sixteen boxes of European fossils," which, as observed, will form "a good nucleus for comparative studies with the American faunas."

Prof. R. S. Tarr has directed attention to a series of artesian well borings which have been carried through the lacustrine delta deposits on which the main portion of the City of Ithaca, New York, is built. The superficial strata comprise clays 40 to 60 feet thick, beneath which are sands and gravels 20 to 70 feet, then glacial lake clays about 100 feet, and at base (resting on the bedrock) a morainic series of till, sand and gravel, 80 feet or more in thickness. The greatest thickness of drift was 342 feet. Artesian water was met with in both series of gravels—that in the upper series being derived from the alluvial fans opposite the mouths of the streams that descend to the Ithaca delta. The water found in the deeper sands and gravels is believed to be derived from the moraine which occupies the Cayuga Valley, distant more than eleven miles from the sites of the wells, and at a sufficient elevation to account for a yield under pressure at one well of 300,000 gallons of water a day.

In an article on the hanging valleys in the Finger Lake region of central New York (*Amer. Geol.*, May), Prof. R. S. Tarr gives reasons for his conviction that the glacial erosion theory cannot be accepted as proved in reference to that area. The land having attained a condition of topographic maturity, represented by the hanging valleys and by the gentle slopes of the main walls above the 800-foot contour, was subjected to rejuvenation. The effects of the elevation were to increase the amount of stream erosion along the main valleys, and although a moderate amount of glacial erosion is allowed, it is not regarded as the main factor in the production of the features.

The 1902–3 eruptions of Mont Pelée, Martinique, and the Soufrière, St. Vincent, form the subject of a report by Mr. E. O. Hovey (*Comptes rendus* ix. *Congrès geol. internat. de Vienne*, 1903). This report is based on data obtained for the American Museum of Natural History, and gives almost exclusively the result of the personal observations of the author. These have been given from time to time in NATURE, especially with reference to the great "spine" which appeared on Mont Pelée. The history of the volcanoes has in the present publication been brought down to the date of printing, February 1, 1904.

To the *Proceedings* of the Geologists' Association (vol. xviii. part vii.), Miss Ethel G. Skeat contributes an article on the Jurassic rocks of east Greenland, wherein the occurrence of Rhætic-Lias and Lower Middle and Upper Oolitic fossils is noted. The finding of such definite Upper Oolitic forms as *Astarte Saemanni* and *Aucella Pallasi* is of much interest. Mr. C. D. Sherborn has prepared a useful index to the four papers on zones of the white chalk of the English coast by Dr. A. W. Rowe and himself, and this is published in the above mentioned *Proceedings*.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Mr. J. Henderson Smith, Balliol College, has been elected first Philip Walker student for three years. The studentship was only founded during the past year, and is for the furtherance of original research in pathology.

The long vacation course of lectures which has been arranged by the Oxford School of Geography was opened on Tuesday last by Mr. H. J. Mackinder, the reader in geography, who delivered an address. During the present week lectures are to be given by Mr. Mackinder on "Leading Ideas of European Geography," by Mr. J. L. Myres on "The Physical Conditions of Greek Civilisation," and by the Rev. E. C. Spicer on "The Structure of the Oxford Region." Next week the lecturers will be Mr. C. R. Beazley, who will take as his subject "The Advance of Geography—Land Travel, Oceanic Exploration and Scientific Geography," and Prof. W. W. Watts, F.R.S., who will speak on "Charnwood Forest as a Study in the Origin of Landscapes."

MISS M. STOKES, PH.D., has been appointed to a demonstratorship in botany at the University of Manchester.

DR. G. SENTER has been appointed lecturer in chemistry at the St. Mary's Hospital Medical School, Paddington.

THE University of London will be represented at the International Congress of Medicine, to be held at Lisbon in April, 1906, by Sir Thomas Barlow, K.C.V.O., M.D., and Dr. A. D. Waller, F.R.S.

A RESEARCH studentship of 100*l.* a year for two years is offered by the London School of Economics and Political Science. The examination will be held on October 11 and 12. Full particulars may be obtained on application to the director of the school, Clare Market, London, W.C.

WE have received a copy of the *Johns Hopkins University Circular* for July, which contains the programme of the courses of study for 1904–5. Next session's work will be the twenty-ninth year of instruction at this university in Baltimore, and the provision made for every class of student is remarkably complete.

PROF. W. E. DALBY has been appointed professor of civil and mechanical engineering at the Central Technical College, South Kensington, in the place of Prof. W. C. Unwin, F.R.S., resigned. Prof. Dalby has hitherto occupied the chair of mechanical engineering and applied mathematics at the City and Guilds Technical College, Finsbury. Applications for the filling of the latter post are invited.

THE Senate of the University of London has accepted the offer made by the Goldsmiths' Company to provide an additional sum of 5000*l.* in connection with the recent gift to the university of the Goldsmiths' Institute at New Cross. This further donation of the Goldsmiths' Company will enable the university to carry on during 1904–5 at the New Cross Institute the classes of a polytechnic character which have proved very popular and useful in previous sessions. The classes to be held next winter will be arranged by the Senate in consultation with the London County Council.

THE Senate of the University of London has decided that in future internal and external candidates for the Bachelor of Science honours degree in botany, chemistry, physics, physiology and zoology must produce note-books of their laboratory work, which may include a record of any research work in which they have participated. The entries in such note-books must be duly certified by the teacher if any, and will be taken into account in estimating the qualifications of candidates, provided only that the research work be not allowed to take the place of such sound general knowledge as should be required from an honours candidate.

THE Senate of the University of London and the council of University College have now agreed on the text of the Bill for the incorporation of the college in the university. The sum required before the formal transfer can actually be effected has not yet been received in full, about 18,000*l.* being still required, but steps are to be taken to deposit the Bill with the view of its introduction next session. The Drapers' Company has announced that, being satisfied with the conditions under which the incorporation is to be effected, it is prepared to pay off the debt on the college land and buildings to the extent of 30,000*l.*, on condition

that both university and college continue to use their best endeavours to raise the balance of the sum required.

THE formation of a separate day department at the Northampton Institute, Clerkenwell, dealing with technical optics has already been referred to in these columns. We have now received full particulars as to the courses of work arranged for the coming session. The chief object of the instruction provided will be so to train the students that they will be in a position on leaving the institute to deal with the numerous problems which all who aspire to take the higher positions in the optical trades must be prepared to solve. The full course as at present contemplated extends over two years, and consists of lectures, laboratory and drawing-office work, and workshop practice. To meet the case of those who cannot devote their whole time to the training, and are already engaged in some optical trade, partial courses requiring attendance on two mornings per week only, but extending over three years, will be given, covering generally the work of the first year of the complete course, but omitting those portions with which such students will be familiar. Practical optical design will be a special feature of the advanced classes.

IN his report under part ii. of the Education Act, 1902, upon the provision and promotion of higher education in Worcestershire, Dr. Rawson, the director of education, directs attention to the fact that there is not in the county for the education of which he is responsible a single technical institution which has any day work for students over sixteen years of age. Because of the impossibility of utilising existing institutions for day technical instruction, which should be their chief use, they are to be turned to account as secondary schools. After explaining that to rejoice because a technical institute is available for a secondary school is really to be glad that an expensive building cannot do the work for which it was built and equipped, Dr. Rawson goes on to show that there is another contributing cause to the lack of technical and higher education. It cannot be denied, he says, that employers of labour are within their rights in taking their "hands" at the age which suits the employer best; clearly, however, the retention of the young workman by the employer all day prevents most completely any day work at the technical school from being possible for such employee. It would be an unmixed blessing for the country, and an unqualified boon to master and man, if day technical instruction could be vouchsafed to the best of the young workmen in the employ of each firm. Many employers in England are now carrying out in their own works these innovations. Reports like this one of Dr. Rawson, giving as they do a bird's-eye view of the existing provisions for education of every grade in each part of the country, are most valuable, and will serve to make clear what deficiencies must at once be made good.

THE regulations for evening schools, technical institutions, and schools of art and art classes have now been published by the Board of Education. The regulations make provision for the promotion of higher technical education of suitable organisation and equipment. We are glad to notice that the board recognises the great advantage accruing from the concentration of interest which is possible only when the student can make study his single aim and devote his whole time to education. The board regards it as of special importance that, by the development of day teaching in technical institutions, there should be no lack of facilities for the instruction of those who, by private means or with the assistance of bursaries given by local education authorities, are able either to prolong their studies beyond the usual school age, or to return to study after a period of apprenticeship or of wage-earning experience. The value of evening classes at the present stage of development of English education is, however, not lost sight of, and regulations are laid down intended to ensure that local education authorities shall make the instruction in such classes suitable for the special needs of a given neighbourhood. The necessity of correlating the component parts of a student's instruction with a view to increase their educational value and practical utility is insisted upon, and it is prescribed that no student may be admitted to any course who is not sufficiently prepared to benefit by the instruction given in that course. The new regulations represent in their main features an amalgamation and simplification of the diverse regulations under which the schools and classes concerned have been administered in the past.

AT the annual distribution of scholarships and prizes at the Royal Indian Engineering College, Coopers Hill, on July 27, Sir William White, president of the Institution of Civil Engineers, delivered an address. Referring to the recent decision to close the college, he said they had now to accept the decision and to express the hope that the good work of Coopers Hill would continue to bear fruit. It is to be hoped that the features of the college, which have been proved to be good, will be in some way or other perpetuated, and that the connection of British engineering institutions with India and its great public works will in the future be quite as close as in the past. He believed that the energy and skill of engineers in the Indian Empire had been one of the greatest forces for consolidating the advance of British dominion, for improving the condition of the people, and for developing the resources of that great continent. After contrasting the condition of India at the present time with its state at the time of the Mutiny, Sir William said that the radical change which has taken place was largely owing to the triumphs of the engineer. We are only yet on the fringe of discovery in the matter of the resources of India. Its mines, its forests, and its other resources are waiting for the work of the engineer for proper development. On those in authority in this country who have the conduct of Indian affairs must depend how that development shall progress, and what shall be the future of the Indian Empire as affected by engineering and British financial enterprise. There must be huge demands for skilled engineers in India, and now that Coopers Hill will cease to be the chief source of supply of engineers for India, we must be sure that some other source of as fully trained and competent men will be provided to ensure that the resources of India do not want for development.

NATURAL HISTORY OF THE MALDIVES AND LACCADIVES.

The Fauna and Geography of the Maldive and Laccadive Archipelagoes. Edited by J. S. Gardiner. Vol. i., parts ii. to iv.; vol. ii., parts i. to iii. (Cambridge: C. J. Clay and Sons, 1902–4.)

As the general scope and character of this important work were referred to at some length in a notice of the first part which appeared in NATURE for April 3, 1902 (vol. lxv. p. 514), it will suffice on the present occasion to confine attention to some of the more generally interesting of the numerous memoirs contained in the parts now before us. By generally interesting, we mean reports which deal more especially with questions connected with morphology, development, the limitations of species, reef-formation, &c., rather than those devoted to systematic zoology, and it is on these grounds that we pass over papers like those by Messrs. Borradaile and Lanchester on crustaceans, and the one by Mr. E. Smith on molluscs (important as they are from their special point of view) in favour of some of those of the former type.

Especial interest concentrates, of course, on the chapters (vol. i., parts ii. and iv.) devoted by the editor to the origin and mode of formation of the two archipelagoes under survey. In the chapters included in part ii., Mr. Gardiner, when stating his general views on this part of the subject, definitely and unhesitatingly rejects the theory that the two archipelagoes can have been formed by the subsidence of a large central island, the topography of the central deep plateau being, in his opinion, unfavourable to such a view. On the contrary, he maintains the former existence of continuous land over the area, which was planed down by the action of currents to an almost flat plateau at a depth of about 160 fathoms, and that on this plateau the different banks originated independently by the slow growth of deep-sea corals, assisted in some small degree by nullipores, &c., but completed by the subsequent growth of a superficial reef formed by true corals and nullipores, aided by a general outward extension of the growing reef by current-borne detritus. When the superficial reef approached the surface, it is considered probable that some land was formed by elevation, or by a change in the level of the ocean. Finally, in the individual atolls the lagoon was formed partially by the more rapid growth of the organisms on the edge of the bank, thereby building up an encircling reef, and partially by the subsequent erosion of the central area. The author adduces evidence to show that certain kinds of coral will grow freely at depths of considerably more than 200 fathoms, and he adds that his views with regard to reef and atoll formation hold good for the islands of the Pacific as well as for those of the Laccadive and Maldive Archipelagoes. In the chapter in part iv. details are given of the various atolls, with remarks on apparent recent changes in the archipelagoes and on the death of corals.

Passing on to the purely zoological reports, we may notice that in dealing with the Chætognatha (Sagitta and its allies), Mr. Doncaster comments on the unstable character of the species in this group, several of which seem to graduate into others. Most remarkable is the fact that such species do not appear to be separated either geographically or in habit, closely allied forms living in the same locality under similar conditions. Consequently, it is difficult to believe that they can have been differentiated by natural selection. In his notice of the echinoderms, Prof. F. J. Bell corroborates previous observations as to the loss of the upper surface of the disc in many feather-stars (ophiurids), and further points out that if gonads are set free by the loss of this disc, and a new disc and new gonads are subsequently formed, the question of germ-plasm may be regarded as answered.

Another group which has yielded results of special interest is that of the alcyonarian polyps, the collection made by Mr. Gardiner's expedition serving to show, according to Prof. Hickson, the untrustworthy character of species formed on the evidence of single specimens. The large series of examples now for the first time available demonstrates the variation in form, colour, and other features of what appears to be one and the same specific type when collected over a large area. If, for instance, a specimen of organ-pipe coral (Tubipora) were collected in Celebes and a second in the Maldives, there is little doubt that they would be regarded as representing two distinct species, but a walk at low tide along a Maldive reef would reveal the existence of a number of intermediate types connecting the two supposed species by imperceptible gradations. These organisms, in fact, exhibit a number of "facies," which have not local limitations.

"If each facies," observes Prof. Hickson, "represents a species, then we have the remarkable phenomenon of a number of closely related species distributed over a wide area and competing in the struggle for existence, with approximately equal success, in many localities of this area. If, on the other hand, all the facies represent but one species, then we have a species capable of extraordinary variation in circumstances apparently identical."

Without recourse to cross-breeding, it is impossible to demonstrate which of the two propositions is true, and the only practical course is therefore to regard as species all the unconnected types.

The species question is resumed in the chapters on madreporiform corals (vol. ii. part iii.), where Mr. Gardiner remarks that he has found much less difficulty in finding the limitations of species among the Astreidæ than was experienced by Mr. Bernard in the case of the perforate group. The puzzle will, he thinks, in both cases be solved by definitely ascertaining which variations are discontinuous and which continuous. Here occasion is taken to notice the favourable conditions presented by corals for the study of variation, owing to the fact that the larvæ have no choice in their environment. Unless there be real action on the part of the local environment in producing discontinuous variation in the gametes of new immigrants, it will be obvious that the species must remain approximately constant.

Another report demanding special notice is the one by Mr. R. C. Punnett on the Enteropneusta, the collection brought together by Mr. Gardiner being the most extensive hitherto made in any one locality. This richness has enabled Mr. Punnett to attempt the study of the variation (that is to say, the development of local forms) displayed by certain members of the group, this having never been previously practicable. In addition to the description of new species of Ptychodera and Balanoglossus, the author takes the opportunity of describing a new generic type from Zanzibar, for which the name *Willeyia bisulcata* is proposed, characterised by its large size and the great length of the proboscis and collar. After discussing many debatable structural features connected with these curious organisms, Mr. Punnett takes occasion to express his opinion of the importance of Willey's theory as to the origin of gill-clefts, which he believes to obtain further support from the evidence of this group. To recapitulate the author's views in detail would occupy too much space, and it can only be mentioned that the gonads are suggested as being the prime factors in the segmentation of the Chordata, each gonad having ultimately acquired an independent aperture of escape from the body, which became subsequently used for respiration, and thus a gill-cleft.

If we pass over the accounts of the Chordata by Messrs. Cooper and Punnett, it is only from lack of that space necessary to do anything like justice to one of the most important biological and physiographical works of our time. To conclude without expressing our opinion as to the business-like manner and thoroughness with which both the expedition itself and the examination and description of the specimens and the codifying of the general results have been carried out (so far as they are yet published) would, however, be alike ungracious and unappreciative.

R. L.

JOHN PARKINSON'S "PARADISUS."

Paradisi in Sole Paradisus terrestris. By John Parkinson. Faithfully reprinted from the edition of 1629. Pp. l+612. (London: Methuen and Co., 1904.) Price *2l. 2s.* net.

THIS is a handsome reprint of a notable book, which, even in its original form, never made so brave a show as does this facsimile, with its fine type, excellent paper, rough edges, and grey paper boards. The page illustrations suffer somewhat in sharpness, owing to the process by which they have been reproduced, in comparison with the cuts in the older editions, which were worked from the blocks themselves. It is a genuine reprint; with the exception of a half-title and the title-page set out above, the old herbalist's book is left to tell its own tale. We are glad to be spared the modern editor's introduction, which in this instance would have been an infliction.

John Parkinson, King's Herbalist, was born in 1567, and with John Gerard occupies a special position in our literature as one of our herbalists. Gerard's "Herball" was based upon Continental work, and very few cuts were due to him; Parkinson's books were his own, woodcuts and text alike. Gerard's "Herball" was edited and much improved by Thomas Johnson in 1633, and was reprinted in 1636; Parkinson's "Paradisus," which came out in 1629, when the author had passed his sixtieth birthday, was reprinted in 1656, six years after his death, practically unaltered. He regarded the "Paradisus" as constituting three parts of a comprehensive treatise on plants—the garden of pleasant flowers, the kitchen garden, and the orchard. Eleven years later, the fourth part, his "Theatrum," appeared, devoted chiefly to medical plants, but in bulk much exceeding his previous publication.

We have before us copies of all the issues; the original issue of 1629, with its thin, foxed paper and striking woodcuts, and its reprints. Parenthetically it may be remarked that these blocks, measuring ten inches by six, do not appear to be built up, as boxwood blocks, but were cut along the grain, and consisted of pear-wood. The actual blocks are not extant, but judging from woodcuts of the same century we are justified in assuming that Parkinson's illustrations were produced as we have said. The old authors were economical of their blocks; Dodoens, Clusius, and their contemporaries were apt to square off their plants to fit the block, or to twist the plant to come within the limits available. Here we find many specimens displayed on the same block, sometimes ingeniously arranged in a give-and-take manner. No book gives a better idea of the gardens of the time, with their plans and plants, than the volume before us; the author starts with general principles of laying out or "ordering" his garden, and then goes on to describe what should grow in it—hardy flowers nearly all, but the variety of tulips, iris, narcissus, and similar plants strikes a modern reader. Many little touches of human personality shine through the accounts given; old colleagues and benefactors by whom certain bulbs or seeds were introduced are mentioned; some of those named may be found in the works of other authors, and we greet them as old friends; some of them appear in connection with their favourite flowers, as "John Tradescant his great Rose Daffodill," or "Mr. Wilmer's great double Daffodill." It is largely due to the revived love for hardy garden flowers, especially the narcissus, that Parkinson's book has of recent years become almost impossible to get, the price having risen from shillings to nearly as many pounds within one generation.

The second issue varied from the first by having a printed title-page in front of the engraved one, and although it boasted of being "much Corrected and Enlarged," many of the printer's errors noted in the first were not corrected in the second edition; the pages are not precisely the same, nor are the tables at the end, and the only noticeable enlargement is the letterpress title-page just mentioned.

The third issue is that now under review, but the publishers seem to have failed to notice the pun in the title, which at length runs thus:—

"Paradisi in Sole Paradisus Terrestris. Or a Garden of all sorts of pleasant flowers which our English ayre will permitt to be noursed upp: with A

Kitchen garden of all manner of herbes, rootes, and fruites, for meate or sause used with us, and An Orchard of all sorte of fruit-bearing Trees and shrubbes fit for our Land together With the right orderinge, planting and preserving of them and their uses and virtues. Collected by John Parkinson, Apothecary of London, 1629." It will be observed that the first five words mean "of Park-in-Sun the Earthly Paradise," and this play upon his own name is missed in the special title of the reprint.

It is impossible even to indicate the charm of this old book; a long notice would still be inadequate, while to those who love old garden flowers and these quaint notices of them, this reprint will afford a new delight.

B. D. J.

MODERN ELECTRIC PRACTICE.

Modern Electric Practice. Edited by Magnus Maclean. In six volumes. Vol. i., pp. viii+270. Vol. ii., pp. vi+297. Vol. iii., pp. vi+285. (London: The Gresham Publishing Co., 1904.) Price 9*s*. net per volume.

THESE volumes have been published with the intention of providing a comprehensive treatise on the subject of modern electrical engineering, a subject now so large and so diversified that it is beyond the power of one man, however expert, to deal with it in all its aspects. The plan has therefore been adopted of inviting the collaboration of a number of authors, each writing of that section with which he is particularly conversant, and thus producing a sort of encyclopædia of electrical engineering which might be compared with such books as Watts's "Dictionary of Chemistry." It is difficult to form an estimate of the value of a book of this kind, which depends as much upon the skill and discretion which are shown in the selection and arrangement of the material as upon the merits possessed by the individual contributions.

Regarded as a whole we consider this compilation disappointing in the extreme. A really standard work of reference on electrical engineering would be a very welcome addition to electrical literature, a book to which a man could turn for information about any matter which happened to crop up in the course of his work, certain of finding a thorough *résumé* of the subject sufficient to give him the outlines of existing knowledge and to put him on the track of more detailed information if he required it. The volumes before us unfortunately cannot claim any such position; indeed, as a work of general reference they are almost useless. A series of text-books by different writers on different subjects does not make a comprehensive treatise because these text-books are bound between the same covers and "not sold separately." No serious effort seems to have been made to coordinate the material properly, and, in fact, almost the only attempt at uniformity which can be discovered is in the direction of print and paper. A single quotation from the preface is enough in itself to support this contention; the editor there says, "rises of temperature are given sometimes in degrees Fahrenheit and sometimes in degrees Centigrade; dimensions of machines occasionally in feet and inches but more often in centimetres; magnetic flux density in lines per square inch in one article, and in lines per square centimetre in another." We can see no way in which to regard this paragraph other than as a confession of careless editing, as we should have thought the very first thing the editor would do would be to adopt a uniform system of units and notation throughout. Other instances of more serious carelessness might be quoted, but we will content ourselves by giving one example. In the three volumes already published we have come across two tables giving the relative conductivities and temperature coefficients of various substances; in one the values of the resistivities are given, in the other the relative conductivities. A very cursory examination shows that the two tables do not agree, and if they are compared more carefully we get results of which the following are specimens (the conductivity of iron being taken as the standard for comparing the two tables):—

Relative conductivity of	iron	Table I.	16·2	Table II. 16·2
,, ,,	copper	,,	97·5	,, 90 & 92
,, ,,	mercury	,,	1·65	,, 1·56
,, ,,	platinum	,,	19·0	,, 13·4
,, ,,	aluminium	,,	52	,, 55

The agreement between the temperature coefficients is equally bad. We have purposely only compared above the figures for elementary substances, as those for alloys such as German silver, manganin, &c., which are in even worse disagreement, are valueless in one table as the percentage composition is not given. Comment on figures of this sort is needless.

Enough has probably been said to show that as a standard treatise on electrical engineering the value of these volumes is little or nothing. This is the more to be regretted as they have been produced in a style which may be described as lavish, and several of the contributors are in the front ranks of the profession, able to write with an authority on their particular subjects which cannot be called in question. It would not have required very much more trouble and care to have converted the publication into a first-class addition to the electrical engineer's library instead of leaving it as a book only to be valued on account of the occasional articles of exceptional merit which it contains. Space would not permit us to review these in detail here even were it profitable to do so. Suffice it to say that there are several contributions which thoroughly deserve to be read, some because of the admirable way in which they treat their subject-matter, and others because, in addition, they are practically the only existing English text-books on the subject. On the whole, however, we think the level is not very high, especially if scientific treatment be looked for; there is a general tendency for too much description, too much of an account of what the practical engineer has made, and too little of the theoretical principles on which his practice is based. It is evident, of course, that the book does not aim at discussing the theoretical side of electricity and magnetism, but even "modern practice" must be studied, if it is to be properly studied, with a certain

amount of theory as a basis, and a book which does not supply, in each branch, the necessary minimum hardly deserves to claim the title of a "comprehensive treatise." MAURICE SOLOMON.

PIONEER IRRIGATION.

Pioneer Irrigation for Farmers in the Colonies. By E. O. Mawson, M.Inst.C.E. With Chapters on Light Railways, by E. R. Calthrop, M.Inst.C.E. Pp. xvi+260. (London: Crosby Lockwood and Son, 1904.)

THE preface states that "this book has been written with the object of supplying pioneer farmers, in arid countries, with information which may assist them in conserving the precarious rainfall, and utilising it for the irrigation of crops"; also that "only the most homely contrivances, such as can be constructed and worked without professional advice or skilled labour are suggested"; and that the object "throughout the volume has been to demonstrate, in the simplest possible manner, how the available water-supply—whether surface-flow or underground—can be used for irrigating crops by means of works easily constructed at a small expenditure, without fear of danger in case of failure." The book, however, is not in reality confined within these prescribed limits; for it refers to earthen dams, with puddle trench, waste weir, and outlet valve tower, masonry dams of moderate height for forming reservoirs in gorges, a masonry aqueduct of several spans, and a barrage or weir across an apparently wide river, closed along the upper portion by a series of automatic sluice-gates. The works, indeed, shown in some of the woodcuts, and especially on plates 3 to 8, 10, and 19, could not possibly be regarded as homely contrivances, capable of being easily carried out by pioneer farmers, without skilled labour, at a small cost, and without danger to the neighbourhood in the event of failure.

The chapters on the value of irrigation and sources of water-supply, underground waters, methods of irrigation, and the cultivation of irrigated crops, vegetables, and fruit trees, contain much information which would be very useful to persons engaged in the cultivation of arid districts; but most of the works described in the chapters on dams and weirs, canals, sewage irrigation, and automatic sluice-gates, would be wholly beyond the resources of pioneer farmers. The storage of rainfall, the collection of the run-off of water in the rainy season by open tanks formed in depressions enclosed by low banks, and the drawing of underground waters from wells, are works which can be readily undertaken with great benefit by cultivators of arid lands; but the formation of large reservoirs by damming up valleys, and the raising of the water level of rivers and the conveyance of the water considerable distances in irrigation canals, constitute works which have to be carried out by a company, the local authorities, or the Government, for the irrigation of large tracts of land. Sewage irrigation, moreover, can only be made use of in the neighbourhood of large communities, and is not available amongst the sparse population of a newly-settled agricultural district.

In a chapter on automatic sluice-gates, a system of hinged gates or shutters is advocated for raising the water level of reservoirs and rivers, which has apparently been patented by one of the authors; but it is not stated that the design has been put into operation; and such automatic contrivances, as in the case of the movable shutter weirs employed long ago for the canalisation of some rivers in France, are liable to be very irregular in their action. The two concluding chapters furnish some interesting particulars about light railways, which are introduced with the view that the conveyance of the produce of irrigated lands to a market is second only in importance to the supply of water. Such works, however, with the great advantages that they afford, have to be carried out in the midst of a thriving community, where both capital and revenue are available; and they are beyond the scope of pioneer farmers who are extending cultivation into new, unoccupied districts. A long appendix is given at the end of the volume, containing various memoranda, tables, and particulars about materials and tools, which may be of service in irrigation works and farming. The book is, in fact, a short manual on irrigation works in general, with some account of the construction, suitable gauges, and rolling-stock of light railways.

OUR BOOK SHELF.

Lehrbuch der Stereochemie. By A. Werner. Pp. xvi+474. (Jena: Gustav Fischer, 1904.) Price 10 marks.

THIS book had its origin in the courses of lectures on stereochemistry delivered during recent years by Prof. Werner in the University of Zurich. The systematic form of the lectures has been adhered to, but by the addition of numerous tables and many hundreds of references to original sources, the author has produced a comprehensive handbook which must prove of great utility, not only to the general chemist who wishes to know something of the advances made in stereochemistry since the conception was first put forward, but also to the specialist whose work is directly concerned with the subject. Notwithstanding the wealth of detail, the book is of moderate compass, and whilst compression in the theoretical portions is occasionally carried to such an extent as to interfere somewhat with intelligibility, yet the book is on the whole both readable and easily comprehensible. The eminence of the author as an investigator in some of the most obscure fields of stereochemical research is sufficient guarantee of his mastery of both theory and material.

The work is composed of two chief parts, of which the first deals with stereoisomerism, divided into subsections according to the elements involved. The first subsection is naturally devoted to the stereoisomeric carbon compounds, and occupies about half of the whole book. In it are treated, amongst other matters, the theory of the asymmetric carbon atom, mirror-image isomerism, racemism and the resolution of racemic compounds, determination of configuration in open chains (more particularly in the sugars and related substances) and in closed chains, the quantitative relations between rotation and the nature of the asymmetric carbon atom, *cis-trans* isomerism in cyclic compounds, and the geometric isomerism of ethylenic compounds. The

succeeding subsection deals with the stereoisomeric carbon-nitrogen compounds, such as the oximes, and is followed by a subsection on the substances that owe their stereoisomerism to the configuration of nitrogen atoms. The first part closes with an account of the optically active sulphur, selenium, and tin compounds, and of the geometric isomerism exhibited by the cobalt and platinum compounds with ammonia and the organic bases.

The second part of the work is concerned with stereochemistry unaccompanied by stereoisomerism, under which head are treated such matters as the stability of carbocyclic and heterocyclic chains, the stereochemical formulæ of benzene, and the influence of space-arrangement on the speed or possibility of chemical reactions, *e.g.* esterisation, formation of amides from esters, formation of triphenylmethane dyes, reduction of nitro-groups. Perhaps this part of the book will be found as useful as any, for it marshals under one point of view a great array of facts otherwise scattered and difficult of access.

Prof. Werner's book should be in the possession of every organic chemist.

The Fauna of British India, including Ceylon and Burma. Published under the authority of the Secretary of State for India in Council. Edited by W. T. Blanford. Rhynchota, vol. ii., part ii. Heteroptera. By W. L. Distant. Pp. i–iv, xi–xvii, 343–503; figs. 168–319. (London: Taylor and Francis, 1904.) Price 10*s.*

THE first part of vol. ii. of this work was published in December, 1903, and was noticed in NATURE for February 25, 1904, and we have not had long to wait for the second part, completing the volume, the preface of which bears date April, 1904. The total number of species described in the second part is 511, bringing up the total number of species described in the first two volumes of the work to 1471. The second part of vol. ii. completes the great family Reduviidæ (subfamilies Acanthaspidinæ to Nabidinæ), which is fam. 12 of Mr. Distant's arrangement. The volume also includes the families Saldidæ, Ceratocombidæ, Cimicidæ, and Capsidæ. This completes the land bugs, with the exception of the Anthocoridæ. These, with the two last families of the Gymnocerata (Hebridæ and Hydrometridæ), which are aquatic or subaquatic, are left over to be included with the Cryptocerata, all of which are aquatic, in the third volume, which will complete the work so far as the Heteroptera are concerned. The Homoptera will also be commenced in vol. iii.

Other volumes of this series in preparation are to include certain families of Coleoptera (especially those of economic importance), the butterflies, and the land mollusca.

Analytical Chemistry. Vol. ii., *Quantitative Analysis.* By F. P. Treadwell, Ph.D. Translated from the second German edition by William T. Hall, S.B. (New York: Wiley and Sons; London: Chapman and Hall, Ltd., 1904.) Price 17*s.* net.

IT is a little curious that this volume, which appeared in German in 1901, should have reached a second edition before finding an American translator, as one might suppose that its many excellences would have hastened the fate which has overtaken a number of less valuable German treatises.

The author states in the preface that the majority of the methods which he describes have been submitted to careful examination in his own laboratory, a fact clearly evident from the minutiæ which are introduced at every step. This is precisely what gives a work on analytical chemistry a real value. There is an introductory chapter on general manipulation, details, and apparatus, including the use of the Gooch crucible, that ingenious and time-saving combination of filter and crucible which is much too little known and used.

The subsequent chapters deal with gravimetric and volumetric estimations of inorganic materials, including such methods as are specially applicable to certain minerals, ores, and metals, and there is a final chapter on gas analysis.

It should be added that the book is one for reference and is not a graduated course of instruction for students. It is, in fact, an abbreviated Fresenius without the undesirable quality of superficial comprehensiveness which characterises that exasperating classic.

J. B. C.

Arnold's Home and Abroad Readers. Book i. Glimpses of the Homeland. Pp. 135. Book ii. Glimpses of the Globe. Pp. 152. Book iii. England and Wales. Pp. 200. Book iv. The British Dominions. Pp. 232. Book v. The World's Great Powers—Present and Past. Pp. 228. Book vi. The World's Trade and Traders. Pp. 228. (London: Edward Arnold, n.d.) Prices from 10*d.* to 1*s.* 6*d.*

THE aim of the anonymous author of these volumes appears to have been first of all to secure the interested attention of his young readers, and then incidentally to teach them a great deal about the physical features of the countries of the world and of the manners and customs of the peoples of the globe. The readers are skilfully graded, well illustrated with maps and pictures, and excellently printed. The books are likely to be popular in elementary schools.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Chemical Action Produced by Radium.

VARIOUS chemical investigations relating to the chemical action of radium bromide have been in progress in this laboratory during the past session, an account of which will shortly be published.

But one of these investigations has yielded results so extraordinary that we think it well to direct attention to the results. On the Rutherford-Soddy hypothesis of the disintegration of the radium atom, an enormous amount of energy is evolved, and at least one simpler product is formed, namely, helium, which is slowly produced during the disintegration of the emanation, which Mr. Soddy and one of the authors have shown to be a gas, following Boyle's law; and with Dr. Collie the spectrum has been investigated.

It has, of course, often suggested itself that such a change should be reversible; that is, that by imparting a sufficient charge of energy to any atom, it should be transformed into different matter, probably by the building up of a more complex structure. Now the only known source of energy in such a concentrated form is that which is given off by radium and its products during their disintegration. The facts which we have to chronicle appear to point towards such a synthesis.

During experiments on the emanation, about 105 milligrams of radium bromide, dissolved in water, were kept in small glass bulbs, connected to a pump. To protect the bulbs against accident, each was surrounded with a small beaker, one of potash-glass and two of soda-glass. The former was coloured brown in the course of some six months, the latter violet. On altering the apparatus these beakers were discarded.

They were all found to be radio-active on both surfaces,

and, what is most remarkable, *the radio-activity was removed by washing with water*. The solution contains an emanation, for on bubbling air through it, and cooling the gas with liquid air, the issuing gaseous air is only feebly active; the main part of the activity was retained in the cooled bulb. This substance can be carried into an electroscope by a current of air, and when the current passes, the electroscope is discharged; but the period of decay of the emanation is very short, and in that respect resembles the emanation from actinium.

The research is not sufficiently advanced to permit of a complete account of the other products, but it may be mentioned that from the solution which has lost all emanating power further active products are obtainable, some of which are precipitable along with mercurous chloride, some along with mercuric sulphide, some with ferric oxide, and some with barium sulphate. The behaviour is different, according as potash- or soda-glass is used. That this is not a case of a body being thrown down by *any* precipitant has been abundantly proved; for example, precipitation along with mercurous chloride or sulphide failed to remove the activity from one sample, while the precipitation of ferric hydroxide in the solution completely threw down the radio-active material. There appear to be several radio-active bodies present which can be separated by the ordinary processes of qualitative analysis.

These substances, it must be remembered, are the products of β and γ rays in conjunction with the material on which they impinge. A silver crucible, too, becomes radio-active on the exposed surface only when placed in the path of β rays. It is important to note that these changes are not due to the material having been in contact with radium or any of its products; they are solely due to the β and possibly to the γ rays. The order of the activity is the same as that of 1 milligram of old uranium oxide, U_3O_8.

Atomic Structure in the Light of Secondary Spectra.

IN making some determinations of the capacity necessary just to produce secondary spectra, I have found that this critical capacity increases very rapidly with decreasing wave-length. The primary spectrum does not go over suddenly as the critical capacity is reached, but the red and yellow portions go over first, then finally, at a much greater capacity, the violet. Critical capacity as a function of wave-length is well represented by the exponential $\epsilon^{\frac{6}{\lambda-\lambda}}$, approaching a constant value in the infra-red and the value infinity in the ultra-violet, perhaps not farther out than $250\mu\mu$.

Consider the radiation from a nitrogen atom. When subjected to feeble electrical excitation its (primary) spectrum is banded, each band being composed of numerous lines not showing the Zeeman effect. But when subjected to excessive excitation, as it is when a large condenser is connected in shunt with the conducting gas, its (secondary) spectrum consists of numerous heavy lines, showing the Zeeman effect, and expressible in Kayser-Runge series.

Runge, having in mind the Zeeman effect, supposes that primary spectra are due to positive ions while negative electrons give secondary spectra, but it is hardly conceivable that feeble excitation should all go to the positive ions while more intense excitation all goes to the negative.

I would suggest that an atom composed of rotating rings of electrons according to recent theories might easily exhibit just such radiating properties as would give primary and secondary spectra, together with the variation of critical capacity with wave-length. Suppose that there are as many rings as there are bands in the primary spectrum. With moderate excitation these rings would vibrate radially and tangentially as well as perpendicularly to their planes, and these vibrations would give rise to the lines comprising each band. Such lines would not show the Zeeman effect. Excessive excitation would break up the rings and allow the electrons to move independently. Radiation from such free electrons would constitute the secondary spectrum, and would show the full Zeeman effect. The larger rings would be the first to break up; the smallest rings, perhaps, could not be broken up at all, hence critical capacity would vary with the wave-length and become infinite for moderately short waves. Metallic atoms have ring systems that are so easily broken up that it is impossible to obtain any primary spectrum from them at all.

Washington, D.C. P. G. NUTTING.

The Flowering of the Bamboo.

CAN your botanical readers give me any information about the flowering of the bamboo? Until recently I was not aware that it presented any extraordinary features, but about the middle of April the bamboo in this locality produced flowers, to the great astonishment of everyone long resident here. The peasants, and many of the more ignorant townspeople, regarded the event with much superstitious terror. It is supposed by them to portend a failure of the crops, and possibly even more serious disasters. A small anti-tax rising, some distance away, appeared for a few days to be a serious matter, and as it was in progress during the time at which the bamboo flowers appeared, many were inclined to exaggerate enormously the danger of the situation. These superstitious terrors (closely resembling the fears formerly aroused in Europe on the appearance of a large comet) sufficiently show the rarity of the phenomenon.

On making inquiry, I could only hear of one man (I did not myself meet him) who had ever seen the bamboo in flower before.

I am told that a species of bamboo in southern California flowers annually, the flower being at the top of the plant only. In the species growing here the flowers were at all heights, arranged at frequent intervals along almost every branch of the plants. I obtained a photograph of a spray in flower, but unfortunately it is so small that the distinction between leaves and inflorescences is very imperfect.

A. TINGLE.

Imperial Provincial College, Chinanfu, Shantung, China, May.

As regards the point raised by your correspondent, I may say that the feeling of alarm aroused in the natives by the flowering of the bamboo seems to be widely spread in the East. I have myself heard of it when in India.

The fact is that the bamboo only flowers once and then dies, and as a rule the whole lot of plants, often covering large areas, bloom together.

The reason of this is that the individuals of a species are commonly gregarious, and are all of the same age, having taken simultaneous possession of ground rendered vacant, perhaps, by a previous and similar depopulation.

A somewhat analogous case is presented by some of the Strobilanths of tropical Asia. These plants live for about seven years, then all burst out into a glorious mass of blue flower, and then die away, leaving, it may be, hundreds of acres of ground destitute of the luxuriant vegetation it previously supported.

Dr. O. Stapf, in a most interesting article that appeared in the *Gardener's Chronicle* this year (Nos. 907–910), gives an account of the introduction into Europe of two bamboos that have suffered a similar fate.

In 1847 seeds of *Arundinaria Falconeri* (and another species) were received at Kew, and were thence distributed to various gardens, some finding their way to the Continent. The plants flowered (and then died) in France in 1875, and in the following year all the English plants, growing in different localities, shared the same fate.

Claremont House, Wimbledon Common, August 2.

The Organisation of Zoologists.

MAY I be allowed to direct the attention of the readers of NATURE to the fact that a meeting of zoologists will be held in the comparative anatomy lecture room at Cambridge on Wednesday, August 17, at 4 p.m., to consider a scheme for organisation suggested by the committee that was appointed in London on January 4. The suggested scheme has been printed and widely circulated, but as it may have failed to reach some of the zoologists of the country, I have been requested to state that all who are interested in zoology and anxious to promote its progress will be welcome.

SYDNEY J. HICKSON.

The Victoria University, Manchester, August 3.

THE BRITISH SCIENCE GUILD.

An organisation is being formed, under the name of the British Science Guild, with the object of insisting upon the importance of applying scientific methods to every branch of the affairs of the nation. A memorandum which describes briefly the objects, methods, and proposed organisation of the Guild is now being circulated, and is as follows:—

It has been a frequent subject of comment that, although the contribution of this country to the progress of science has been second to that of no other nation, the English people do not manifest that interest in, and belief in the powers of science which is noticeable among the peoples of the Continent, or of America. In spite of the efforts of many years, the scientific spirit, essential to all true progress, is still too rare, and, indeed, is often sadly lacking in some of those who are responsible for the proper conduct of many of the nation's activities. It is with the view of attempting to remedy this evil, and to bring home to all classes the necessity of applying scientific treatment to affairs of all kinds, that the proposal is made to bring together those convinced of this necessity by founding "The British Science Guild."

The objects and organisation of the Guild, which will be entirely disconnected from party politics, are as follows:—

Objects.

(1) To bring together as members of the Guild all those throughout the Empire interested in science and scientific method, in order, by joint action, to convince the people, by means of publications and meetings, of the necessity of applying the methods of science to all branches of human endeavour, and thus to further the progress and increase the welfare of the Empire.

(2) To bring before the Government the scientific aspects of all matters affecting the national welfare.

(3) To promote and extend the application of scientific principles to industrial and general purposes.

(4) To promote scientific education by encouraging the support of universities and other institutions where the bounds of science are extended, or where new applications of science are devised.

Methods of Attaining these Objects.

(*a*) By publications.
(*b*) By meetings.
(*c*) By conferences and lectures.
(*d*) By deputations.

Organisation.

Admission of Members.

All British subjects, both men and women, are eligible for membership of the Guild; it is expected, however, that its members will be recruited principally from the following:—

The House of Lords.
The House of Commons.
Colonial Legislatures.
County, District, Borough, and Parish Councils; Municipalities; Educational Committees.
Scientific and Literary Societies and Organisations.
Commercial and Industrial Chambers and Organisations.
The Learned Professions.
Universities, Colleges, Educational Bodies and Graduates of all British Universities.
Representatives of Labour.

At a meeting of the promoters of the Guild, held, by permission of the officers, at the rooms of the Royal Society on April 20, it was decided that the steps preliminary to the formation of the Guild should be taken by an organising committee, of which the following were appointed members, with power to add to their number:

Lord Avebury, F.R.S.
Prof. W. E. Ayrton, F.R.S.
Sir George Sydenham Clarke, K.C.M.G., F.R.S.
Captain E. W. Creak, R.N., C.B., F.R.S.
Mr. Clive Cuthbertson.
Dr. William Garnett.
Mr. Sidney Lee.
Sir Norman Lockyer, K.C.B., F.R.S.
Lady Lockyer.
Mr. N. Maccoll.
Prof. Raphael Meldola, F.R.S.
Sir Gilbert Parker, M.P.
Prof. J. Perry, F.R.S.
Sir William Ramsay, K.C.B., F.R.S.
Dr. W. N. Shaw, F.R.S.
Prof. S. P. Thompson, F.R.S.
Dr. Augustus Waller, F.R.S.
Sir Henry Trueman Wood.

The organising committee has elected Sir Norman Lockyer president, Lord Avebury honorary treasurer, Lady Lockyer honorary assistant treasurer, and Mr. C. Cuthbertson honorary secretary.

It was resolved that life members of the Guild shall pay, on admission, two guineas, which includes a registration fee of 2*s.* 6*d.*, and that annual subscribers shall pay, on admission, 5*s.*, and in each subsequent year 2*s.* 6*d.* It was also resolved that donations may be accepted.

The committee is now engaged in communicating with those corporate bodies and individuals whose support and sympathy are desired.

A general committee will be appointed, which will subsequently select from among its members an executive committee for the management of the affairs of the Guild. The executive committee will meet from time to time as their chairman may direct, and will formulate such rules as experience may suggest for the approval of the general committee.

The general committee will probably take power to appoint or approve local and special committees, which will act as branches of the Guild.

The following have already signified their general approval of the objects and proposed organisation of the Guild:—

The Right Hon. Lord Alverstone, G.C.M.G.
The Right Hon. Lord Avebury, F.R.S.
Prof. Ayrton, F.R.S.
Sir John Wolfe-Barry, K.C.B., F.R.S.
Dr. W. T. Blanford, F.R.S.
Sir James Blyth, Bart.
Mr. Brabrook, C.B.
Sir George Birdwood, K.C.I.E.
Sir John Brunner, Bart.
Sir Lauder Brunton, F.R.S.
Major-General Sir Owen Tudor Burne, G.C.I.E.
Sir Edward Busk.
Mr. R. H. Caird.
Sir William Church, Bart., K.C.B.
Sir George Sydenham Clarke, K.C.M.G., F.R.S.
The Hon. Sir John Cockburn, K.C.M.G.
Captain Creak, R.N., C.B., F.R.S.
Mr. Clive Cuthbertson.
Prof. W. E. Dalby.
Dr. Ferrier, F.R.S.
Sir Michael Foster, M.P., F.R.S.
Dr. William Garnett.
Sir Archibald Geikie, F.R.S.
Sir Robert Giffen, K.C.B., F.R.S.
Mr. Hammond-Chambers, K.C.
Prof. Herdman, F.R.S.
Prof. J. Larmor, F.R.S.
Dr. Sidney Lee.

SIR NORMAN LOCKYER, K.C.B., F.R.S.
LADY LOCKYER.
DR. LOCKYER.
MR. MACCOLL.
PROF. R. MELDOLA, F.R.S.
SIR A. NOBLE, BART., K.C.B., F.R.S.
SIR GILBERT PARKER, M.P.
PROF. PERRY, F.R.S.
SIR WILLIAM RAMSAY, K.C.B., F.R.S.
THE LORD REAY, G.C.S.I.
SIR WEMYSS REID.
SIR WILLIAM RICHMOND, K.C.B., R.A.
MR. E. ROBERTSON, M.P.
SIR HENRY ROSCOE, F.R.S.
SIR A. RÜCKER, F.R.S.
DR. W. N. SHAW, F.R.S.
MR. ALEX SIEMENS.
THE LORD STRATHCONA AND MOUNT ROYAL.
SIR L. ALMA TADEMA, R.A.
PROF. SILVANUS P. THOMPSON, F.R.S
DR. A. D. WALLER, F.R.S.
FIELD MARSHAL VISCOUNT WOLSELEY, G.C.B.
SIR HENRY TRUEMAN WOOD.

NEW REGULATIONS OF THE BOARD OF EDUCATION.

NO system of national education is complete which fails to recognise the essential importance of the work of the satisfactory secondary school. Its importance, that is, both as providing a means by which the exceptionally well endowed boys and girls of the elementary schools may continue their education under better conditions, and also as affording an adequate preparation for those pupils who later will become technical students and university undergraduates, or who will without further instruction enter upon the active duties of life. The recent Education Act gave an official recognition to what has long been urged by those who understand our educational needs, that true education from beginning to end is an organic whole. The duty has, in fact, been laid upon the Board of Education of superintending and promoting the supply by local education authorities of education other than elementary. The Board is now the final court of appeal in all matters pertaining to the administration of secondary education.

It is considerations such as these which lead us to regard the regulations [1] recently issued by the Board of Education for the government and administration of English secondary education as one of the most important of the educational documents of recent years. For, since the Board is in a position to reward by substantial grants a due adherence to the regulations here formulated, it is clear that the principles advocated officially will, whether they are right or wrong, exercise a profound influence upon the curriculum and ideals of the schools.

Such being the case, it is gratifying to find that on the whole the regulations are framed on broad and liberal lines, though, as we shall have occasion to indicate, there are dangers which it is imperative those in authority should avoid, and indications that the claim of instruction in scientific method to a place in every stage of education may be disregarded if certain phrases in the regulations are followed too literally.

It will serve to give a clearer idea of the influence the regulations are likely to exert if an attempt is made first to review some of the definitions put forward in the official publication. A secondary school is described as

"any Day or Boarding School which offers to each of its scholars, up to and beyond the age of sixteen, a general education, physical, mental and moral, given through a complete graded course of instruction of wider scope and more advanced degree than that given in Elementary Schools."

[1] "Regulations for Secondary Schools (from August 1, 1904, to July 31, 1905)." [Cd. 2128.] Price 2*d*.

Explaining what should be the characteristics of a secondary school course of instruction, the prefatory memorandum to the regulations states that it should be general, complete, and graded in its various branches. The explanation as to the precise meaning to be attached to the description "general" deserves—both because of its fairness and catholicity—to be quoted in full:—

"The instruction must be general; *i.e.* must be such as gives a reasonable degree of exercise and development to the whole of the faculties, and does not confine this development to a particular channel, whether that of pure and applied Science, or literary and linguistic study, or of that kind of acquirement which is directed simply at fitting a boy or girl to enter business in a subordinate capacity with some previous knowledge of what he or she will be set to do. A Secondary School should keep in view the development and exercise of all the faculties involved in all these different kinds of training, and will fail to give a sound general education to its scholars in so far as it sends them out, whether to further study or to the business of life, with one or other of these faculties neglected, or with one developed at the expense of the rest. Specialisation in any of these directions should only begin after the general education has been carried to a point at which the habit of exercising all these faculties has been formed and a certain solid basis for life has been laid in acquaintance with the structure and laws of the physical world, in the accurate use of thought and language, and in practical ability to begin dealing with affairs."

Secondary education such as is outlined in this paragraph will meet with the approval of every man of science. Education conducted on scientific lines is that which gives a "reasonable degree of exercise and development to the whole of the faculties." If the Board takes care that in interpreting its regulations in the schools the inspectors strive to secure this all-round, healthy mental development of English boys and girls, the hearty cooperation and sympathy of men of science may be depended upon. For to ensure the exercise and development of all the faculties, a training in experimental science is necessary, just as a course in literary and linguistic studies is essential. As the quotation shows, the Board of Education is aware that for a complete education many studies are required, each with its own object and special work. It is important to bear in mind also that the main groups of studies cooperating for the complete education of the child are of equal importance. Just as the study of literature and language can promote the growth of and strengthen some faculties to which practical studies are unable to appeal, so a training in experimental science is the best and only means of ensuring the healthy unfolding of other sides of the human brain. The classical scholar ignorant of the laws and phenomena of nature is an uneducated man, just as is a man of science who has no knowledge of the literature of his own and other countries.

This view of true education is admirably set forth in the statement prepared by the president of the British Association, and revised by a committee including the deputy Vice-Chancellor of the University of Oxford, the Vice-Chancellor of the University of Cambridge, and representatives of the modern English universities, for presentation to the Prime Minister by the recent deputation which waited upon him with reference to increased State aid for university education.

"The men upon whom the nation must chiefly depend for aid under the complex conditions of the modern world must not be entirely untrained in the study of the nature and causes of the things which surround them, or of the

forces which have to be utilised in our daily life; their training and education in humanities must also have been of the widest.

"Such men cannot be produced either by a university which neglects science or by a technical college which neglects the humanities.

"Hence the universities must be enabled to combine these two sides of a complete education, and they must also be enabled to foster research along both lines, for research is the highest and most important instrument of education, as well as its most valuable result."

And what is true of higher education is true also of secondary education upon which it rests.

It is desirable thus to recapitulate these important truths in view of section viii. of the memorandum. This paragraph is likely to lead to misapprehension and to create doubts in the minds of some men of science as to how much of the declaration of faith quoted with approval above is to be regarded as more than the mere expression of a pious hope. Section viii. informs us that all types of secondary schools fall into three main classes, and that in respect of the kind of education they offer they may be discriminated roughly as the literary, the scientific, and the commercial types of school. The boys from the literary, or first-grade school—the section goes on to explain—proceed to the university; the boys of the scientific, or second-grade school, are educated to the age of eighteen or nineteen but do not proceed to the university; the boys of the commercial, or third-grade school, leave at sixteen years of age and go into business and commerce, train to become teachers, or proceed into technical and industrial pursuits. The objects of these schools as set forth in this extraordinary paragraph must be placed before the reader:—

"The first of these paying special regard to the development of the higher powers of thought and expression, and that discriminating appreciation of what is best in the thought and art of the world, in other ages and countries as well as in our own, which forms the basis of all human culture; the second, to the training of the intellect towards understanding and applying the laws of the physical universe; and the third, to the equipment of the scholars for practical life in the commercial and industrial community of which they are members."

After studying this section one is led to believe that it has crept in by mistake; it may safely be said to have been written by somebody other than the author of the definition of general secondary education given earlier. Here we detect the old pestilent heresy that culture is the prerogative of the classical man alone, and that "a discriminating appreciation of what is best in the thought and art of the world" is forever impossible to boys from first- and second-grade schools. If the secondary education in all types of school is to give "a reasonable degree of exercise and development to the whole of the faculties," why are not all boys and girls—whether they leave school at sixteen or eighteen—each in their degree cultured?

The future in life allotted in this section to the products of each grade of school is equally preposterous. The paragraph makes it appear as if all the useful work of the world is done by people who leave school at sixteen, and as if all university men spend their lives in indulging their "discriminating appreciation of what is best in the thought and art of the world."

As readers of NATURE at least know, the sorry figure this country has cut recently in the industrial competition of the nations, and in another direction in South Africa, is precisely because of the disposition in times past, on the part of those responsible for English education, to regard "the training of the intellect towards understanding and applying the laws of the physical universe" as the work of some special kind of school instead of being a necessary and important part of every grade of education. It is surely time that it was recognised on all hands that "practical life in the commercial and industrial community" needs and deserves as good and careful an education on the part of those who pursue it as any other sphere of human activity. But, as we have said, this maladroit section viii. is an incongruity so far as the regulations as a whole are concerned, and we trust the inspectors may be instructed to ignore it.

To turn to the question of the grants to be awarded to secondary schools recognised as efficient by the Board of Education. As the sum is limited which Parliament at present places at the disposal of the Board for grants in aid of education other than elementary, the grants payable under the new regulations are to be made in respect of a four years' course only. The average age of the scholars in any class commencing the course must not be less than twelve years. The earlier education leading up to this course, and the further education, if any, given beyond it, are to be regarded as forming together with it a single organic and progressive system. Subject to certain conditions, a grant will be paid on account of each scholar attending the approved course in accordance with the new regulations on the following scale:—in the first year of the course, 40*s.*; in the second, 60*s.*; in the third, 80*s.*; and in the fourth, 100*s.*

The definition of rational secondary education occurring in the prefatory memorandum is not the only guide given to schoolmasters as to the subjects which must be taught to boys taking the grant-earning course between the ages of twelve and sixteen years. In section iv. of chapter i. the subjects of the course are enumerated. We find:—

"The course should provide for instruction in the English language and literature, at least one language other than English, geography, history, mathematics, science and drawing, with due provision for manual work and physical exercises, and, in a girls' school, for housewifery. Not less than $4\frac{1}{2}$ hours per week must be allotted to English, geography, and history; not less than $3\frac{1}{2}$ hours to the language where only one is taken or less than 6 hours where two are taken; and not less than $7\frac{1}{2}$ hours to science and mathematics, of which at least three must be for science. The instruction in science must be both theoretical and practical. Where two languages other than English are taken, and Latin is not one of them, the Board will require to be satisfied that the omission of Latin is for the advantage of the school."

Most practical schoolmasters, and men of science too if they are acquainted with the actual conditions of school work, will admit that we have outlined in these sections a rational curriculum which, in the hands of properly trained teachers, will lead to good results. We are sorry, however, to find the distinction made between theoretical and practical instruction in science; it would be better to insist simply that the time allotted to science should be devoted to experimental science. It is difficult to understand, also, why in enumerating, in section ii., the subjects of the curriculum for a course of work preparatory to that of the grant-earning years, no mention is made of science, since modern practice has demonstrated that useful preliminary work in science may be begun in the lowest forms of a secondary school.

But however admirable the regulations drawn up for the government of a secondary school, and however logical and complete the statement as to its curriculum, the success of its work in educating its pupils depends finally upon the masters to whom its work is entrusted. If these men have themselves received a broad education and have been trained for their duties along scientific lines, the boys proceeding from the school will leave it properly equipped to occupy the station to which they will be called. The training of teachers

for any and every kind of school is, in fact, the most difficult and far-reaching of all the tasks which fall to the lot of educational administrators. A second publication of the Board of Education[1] published last month assumes in consequence especial importance, and will be consulted throughout the country with the greatest interest. It is true its instructions and rules apply at present only to the preparation for their career received by teachers destined to rule in elementary schools, but it is useful as indicating the subjects which in the opinion of the Board of Education should engage the attention of the prospective teacher. Moreover, the general principles which apply to the training of teachers for elementary schools are in a large measure applicable to the professional training of their secondary school colleagues. The new regulations for the training of teachers may surely then be taken as indicating what, in the opinion of the Board of Education, should be regarded as of vital importance in any scheme for the professional preparation of every grade of teacher.

It is consequently satisfactory to find that the place of greatest prominence in the group of studies which is to engage the attention of the budding schoolmaster is given to a training in scientific method. To quote the regulations:—

"Much of the instruction which is given in all subjects must necessarily be founded upon the statements and the experience of other persons; but every education which deserves to be called complete must include some training of the student in those systematic methods of enquiry which are necessary for any assured advance in knowledge, and which are the most truly educative of all mental processes.

"If this scientific spirit is to find its right expression in the teaching given in elementary schools it must be made to imbue the whole study of the intending teacher during his course in the Training College. It must not be confined to any one branch of the curriculum. It is true that, partly as the result of tradition and partly from other reasons, the term 'scientific method' has come to be associated more particularly with the study of natural phenomena. But as a matter of fact, scientific method is of equal importance, and is indeed of ancient application, in the field of history, literature, language and philosophy; and wherever knowledge of these has made advance, it may be discerned that the essential processes of scientific enquiry have been employed."

The specific references to the kind of instruction in science which the Board intends to encourage are deserving of even higher commendation, and if these wishes are carried into effect in the colleges in the case of each and every student in training, it will not be many years before a distinct improvement will be noticed in the teaching given in elementary schools. To refer to the regulations again:—

"But in addition to all this, and particularly in view of the courses which have for many years existed in most of the Training Colleges, a certain special regard must be given to this aspect of instruction and training, in the case of the Natural Science portions of the curriculum. It is in this branch of study that the student can in some ways learn most effectively to depend in some measure upon his own powers, and discover that he need not take everything unverified and on trust upon the statement of text books or lecturers. For by wisely planned and supervised laboratory work the student may be brought into immediate touch with the facts of nature, and learn to find some things out for himself, and to form conclusions upon the results of his own observations. For these reasons the student's work in science should be so arranged that his experiments in the laboratory will precede and lead up to such generalisations in the formal lectures as can safely be established upon what the student has himself observed."

[1] "Regulations for the Training of Teachers and for the Examination of Students in Training Colleges." [Cd. 2134.] Price 4*d*.

It seems to us that the Board of Education has shown a generous appreciation of the value of scientific studies both in the professional training of teachers and in the work of the secondary school. We are promised exactly that for which men of science have frequently and consistently pleaded in these columns. It only remains now to look for the loyal cooperation of school governors and headmasters, and the reproach as to the absurdly bookish nature of English education will soon become merely a matter of history. We earnestly hope that the inspectors and other interpreters of the regulations will be inspired by the same spirit which prompted the framer of most of the sections of the prefatory memoranda to these official publications.

PHYSICAL DETERIORATION.[1]

ELEVEN months ago the large percentage of rejections for physical causes of recruits for the Army led to the appointment of this committee. The members were the clerk of the council, the inspector of physical training, and the principal assistant secretary to the Board of Education, inspectors of reformatory and industrial schools and of marine recruiting, the assistant secretary of the Scotch Education Department, a representative of the General Registry Office, and a secretary.

The committee was directed "(1) to determine, with the aid of such counsel as the medical profession are able to give, the steps that should be taken to furnish the Government and the nation at large with periodical *data* for an accurate comparative estimate of the health and physique of the people; (2) to indicate generally the causes of such physical deterioration as does exist in certain classes; and (3) to point out the means by which it can be most effectually diminished."

This committee, composed of members of high critical faculty, has been able to focus much of the knowledge of sanitary and social science of the past generation as presented to them by wisely selected witnesses, and has evidently produced an epoch-making report.

A few items from this panorama of lives of women and children of the poorest classes may be quoted as samples of the thoroughness of this report.

While bad physique practically centres round feeding, great care has been exercised in proposing the remedies for underfed children at school, and the report states:—"Education is a great social need which individual citizens are, as a rule, not able to provide for their children on a sufficient scale, but food like clothing and lodging is a personal necessity, which in a well ordered society it is not inherently impossible for parents to provide, and the effort to supplement their deficiencies and to correct the effects of their neglect should aim in the first instance at the restoration of self-respect and enforcement of parental duty."

In the course of a full memorandum by the principal lady inspector of factories referring to employment of mothers in factories and workshops, we read:—"It is impossible, however, not to be impressed by the universal preference amongst the women for factory over domestic life. I was continually being told how greatly they preferred their work in the factory to the minding of children, and how depressed and out of health they became if they were obliged to remain at home. Surprising as this appears at first, it becomes less so on consideration. At thirteen years of age the majority of these women would have begun to work in a factory, to handle their own earnings,

[1] Report of the Inter-departmental Committee on Physical Deterioration. (Eyre and Spottiswoode, 1904.) Price 1*s*. 2*d*.

to mix with a large number of people with all the excitement and gossip of factory life. They would thus in most cases grow up entirely ignorant of everything pertaining to domesticity. After marriage, therefore, it is hardly probable that they would willingly relinquish this life to undertake work of which they are in so large a measure ignorant, and which is robbed of all that is to them pleasant and exciting. Until as girls they have been taught to find a pleasure in domestic life, and until there is a greater supply of healthy and suitable recreations and amusements in the reach of all women, to counteract the prevailing squalor and gloom of these pottery towns, it is useless to expect them to relinquish factory life."

Under the heading of alcohol, its devitalising effects are duly noted, and finally attention is directed to their steady decrease owing to wise legislation in Norway and Sweden. "The reverse of the picture presented by France is complete, seeing that besides a diminution in crimes, suicides and deaths from alcoholism and syphilitic diseases, the percentage of conscripts refused has been steadily reduced, showing an elevation in the standard constitution of the people. Thus in Sweden the consumption of spirits containing 50 per cent. of alcohol in 1830 was 46 litres, and in 1890, 6 litres per head. The percentage of rejection of conscripts in 1845 was 34.46, and in 1885, 19.61."

The evidence generally is of a cogent character, and has led to many recommendations for the common weal such as seem to be at present opportune. These are summarised under no less than fifty-three headings, which fill eight pages of the Blue-book.

We may quote in full two recommendations which are made with emphasis:—

"The Committee are emphatic in recommending the creation of an Advisory Council, representing the Departments of State, within whose province questions touching the physical well-being of the people fall, with the addition of members nominated by the medical corporations and others, whose duty it should be, not only to receive and apply the information derived from the Anthropometric Survey and the Register of Sickness, but also to advise the Government on all legislative and administrative points concerning public health in respect of which State interference might be expedient; and to them might be remitted for consideration and report all the problems affecting public health which the requirements of a complex social organisation are constantly bringing to the front. Such a Council, the composition of which might be modelled to some extent on *Le Comité Consultatif d'hygiène publique de France*, would be, the Committee believe, of great assistance, especially to the Local Government Board, and would be calculated to supply the knowledge and stimulus which are necessary in order to give to the Public Health side of the Board's administration a prominence which the multiplicity of its other functions may have tended to obscure, and to attract to its work that measure of public interest and support which has perhaps been lacking hitherto."

"The Committee are emphatic in recommending that a systematised medical inspection of children at school should be imposed as a public duty on every school authority, and they agree with the Royal Commission on Physical Training (Scotland) that a contribution towards the cost should be made out of the Parliamentary Vote. With the assistance of teachers properly trained in the various branches of hygiene, the system could be so far based on their observations and records that no large and expensive medical staff would be necessary. The lines on which the inspection should be conducted are laid down in paragraphs 323-326 of the Report."

Many other recommendations like these make provision to inform the authorities; such are:—register of owners of houses; local sanitary authority to report its action or inaction to Local Government Board; Local Government Board to inform all local authorities what the law and the powers it confers are as to insanitary and overcrowded house property; infant mortality rates to be published for particular areas and for particular industries.

Educational effort is recommended with regard to:—alcoholism; rural opportunities at rural schools; food and cookery; cookery, hygiene, and domestic economy; infant feeding; training of mothers; health associations.

Games, exercises, and physical education form the subject of several recommendations.

Existing legal powers should be employed for:—the enforcement of a standard and drastic dealing with overcrowding in certain of the worst districts; smoke pollution; the remedying of the dearth of country cottages; the precautions to procure the purity of milk supply.

New powers, apparently, are called for in regard to:—labour colonies and public nurseries; smoke pollution from dwelling houses; medical inspection of factories, coal mines, workshops; provision of a grate suitable for cooking in every dwelling let for the occupation of a family; prohibiting the sale of tobacco to children below a certain age.

Upon several points the committee ask for further inquiry to be carried out—over-fatigue in women; sterilisation and refrigeration of milk; and some special subjects.

In conclusion, "the committee hope that the facts and opinions they have collected will have some effect in allaying the apprehensions of those who, as it appears on insufficient grounds, have made up their minds that progressive deterioration is to be found among the people generally. At any rate the committee believe that their labours will result in giving matter for reflection to those who realise the importance of evidence towards the determination of issues of such uncertainty and complexity, and that these persons, who they would fain hope are the larger portion of the thinking community, will await the necessary steps being taken to secure that body of well sifted and accurate information, without which it is impossible to arrive at any conclusion of value as to the general problem.

"It may be argued that there is here no immediate remedy, and that years must elapse before the lack of knowledge is supplied; but in regard to those evils the existence of which is admitted, the committee have recognised what can be done in the interval, and are confident that if their recommendations are adopted a considerable distance will have been traversed towards an amendment of the conditions they have described.

"In the carrying out of their recommendations for the rectification of acknowledged evils, the committee do not rely upon any large measure of legislative assistance; the law may with advantage be altered and elaborated in certain respects, but the pathway to improvement lies in another direction. Complacent optimism and administrative indifference must be attacked and overcome, and a large-hearted sentiment of public interest take the place of timorous counsels and sectional prejudice."

The workmanship shown in the elaboration of this report is stimulating. The recommendations bid fair to inaugurate great social amendment. They appeal to the public as much as to our legislators, and afford to all a view of many fields for doing one's duty to one's neighbour, for encouraging good local government, and for raising the standard of citizenship.

THE ESSENTIAL AUSTRALIAN.[1]

IT is not too much to say that the publication in 1899 of "The Native Tribes of Central Australia" marked an epoch in anthropological research. A lengthy residence amongst savages, who still lived in their original isolation, uncontaminated by European influences, resulted in a remarkable study of a scientific accuracy and completeness hitherto unknown. The authors, both competent ethnologists, the one a distinguished biologist, the other a protector of aborigines, were fortunate in their subject, which proved to be the most interesting section of that most interesting of all primitive peoples, the Australian race. Peculiarities of organisation and belief were revealed which threw new light on many old questions, and reversed many an old theory. In the present work Messrs. Spencer and Gillen supply a sequel to the earlier volume, completing their study of the tribes of the centre by an account of those occupying the country between the Macdonnell Ranges and the Gulf of Carpentaria. The main result is to show a fundamental agreement in important characters between all the central tribes, and the authors repeat their previous conclusion that "the central tribes which for long ages have been shielded by their geographical isolation from external influences, have retained the most primitive form of customs and beliefs." The main features of the Arunta and Urabunna tribes are recapitulated, and we are thus enabled to study comparatively the whole series. Several points in the earlier work are cleared up, and some answer to objections is given by the way. As before, the photographs are excellent and numerous. The new volume possesses the same unique character and value which were conspicuous in "The Native Tribes."

The new types of aborigines present a high average of physical development, but strike one as being less prepossessing in aspect than the Arunta. There are none of the faces which in the other book reminded one of English bishops and fellows of the Royal Society. We are struck by the great number of dialects, each of which has varieties, a fact which must have rendered the task of the investigators very difficult, were it not the case that every blackfellow is, like Ennius, the master of two languages besides his own. As before, the authors point out many fallacies in popular works. For instance, "nothing could be further from the truth" than the notion that "the various tribes were in a state of constant hostility." Again, "there is no such thing as the acquisition of fresh territory"; the blackfellow holds "not only that his country is his by inheritance, but that it would be of no use to anyone else, nor would any other people's country be any use to him." There are no chiefs or head-men; the old men constitute an informal council, which punishes crime, chiefly "bone-giving" and the breaking of marriage-laws, organises the ceremonies, and from time to time inaugurates sound reforms. There is no haranguing of the meeting, which in its etiquette and procedure is the replica of an English committee. "As to the capture of women," the authors state, "we have never in any of these central tribes met with any such thing. . . . What looks like a capture to the casual observer is in reality an elopement, in which the woman is an aiding and abetting party." A good instance this of the necessity of trained and sympathetic inquiry, going far to indicate that many of the old and still accepted theories of primitive culture may be founded on the sands of ignorant and prejudiced mal-observation.

A valuable feature of this, as of the previous work, is the way in which the daily life of the native is visualised for the reader, and in this connection there are two facts which receive especial emphasis. Before initiation, which takes place about the age of fourteen, the boy is free; after this ceremony his life is regulated for him, and is sharply divided into two spheres, the ordinary daily round of food-getting and corroborees, and "what gradually becomes of greater and greater importance to him, the portion of his life devoted to matters of a sacred or secret nature. As he grows older he takes an increasing share in these, until finally

FIG. 1.—Ceremony of Alkira-Kiuma Arunta tribe. Throwing the novice up into the air.

this side of his life occupies by far the greater part of his thoughts. The sacred ceremonies which appear very trivial matters to the white man, are most serious matters to him." They are connected with the Great Ancestors of the Alcheringa, "the dream-time," and he believes that his spirit will after death be in communion with them. "It is astonishing how large a part of a native's life is occupied with the performance of these ceremonies, the enacting of which extends sometimes over the whole of two or three months, during which time one or more will be performed daily." In one tribe there is the unique case of a ceremony performed to promote the physical and mental development of the boys and girls. Sometimes a man will, in a similar fashion, induce his bride-elect to grow, or a father will assist the development of his unborn child. In the second place, the food-supply is organised on a most effective system by the cooperation of the totemic groups. "If I am a kangaroo man, then I provide kangaroo flesh for emu men, and in return I expect them to

[1] "The Northern Tribes of Central Australia." By Baldwin Spencer, M.A., F.R.S., sometime Fellow of Lincoln College, Oxford, Professor of Biology in the University of Melbourne, and F. J. Gillen, Special Magistrate and Sub-Protector of Aborigines, South Australia. Pp. xxv+784; 2 plates, map, 315 figures. (London: Macmillan and Co., Ltd., 1904.) Price 21s. net.

provide me with a supply of emu flesh and eggs, and so on right through all of the totems. . . . It is the duty of every one to supply certain other older people with food, and this they do cheerfully and ungrudgingly. In this way and in accordance with the needs and conditions of the community, these savages have long ago settled the question of an old-age pension, or rather they have rendered any such thing quite unnecessary."

The remarkable marriage-systems of the Arunta and Urabunna are repeated with varying gradations right through the central tribes. As to the "group-marriage" of the Urabunna, the authors now state explicitly that the supernumerary husbands and wives are called *Piraungaru*, as amongst the Dieri. The present writer once compared the facts with Mr. Howitt's evidence as to the Dieri custom. The authors repeat with insistence that "individual marriage does not exist either in name or in practice amongst the Urabunna tribe." Again, "this state of affairs has nothing whatever to do with polygamy any more than it has with polyandry," a statement which I confess I do not understand. They add that this group-marriage is not abnormal, because a gradation to individual marriage can be traced among the other tribes; but what we suggest is that group-marriage is abnormal for humanity as a whole. As to the connection of totemism with the bisectional marriage-system, their conclusion for these tribes is important:—"the two systems have become associated together in various ways in different tribes, but are perfectly distinct from one another in origin and significance." The account of relationships is fuller than before. New facts as to the custom of exchanging wives are given, and in particular the account of the elaborate Fire Ceremony of the Warramunga, a typical Saturnalia, proves that one object at least of these primitive "bursts," in which everything is topsy-turvy and goes by opposites, is, as the present writer had suggested, to promote harmony and union, "to make every one good-tempered and kindly disposed."

FIG. 2.—Visit to tree grave at sunrise, a few days after the death of a man, to try and discover some clue to the supposed murderer. Warramunga tribe. The men in the tree are examining the body.

Two remarkable beliefs, which were among the new facts brought to light by the previous work, are found to prevail right through the tribes. These are the belief that each individual is the reincarnation of an ancestor, and the queer notion, difficult to regard as absolute, that the intercourse of the sexes has *nothing to do* with conception. The Urabunna and Warramunga systems necessitate that in each successive reincarnation the spirit-child changes its sex, its totem, and its moiety. There are curious folk-tales, in one of which a man propagates himself by fission, in another by a sort of budding; the hero of another shakes himself, whereupon children emanate from his muscles. We find new "totems," such as darkness, "laughing boy," and "full-grown man," which will give pause to framers of definitions of this very comprehensive term. *Intichiuma* ceremonies are actually performed by the Kaitish to increase the supply of flies and mosquitoes! Further interesting details are given as to those interesting articles, the *Churinga*, or sacred bull-roarers; in one case they are used to effect moral amelioration—to lessen a man's appetite and to make him willing to share his food with others, he is rubbed and prodded violently in the stomach with a heavy stone *churinga*. One incident of the initiation of young men among the Urabunna is a sort of tossing in the blanket—without the blanket; the patient is smacked as he comes down to a chorus of "I will teach you to give me some meat." Everyone here is a worker of magic. Husbands and wives are obtained by its means; the charms of the fair sex are literally "charms." A popular cure for head-ache or stomach-ache is to wear your wife's bonnet or its native equivalent. Among these tribes, as also shown in the earlier work, magic practically takes the place of religion. The Central Australian is a professing atheist; at initiation he learns that "the spirit creature whom up to that time as a boy he has regarded as all powerful is merely a myth, and that such a being does not really exist, and is only an invention of the men to frighten the women and children." In this connection one wonders if the Central Australian really represents a more primitive stage of culture than other savages.

A very full description is given of the tools and implements used by the natives, and of their decorative art. A remarkable application of the latter is to be found in the ground-drawings, showing considerable power of design, which are made for the numerous ceremonies.

If there is any defect in this fine monument of anthropological science, it is perhaps one that is due to its chief merit the objective character of the study; one desiderates further analysis of the psychology of the blackfellow.

Thanks to investigators like Howitt, Fison, Roth, and Spencer and Gillen, we know the Australian of the east and centre better than any savage in the world, and we may hope that our authors will be able, before it is too late, to crown their work, already invaluable, by a study of the western districts, at present a *terra incognita*.

ERNEST CRAWLEY.

THE WIRELESS TELEGRAPHY BILL.

A MEMORANDUM explanatory of the Wireless Telegraphy Bill which was introduced by Lord Stanley, the Postmaster-General, has been issued as a parliamentary paper. We have already referred to the

proposals made in this Bill in our notes columns, but a brief abstract of the memorandum and of the provisions of the Bill may be of interest to readers of NATURE. The paper opens by pointing out that the rapid development of wireless telegraphy which has been and is still going on makes some form of State control practically essential in the interests of the naval and military requirements of the Empire. The United Kingdom stands, in fact, almost alone in not having any such control; in ordinary circumstances the powers of the Postmaster-General do not extend beyond the three-mile maritime limit; although in times of war or emergency the Government can take over the telegraphic business of incorporated companies, this power does not extend to the installations of private individuals. Obviously a private individual, were he maliciously inclined, could cause a great deal of trouble with a wireless telegraphy installation in the neighbourhood of important strategical signalling stations. A certain very limited power of control exists by an arrangement already made with several foreign Powers by which these Powers undertake not to permit the establishment of systems for communication with the United Kingdom except after consultation with the British Government; this safeguard, such as it is, would naturally fail in the event of war. It is especially in the case of war that control becomes of vital importance, and it is necessary to introduce legislation to meet this event.

The points which have to be particularly considered are:—

(1) That there must be means of preventing information being conveyed to the enemy, and of preserving secrecy as to plans and preparations.

(2) That all possibility of outside interference with Government signalling must be removed.

It is therefore desirable for the Government to have in their power (*a*) the control of the transmission of messages; (*b*) the prevention of the establishment of unauthorised stations; and (*c*) the disposition of stations in the most advantageous way so as to obtain the best results in working, free from interference, accidental or intentional.

In addition to these strategic reasons other considerations make Government control of wireless telegraphy desirable, notably, for example, the advantages to be gained by international agreement on the subject, which at present the British Government could not enter into as it has not the power to enforce any agreement which might be made.

On all these grounds it is proposed in the Bill that the Government shall exercise control by granting licences; these shall be granted by the Postmaster-General, but the consent of the Admiralty and the War Office shall be necessary in order that the strategic considerations may be duly regarded. The Board of Trade is to be added as a third party whose consent is necessary; this is done because the progress of wireless telegraphy affects so closely the trade and commerce of the country. The Bill provides penalties for the unlawful establishment or working of a wireless telegraph station. It is also provided that special licences may be granted by the Postmaster-General for experimental purposes. It is understood that the Government proposes to push the Bill through this session if possible, the reason for its wishing to do so being partly that it may have power to act at the next international wireless telegraph conference, which is to be held early in October, probably at Berlin.

M. S.

NOTES.

A STANDING Committee on machinery designs has been appointed by the Admiralty. Prof. A. B. W. Kennedy, F.R.S., is to act as president of the committee; the other members will be Engineer Rear-Admiral J. A. Smith and Mr. J. T. Milton, chief engineer-surveyor to Lloyd's Register.

A REUTER telegram from Vardö, Norway, states that the relief party of the Ziegler North Polar Expedition arrived at that place on August 3 on board the steamer *Frithiof*. In consequence of fog and ice the *Frithiof* had been unable to establish communication with the expedition on board the *America*. A later telegram states that the *Frithiof* left Vardö on Friday last for Franz Josef Land.

A REUTER telegram from Wellington, New Zealand, reports that the heaviest earthquake for many years was experienced at that place at 10.22 on the morning of August 9. Several public buildings were seriously damaged, and many private firms and householders sustained heavy losses. No loss of life is reported. The shock was felt in both islands. A slight earthquake shock was also felt at Lisbon and its vicinity at 11 o'clock on the night of August 8, but no damage was done.

THE death is announced, at the age of fifty-nine years, of Dr. Carl Weigert, director of the Pathological and Anatomical Institute of Senckenberg.

NEWS of the sudden death, on the Continent, of Sir William Mitchell Banks has been received. Sir William Banks was born in 1842. He was educated at Edinburgh Academy and University, became M.D., and took the university thesis medal in 1864, and in 1899 was made honorary LL.D. He acted for a time as demonstrator of anatomy in the University of Glasgow, and settled in Liverpool in 1868 as a consulting and operating surgeon, being particularly distinguished in cancer research. Dr. Banks, who was knighted in 1899, rendered valuable service as one of the founders of the new Royal Infirmary, Liverpool, in the establishment of University College, and in the movement which resulted in the formation of Liverpool University.

MAJOR RONALD ROSS, C.B., F.R.S., and Dr. Weir Mitchell have been elected foreign corresponding members of the Paris Academy of Medicine.

THE Vienna correspondent of the *British Medical Journal* states that a meeting was recently attended by the Senate of the Vienna University to celebrate Prof. v. Vogl's seventieth birthday, and to bid him farewell on his retirement from the position he has so long held in the university. Prof. v. Vogl's successor has not yet been appointed, but he will, it is thought, probably be one of the retiring professor's former assistants.

THE sixty-first annual congress of the British Archæological Association was opened at Bath on Monday last, and will remain in session until Saturday next.

THE arrangements for the annual meeting of the Society of Chemical Industry, which is to take place in New York from September 7 to 12 next, have now been completed. The president, Sir William Ramsay, K.C.B., F.R.S., is to give an address in the gymnasium of the University of Columbia on September 8, and in the evening of that day the annual dinner of the society will be held at the Waldorf-Astoria. A tour has been arranged, to last from Monday, September 12, until Thursday, September 29, with the object

of affording members and guests an opportunity of attending the international congresses in St. Louis during the week beginning Monday, September 19. Among the cities to be visited in the course of the tour are Philadelphia, Washington, Pittsburg, St. Louis, Chicago, Detroit, Buffalo (Niagara Falls), and Boston, the last named to be reached on Thursday, September 29. Ninety-four persons, in addition to those resident in America, have already signified their intention of attending the meetings. Further particulars may be obtained from the general secretary of the society, whose address is Palace Chambers, 9 Bridge Street, Westminster.

ACCORDING to the *Pioneer Mail*, Allahabad, an irrigation conference lasting four days will assemble at Simla on September 5. Some thirty papers on subjects covering a large range of irrigation practice have been promised, and it has been suggested that if time permits the following subjects shall also be discussed:—(1) The most suitable value of "N" in Kutter's formula, for use in designing channels. (2) American practice and the two or three notions described in Mr. Kennedy's recent report, paragraphs 15–18, circulated as technical paper No. 157. (3) Distribution of water by measurement. As a basis for discussion, the remarks of the Irrigation Commission in vol. i., paragraphs 275–290, and Mr. Kennedy's memorandum, published on pp. 59–63 of the appendix, vol. iv. of that report, may be studied. (4) Loss by absorption from channels.

AN International Exposition of Hygiene is about to be held in Paris. The following congresses will take place in connection with it, viz.:—life-saving, from August 25 to 31; public health, from September 10 to 20; fisheries, from October 1 to 10; social economy, from October 11 to 20; hygiene, from October 21 to 31; and tuberculosis at a later date.

A CONGRESS of climatotherapy and urban hygiene has been arranged for at Arcachon, France. It will be held from April 24 to 29, 1905, under the presidency of Prof. Renaud, of Lyons. The general secretary is Dr. Lalesque, of Arcachon. Communications relative to the congress should be addressed to Dr. Festal, Villa David, Arcachon.

ON the initiation of the Austrian Minister of Public Instruction, an International Congress of Botany is to be held in Vienna from June 10 to 18, 1905.

THE *Novoe Vremya* states that the Medical Department of the Caucasus has decided to disinfect all letters and parcels coming from Persia to guard against the spread of cholera from Persia to Russia, and that to assist the work three sanitary bacteriological sections (each consisting of a medical man, a medical woman, assistants and sanitary officers) have been fitted out with bacteriological laboratories, disinfectants and drugs, at the expense of the Discount and Loan Bank of Persia, which is a branch of the Russian Imperial Bank. The work of organising these bodies was carried out by the Institute of Experimental Medicine.

INDIAN papers report that a provincial museum is to be erected at Rangoon, and the proposal has been made that the collections at present in the Phayre Museum shall be handed over to the Government to be deposited in the new museum. It is also proposed that the proceeds of the sale of old materials shall be applied either in adding to the collection or towards the building of a portion of the provincial museum, and that the collection shall either be kept together and be called the Phayre collection, or that the name of Sir Arthur Phayre shall be connected with some part of the new building.

THE sum of 300*l*. recently voted by the New York State Legislature for cooperative hydrographic work with the U.S. Geological Survey will, it is stated in *Science*, be used in maintaining records of the rise and fall, the ordinary outflow, floods and droughts of many streams in the State. The work has gradually grown until there is hardly a section of the State in which some river is not systematically measured, and at the present time the condition of streams in more than fifty places in the State is regularly reported.

IT is stated in the American papers that an aquarium, costing from 600,000*l*. to 800,000*l*., is to be established in San Francisco by Dr. H. Tevis in memory of his late father, Mr. Lloyd Tevis, and that plans for the building are being prepared.

THE County Council of Aberdeen has voted for another year a grant of 200*l*. to enable the Agricultural Research Association of Aberdeen to prosecute its inquiry further into a function of latent plant food in soil.

ANOTHER line of steamers—the Allan—is to have an ocean newspaper published on board its vessels. The company has, it is stated, arranged with the Marconi Company to have the most important news transmitted to its boats crossing the Atlantic, both homeward and outward bound, as soon as they come within effective distance.

THE railway department of the Grand Duchy of Baden has, says *Engineering*, presented to the Museum of Masterpieces of Natural Science and Technics at Munich an interesting collection of drawings and plans from the early days of railways. The collection includes diagrams of the first passenger and goods cars of Baden from the years 1839 to 1841, of carriages of the Nürnberg-Fürth Railway of 1837, of the Taunus Railway of 1841, of the London and Birmingham line, and further detailed diagrams of the cars of the Elberfeld experimental railway of the year 1832.

IN the latter part of 1902 arrangements were made for the establishment of a mineralogical survey in Ceylon, to last for a period of three years, the objects in view being an examination of the occurrence of economic minerals in the island with the view of their further development, and the preparation of a report descriptive of the mineral resources, as well as the arrangement of the geological collections in the museum and the accumulation of further specimens, a duplicate series being reserved for exhibition at the Imperial Institute. The report of the director of the survey for 1903 has just reached us, and tells of much work done during the period under consideration. In 1903 the area examined amounted to 512 square miles, but, as is pointed out, the work of the survey can only partially be judged by area, as in the event of the examination of important economic minerals being necessary a prolonged stay in one area may be required. At the conclusion of his report the director asks for a special grant of 1000 rupees to enable him to procure a collection of gems for the museum, the present collection being poor.

THE nature and importance of the work accomplished by the director of the Royal Botanic Gardens, Ceylon, and his staff may be judged from the report issued for last year, from which it is evident that the scientific staff is kept continuously busy in dealing with numerous inquiries and with the investigation of various horticultural problems. At the principal experiment station, Peradeniya, the treat-

ment of cacao canker has occupied considerable attention, also the value of different manures for tea plantations, and of green manures generally. The branch garden at Nuwara Eliya has been utilised for the purpose of experimenting with grasses and fruit trees upon the patana soil, and a new area of 150 acres has been reserved in the dry zone at Mahailuppalana, where cotton has already been planted, and later the cultivation of rubber and cacao under irrigation will be tried. The Government chemist, Mr. Kelway Bamber, has made an important discovery of a trustworthy test which will determine the amount of adulteration in citronella oil.

It is instructive to have the opinion of a zoologist on the results obtained by Prof. de Vries in his experiments on the production of new plant species. Prof. A. W. Hubrecht has contributed a critical review to the *Popular Science Monthly* for July which is interesting not only because it discusses the essential points of de Vries's theory, but also because the writer takes considerable trouble to show that the mutation theory modifies, but is not opposed to, the views expressed in the "Origin of Species."

In an article contributed to the *Journal of Botany* (July) Mrs. Gepp contrasts the sporangia of *Halimeda gracilis* with those of *Halimeda Tuna*, and describes the methods of communication between the central filaments in the thallus which serve as a basis for a systematic arrangement of the genus. In the same number Canon Lett describes a new hepatic, *Adelanthus dugortiensis*, from Ireland which appears to represent an ancient flora, since it has affinities with a group of hepatics found in hot climates.

An elaborately illustrated "Catalogue of Exhibits of Insect Enemies of Forests and Forest Products" at the Louisiana Exposition has just been issued by the U.S. Department of Agriculture (division of entomology), and will well repay perusal by economic entomologists and all who have to do with forestry operations. The catalogue has two indices, one of scientific and the other of common names.

The issue of the *Proceedings* of the Philadelphia Academy for the latter part of April and May contains several papers of interest. Among them is one by Mr. J. P. Moore on polychætous annelids from California, and a second, by Dr. H. C. Chapman, on the anatomy of the hyrax, in the course of which he raises the question whether the so-called "coney" of the Bible is really the Syrian representative of that group. Of more importance is the article by Mr. A. E. Brown on post-Glacial Nearctic centres of dispersal for reptiles, the title of which has been previously quoted in our columns. The absence in post-Glacial times of a circumpolar reptile fauna renders the retention of a Nearctic and a Palæarctic region convenient when discussing the distribution of this class, although this is no bar to the merging of the two into a Holarctic region for general purposes. Their present distribution points to two post-Glacial centres of dispersal for Nearctic reptiles, one in the south-eastern Austro-riparian, and the other in the Sonoran province, and temperature and humidity have been important factors in regulating such dispersals.

Vol. xl., No. 2, of the *Proceedings* of the American Academy contains an elaborate essay by Mr. G. M. Allen on the heredity of the colour of the coat in domesticated breeds of the common mouse, as illustrative of Mendelian principles. The language now used in studies of this description is so excessively technical that it is almost impossible to give a summary of the author's conclusions which would be intelligible to the ordinary reader. It has been found, however, that complete albinism is a character "recessive" towards pigmentation. The grey of the common mouse (composed of black, chocolate, and yellow) is predominant over the colours of the "fancy" breeds, so that when the latter are crossed with wild mice grey offspring result. Black mice breed true, and the "golden-agutis" also generally do the same, but may give rise to chocolate forms. The predominant grey may be produced synthetically by crossing blacks with golden-agutis, the three pigments of the former being thus brought together. Finally, black, chocolate, and the golden-aguti strains may be produced by a resolution of the original compound grey.

Another short communication to hand this week, from Reichenow's *Ornithol. Monatsberichte* for July and August, contains a continuation of Dr. J. Thienemann's observations on the birds of Rositten, dealing in this instance with the members of the crow family. The author takes the opportunity of thanking all who have assisted him in his investigations, and begs for the continuance of their kind help.

Mr. L. W. Lambe has sent us a short extract from the *Ottawa Naturalist* for 1904 in which he discusses the nature of the squamoso-parietal crest in two species of horned dinosaurs from the Alberta Cretaceous.

We have received a copy of a paper by Mr. G. H. Carpenter on injurious insects and other animals observed in Ireland during 1903, forming No. 12, part v., of the first volume of *Economic Proceedings* of the Royal Dublin Society. As was observed during the preceding year, the grubs of crane-flies (Tipulæ) are the most serious insect enemies against which the Irish farmer has to contend, although the potato-flea-beetle (*Psylliodes affinis*) did some amount of harm.

The contents of the *Entomologist* for June include descriptions of new South American beetles of the genus Chlamys by M. Jacoby, a paper on new African butterflies of the family Lycænidæ by Miss Sharpe, a supplementary list of Lepidoptera from Capri by Mr. C. S. Browne, and the continuation of a paper by Mr. P. Cameron on various new forms of Hymenoptera.

Prof. Simon Newcomb has applied mathematical analysis to an inquiry into the probability of the causes of the production of sex in human offspring. In the entire Semitic race, over the whole of Europe and America, there is a small and uniform preponderance of male over female births. There is thus on the whole a unisexual tendency in the male direction among parents of the Semitic race. In isolated families the unisexual tendency becomes more marked and may be in either direction; in some families the offspring may be either mainly male or mainly female. Among the negro race the preponderance of male over female births is either quite small or non-existent. Prof. Newcomb, analysing the data by the method of probabilities, concludes that the sex is not determined at any one moment or by any one act, but is the product of a series of accidental causes, that the functions of the father have probably little influence, the sex being determined wholly by the mother, and that it seems in the highest degree unlikely that there is any way by which a parent can influence the sex of his or her offspring. The first-born child of any mother is more likely to be a male in the proportion of about 8 to 7, and there is probably a smaller preponderance in the case of

the second child, but there is no conclusive evidence that after a mother has had two children there is any change in her tendencies.

In the *Monthly Review* for August Mr. J. E. S. Moore discusses "the cancer problem to-day," in which he details recent investigations into the cytology of malignant growths; and in the *Fortnightly Review* Dr. Alfred Mumford writes on the alleged physical degeneration of the race. The general trend of this article is that the deterioration in the vigour and health of the British race as a whole has been exaggerated, and that all the combined effort of the past for the permanent improvement of the race cannot have been without result.

At a special meeting of the Academia dei Lincei held on June 5, the results of the competition, which closed on December 31, 1902, for the royal prizes of the academy were made known. In the section of philology, a royal prize is awarded to Prof. A. Trombetti for a work on the genealogical connection between the languages of the ancient world. The prize for astronomy is divided between Prof. E. Millosevitch and Vincenzo Reina, and that for philosophical science between Prof. Sante Ferrari and Prof. Covotti. To celebrate the tercentenary of the academy, which is the oldest institution of its kind in the world, it is announced that Prof. Pirotta is preparing for publication the botanical works of Prince Federico Cesi, who, with Galileo Galilei, founded the Lincei in 1603.

In the *Physikalische Zeitschrift* (No. 15) H. Mache concludes that the emanation from the Gastein thermal spring, which is so strongly radio-active, is identical with that of radium, as the activity of both emanations decays according to the same law. Moreover, the activity induced in other bodies by the emanation from the water is of the same character as that caused under similar conditions by radium. In the same number E. F. Burton shows that the diminution in the conductivity of air enclosed in a metal vessel which is produced by surrounding the vessel with water is proportional to the thickness of the aqueous layer. The view that the radiations causing the discharge come from an external source is thus confirmed. It is also shown that, on diminishing the pressure of air in the vessel surrounded by water, the conductivity falls off continuously with the change of pressure.

In the *Physical Review* for June, E. L. Nichols and Ernest Merritt give an experimental confirmation of Lommel's contradiction of Stokes's law that, in fluorescence, the fluorescent light is always of greater wave-length than the exciting light. The variation in the intensity of the light throughout the fluorescence spectra of such substances as fluorescein, eosin, and naphthalene-red was measured by means of a spectrophotometer, and it is shown that, whatever be the wave-length of the exciting light, the curve connecting intensity of light with wave-length in the fluorescence spectrum is always of the same character. The maximum of intensity in the excited spectrum may have a wave-length much smaller than that of the exciting source. Thus in the case of eosin, with an exciting light of wave-length λ 585–605, the maximum in the fluorescence spectrum is at λ 580, the whole spectrum extending from λ 535 to λ 640.

Part ii. of the *Bulletin* of the French Physical Society for 1904 contains a description by A. Turpain of a new apparatus for cleaning large quantities of mercury. The cleaning agent is a solution of mercurous nitrate, and the mercury, after being cleaned, is dried by means of concentrated sulphuric acid, any free acid in the mercury being subsequently removed by potash. The apparatus works automatically during long periods, and needs little attention.

In the July number of the *American Journal of Science* Mr. H. A. Bumstead describes experiments on atmospheric radio-activity, which indicate that the activity acquired by a negatively charged wire exposed in the open air at New Haven, is of a two-fold character. From the rate of decay it is concluded that thorium as well as radium excited activity is present. With a three-hour exposure of the wire, 3 to 5 per cent. of the initial effect is due to the thorium activity, and with a twelve-hour exposure the thorium activity is sometimes 15 per cent. of the whole. Messrs. Trowbridge and Rollins communicate that the electrical resistance of an aluminium wire is not altered to a measurable extent when subjected to the action of radium.

The *Geographical Journal* for August contains a very clear map showing the work of the National Antarctic Expedition. The map is the work of Lieut. Mulock, R.N., who joined the *Discovery* from the *Morning* in February, 1903. The positions fixed by observations, magnetic variations, soundings, heights, and the tracks of the sledge travellers are clearly shown, as well as the track of the ship to her furthest point along the coast of King Edward VII. Land. An inset map shows the position of the discoveries with reference to the circumpolar area. The same number also contains the paper on "The German Antarctic Expedition" which was read before the Royal Geographical Society in April last by Dr. E. von Drygalski. It is illustrated by some remarkable reproductions of photographs of icebergs, &c.

The current *Century Magazine* contains two contributions which should be of interest to all students of nature, one, by that careful American observer, John Burroughs, on "What do Animals Know?" in the course of which a good deal of out-of-the-way knowledge is given in a charming manner, the other, illustrated by some striking engravings (one in colour), on "The Colossal Bridges of Utah," which deals with the wonderful arches or natural bridges that are to be found near the head of White Cañon, in San Juan County, Utah. One of these bridges, named by the discoverers the Caroline, measures two hundred and eight feet six inches from buttress to buttress across the bottom of the cañon. Its height is one hundred and ninety-seven feet from the surface of the water, while its thickness at its highest point is one hundred and twenty-five feet. The floor of the bridge is one hundred and twenty-seven feet wide, so that, as is pointed out, an army could march over it in columns of companies, and still leave room at the side for a continuous stream of artillery and baggage waggons. Two other magnificent bridges, named respectively the Augusta Bridge and the Little Bridge, are described and figured in the article, which is well worth perusal.

OUR ASTRONOMICAL COLUMN.

Ephemeris for Encke's Comet.—A set of elements for Encke's comet, corrected only for the Jupiter perturbations of the first order between 1901 and 1904, is published by MM. Kaminsky and Ocoulitsch in No. 3962 of the *Astronomische Nachrichten*. These elements are given below, together with an extract from a daily ephemeris for the period August 1 to October 16:—

Epoch and Osculation 1904 *November* 9·0 (*M.T. Berlin*).

$$\left.\begin{aligned} M &= 341^\circ\ 3'\ 39'' \\ \pi &= 159\ \ 2\ \ 39 \\ \Omega &= 334\ 27\ \ 8 \\ i &= 12\ 35\ 37 \end{aligned}\right\} 1904 \cdot 0$$

$$\phi = 57\ 54\ 20$$
$$\mu = 1075''\cdot666$$
$$\log a = 0\cdot34555$$

T = 1905 Jan. 11d. 8·8h. M.T. Berlin.

Ephemeris 0*h*. (*M.T. Berlin*).

THE REVISION OF THE CAPE PHOTOGRAPHIC DURCHMUSTERUNG.—In the third volume of the Cape Durchmusterung Sir David Gill referred to several lists of stars which Prof. Kapteyn had prepared in order that the objects might be re-observed and the origins of the discrepancies between the Cape and other catalogues discovered. The work of revision was commenced by Mr. Finlay, but has been continued, since 1896, by Mr. Innes. Parts i., ii., and iii. of vol. ix. of the Cape Observatory *Annals* contain the results of this revision, giving the observer's full notes and copious remarks concerning each object observed. Mr. Innes believes that not a single uncoloured star of the ninth magnitude or brighter, and south of declination −19°, is now missing from the catalogue.

Many of the questionable objects have been found to be variables or highly coloured, whilst others are fainter than the ninth magnitude. Part ii. is especially devoted to full particulars of each variable star observed at the Cape between 1896 and 1902, the elements, the curve, the region-charts, and all the available information—or references to the same—being given for each of the seventy-three objects observed.

A summary of the number of stars in the C.P.D. exhibits several interesting points. For example, whereas M. Stratonoff found that the B.D. (dec. +90° to −20°) gave a mean of 4·895 stars brighter than the ninth magnitude for every square degree, the corresponding value in the C.P.D. (dec. −19° to −90°) is 5·85. Part of this difference, at least, may, however, be due to a difference of magnitude standards. The total number of stars now contained in the C.P.D. is 91,358, and the richest region is near to η Argus, for in the −59° zone, between 10h. and 11h., there are 256 stars, or 32·7 per square degree, brighter than the ninth magnitude.

Part iii. tabulates, and comments on, the errors found by Prof. Kapteyn—and others discovered since—in other southern star catalogues for the regions south of dec. −19°, and concludes with a table of reference to all the published errata.

DETERMINATION OF LATITUDE AND ITS VARIATIONS.—In No. 3962 of the *Astronomische Nachrichten* M. E. Bijl, of the Royal Belgian Observatory at Uccle, gives the results of 685 determinations of latitude made by him during the period 1898·4–1899·5. The table given shows the time of each observation and the corresponding latitudes as deduced from the star positions given in the Berliner Jahrbuch and Newcomb's catalogue respectively. There is a constantly positive value for the difference Newcomb-B.J. of something of the order of +0″·6. The resulting latitudes show a range of about 0″·7 with a maximum at 1888·6, a minimum at 1889·0, and a lower maximum at 1889·3–1889·4.

THE STANDARDISATION OF ROWLAND'S WAVE-LENGTHS.—In an article appearing in No. 1, vol. xx., of the *Astrophysical Journal*, Prof. Hartmann answers the criticisms which have been passed on the proposals of his previous article, wherein he strongly urged the standardisation of Rowland's wave-lengths to a uniform *relative* scale. It has been urged that Michelson's absolute values should be used for the construction of an *absolute* scale, but Prof. Hartmann points out that the adoption of this idea would necessitate a wholesale revision each time a new estimate of the absolute wave-lengths was made.

In lieu of this he again suggests that the wave-length of the red line in the cadmium spark spectrum in air at +20° C. and 760 mm. pressure be adopted as λ=0438·6911 for all time, and that a coordination of a system of *relative* wave-lengths should be made with this as the standard.

The most urgent need before such a system can be completed is that an observer having the control of a large grating spectrograph shall continue Kayser's work in establishing a system of standard iron lines in the region as yet untouched by that observer. This need supplied, the values obtained by Michelson, Hamy, Fabry and Perot for a number of metals would furnish the connecting links for the completion of the proposed system.

SATURN'S NINTH SATELLITE.—From a note by Prof. E. C. Pickering in No. 3962 of the *Astronomische Nachrichten*, it appears that the position angles and distances of the satellite Phœbe, which were recently published in a Kiel *Circular*, were obtained from an ephemeris corrected to agree with the positions determined from eleven photographs obtained by Prof. Frost at Arequipa. These allowed the path of the satellite to be followed from April 16 to June 9.

DISTRIBUTION OF SUCCESSES AND OF NATURAL ABILITY AMONG THE KINSFOLK OF FELLOWS OF THE ROYAL SOCIETY.

THE result of this inquiry is to prove the existence of a small number of more or less isolated hereditary centres, round which a large part of the total ability of the nation is clustered, with a closeness that rapidly diminishes as the distance of kinship from its centre increases.

The materials are derived from the replies to a circular which I sent with a blank schedule, to all fellows of the Royal Society, asking for the names and achievements of their "noteworthy" kinsfolk in each degree of near kinship as specified in the schedule. Noteworthiness was defined as including any success that was, in the opinion of the sender, at least equal in its way to that in which the honour of a fellowship of the Royal Society is held by scientific men.

Returns are still dropping in, and now exceed two hundred. They continue to be very acceptable, but I judged it best to content myself with the number received up to a date when I could conveniently work at them, and to publish preliminary results without longer delay. The total number of returns received up to the date in question, that contained one or more noteworthy kinsfolk, was 110.

Subjoined are classified lists of the qualifications that were considered by one or other of the 110 correspondents as warrants of noteworthiness. I attached to each of these more or less noteworthy kinsmen (for my own private use in this inquiry) a *, a +, a −, or a o, signifying respectively 3, 2, 1, or no marks. In doing this, account was taken of honours, of biographical notices, and of the context of the communication, which often helped in deciding cases. Only one of these symbols was allotted to each individual.

*A List.—Mostly recipients either of a * or a +.*

Ministers of State, Heads of Departments, Permanent Secretaries, and other high posts in public offices. Member of Parliament, but subject to reservation.
Foreign Ambassador or Minister, Consul General, Secretary of Legation.
Governor of a Colony, Colonial Secretary, high Colonial Office.
Admiral or General in important command, high Staff appointments.
Clerical dignitaries, eminent ministers, philanthropists.
Legal dignitaries at home and in the colonies.
Medical men of distinction.
Professors in great universities, heads of the more important colleges and schools. University scholarships, first or second place in class lists of universities or in competitive examinations for Woolwich, Indian Civil, or principal home services.
Distinction in any form of Art—as poet, musician, singer; architect sculptor; painter, engraver, caricaturist; actor.
President or secretary of great institutions connected with science, literature, art, or purposes of public utility.
Authorship of a standard work, editorship of an important journal, authorship of valuable memoirs.
Inventor in any branch, scientific traveller.
Founder of a great business, management of great commercial undertakings, pioneer of a new industry.

B List.—Useful to corroborate and to check.

Honours: From the Crown—as knighthood and all superior orders. From public bodies—as honorary university degrees, Fellowship of Royal Society (all F.R.S. were granted a ∗), of Royal Academy, and other selected associations.

Biographical notices—as in Dictionary of National Biography and in other standard collections. Obituary and other notices in the journals of literary and scientific societies. Special memoirs. Men of the time; Who's Who?

C List.—Personal estimates taken into account.

Prominent county man. Active in public affairs, successful in business. Forward in civic matters. Good professional position. Of high repute as a scholar, &c.

D List.—Referring wholly to women.

A social leader. Great force of character. Reputed very clever. Artistic (in any way) to an exceptional degree. Successful work in educational, civic and philanthropic matters was also taken into account. Brilliant prize winnings at school or college. The following are examples of the more suggestive returns (but slightly modified). "I have no hesitation in judging her to be 'noteworthy.'" "Acquisitive mind of a high order." "Learned both Greek and Hebrew unassisted." "Had a great and recognised influence in forming the character of her (distinguished) sons." "Helped her husband greatly in his (standard) work."

E List.—Referring to youths only, and reaching at most the qualification of—

Good place in examinations, though lower than the very high ones mentioned above. School scholarships and exhibitions of fair importance.

Much less difficulty was experienced in assigning marks than had been anticipated. The totals of the number given were 183 of ∗, 188 of +, 83 of −.

The 183 ∗ included 23 fellows of the Royal Society. Brothers were only counted once.

Abbreviations used in the schedule are employed here also, to distinguish different kinds of kinship that bear the same popular names, as uncles and first cousins. They are convenient, and seem to have been easily understood. They were first suggested by me in NATURE of January 28 of this year:—*bro* = brother; *da* = daughter; *fa* = father; *Hu* = husband; *me* = mother; *si* = sister; *so* or *son* = son; *Wi* = wife. *fa bro son* means "MY father's brother's son IS"; *me da* means "MY mother's daughter IS"; *so Wi bro* means "MY son's wife's brother IS," &c.

The total amount of marks that were thus assigned to each grade of kinship are given in Table I. For example, out of the 110 *fa fa fa* of the 110 senders, 3 were allotted a ∗, 1 a +, and none a −. Out of the 110 *fa* the corresponding numbers were 27, 25, 5.

TABLE I.—*Distribution of Symbols and of Indices of Success among the Kinsfolk of the* 110 *Senders.*

Kinship	Symbols ∗	+ 2	− 1	Indices of success	Kinship	Symbols ∗ 3	+ 2	− 1	Indices of success
fa fa fa	3	1	—	11	*me fa fa*	2	1	—	5
fa fa bro	8	1	—	26	*me fa bro*	3	1	—	11
fa me bro	1	—	—	3	*me me bro*	1	1	—	5
fa fa	16	8	3	67	*me fa*	13	8	3	58
fa bro	11	15	3	66	*me bro*	11	14	3	64
fa si	1	4	1	12	*me si*	—	4	1	9
fa me	—	1	3	5	*me me*	1	3	1	10
fa	27	25	5	136	*me*	4	4	4	24
bro	37	21	17	170	*si*	3	6	5	26
Half brothers *fa son*	3	3	—	15	Half sisters *fa da*	—	—	—	—
Half brothers *me son*	—	—	—	—	Half sisters *me da*	—	—	—	—
bro son	4	11	2	36	*si son*	1	4	1	12
bro da	—	2	—	4	*si da*	1	1	1	6
fa bro son	10	7	1	45	*me bro son*	9	9	1	46
fa bro da	—	—	1	1	*me bro da*	1	1	—	5
fa si son	5	3	4	25	*me si son*	6	5	3	31
fa si da	—	2	1	5	*me si da*	—	—	—	—
son	1	16	14	49	*da*	—	6	5	17

Total 183 of ∗, 188 of +, 83 of −.

Examples:—the index for *fa fa fa* is equal to 3 multiplied into 3, *plus* 2 multiplied into 1, = 9 + 2, = 11; that for *si son* is equal to (1 × 3, + 4 × 2, + 1 × 1) = 3 + 8 + 1 = 12.

Tables II. and III. are based on Table I.

TABLE II.—*Successes of Kinsmen of Fellows of the Royal Society.*

A.—Through Male lines. Kinship	Index of successes	B.—Through Female lines. Kinship	Index of successes
fa fa bro	26	*me me bro*	5
fa bro son	45	*me si son*	31
fa fa	67	*me fa*	58
fa bro	66	*me bro*	64
	204		158

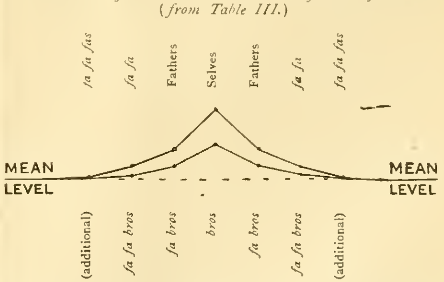
A popular notion that ability is mainly transmitted through female lines is more than contradicted by these figures.

The families of the fellows of the Royal Society must be fertile, because the number of brothers, whether of selves or of fathers, came out closely as 2·43. I will not now pursue the analysis, as the other kinds of kinship are hardly numerous enough in the present collection to justify conclusions.

TABLE III.—*Indices of Success among near Kinsmen in Ascending Generations of the* 110 *Contributors.*

Generation	110 persons in each class: Kinship	Observed indices	Accepted indices	Brothers of 110 persons in each class: Kinship	Observed indices	Accepted indices
I.	Selves	330	330	Brothers	170	170
II.	fathers	136	136	*fa bros*	66	65
				me bros	64	
III.	*fa fa*	67	62	*fa fa bros*	26	16
	me fa	58		*me me bros*	5	
Additional	*fa fa fa*	11		*fa me bros*	3	
				me me bros	5	

Distribution of Success in the Families of Successful Men (*from Table III.*)



The upper line of the diagram indicates the successes of direct male ancestors, the lower line those of their brothers. The mean level of the community was inferred from the fact that it cannot be higher than the lowest entries in Table III., so far as these are to be trusted, and that these would be of barely perceptible magnitude in the small diagram.

Relation of Success to Natural Ability.—The success of

a man is wholly due to the combined effect of Natural Gifts and of Circumstances. More, however, being included under the title of natural gifts than can influence success, this part may be disregarded. The remainder comprises intellectual power, appropriate tastes, a persevering disposition, and much else, forming a large group which will be briefly termed "Natural Ability." The Circumstances, so far as they affect success, include healthy rearing, family and social influences, education, money, leisure, and surroundings that encourage work or idleness.

Men whose histories are known can be sorted with rough fairness, and with little difficulty, into three grades of natural ability, one-third of the whole number being classed as "above mediocrity" and marked +1, another third being classed as "mediocre" and marked 0, the remaining third being classed as "below mediocrity" and marked −1. After this has been done and the results recorded, the same men may be sorted afresh and independently into three grades, according to their Circumstances, one-third of them consisting of those whose circumstances conduced to success and are marked +1, the other thirds being respectively marked 0 and −1 on the principle already explained. Assuming for the moment (the question will be discussed later on), first, that Natural Ability and Circumstance are independent, and, secondly, that the mark for Success will always be equal to the sum of those for Ability and Circumstance, then the relation of Success to Ability is easily found. A square table (Table IV.) is made with three columns and three horizontal bands; it consequently contains nine compartments. The "arguments" at the head of the several columns will be +1, 0, −1; so will be those that precede the several bands. Then an entry is made in each compartment equal to the sum of its two arguments. The next step is to sort the successes in order of their values, annexing to each the various grades of ability that have been associated with it, and to enter the averages of them at the side as in Table V.

TABLE IV.—*Distribution of Successes, under the assumption that each differs little from that of the sum of its two variable constituents, and that these vary independently.*

Circumstance	Natural ability		
	+1	0	−1
+1	+2	+1	0
0	+1	0	−1
−1	0	−1	−2

The entries in the body of the table represent the Successes. Each is the sum of its two arguments, which refer respectively to Natural Ability and to Circumstance.

TABLE V.—(*Extracted from Table IV.*)

Grades of success	Associated grades of natural ability			
	All of the observed values			Average values
+2	+1	—	—	+1
+1	0	+1	—	$+\frac{1}{2}$
0	−1	0	+1	0
−1	−1	0	—	$-\frac{1}{2}$
−2	−1	—	—	−1

The result is that the average quantity of exceptional ability which is associated with any given amount of exceptional success is exactly its half. This same conclusion is reached by an *a priori* argument. Thus, let S, A, C be three independent variables, and $S=\frac{1}{2}(A+C)$. Then if C be unknown, its *average value* will be mediocrity, that is, $=0$. Consequently S will *on the average* be associated with $\frac{1}{2}(A+0)$, that is, with $\frac{1}{2}A$. There is a uniform rate of regression towards mediocrity. The same will take place if the cases are sorted in such proportions that the mediocrities shall be twice as numerous as either of the extreme groups. The table will then have four columns and four bands, with the arguments +1, 0, 0, −1, and it will have sixteen compartments. The result will still be the same if the mediocrities should be thrice as numerous as either of the extreme groups, and so on.

The two assumptions that have been made with the purpose of giving a rough idea of what would really occur must now be justified so far as may be. The first assumption was that natural ability and circumstance may be treated as *independent* variables. This position would be indefensible if we were making a precise analysis, because the two are certainly correlated to some extent. Thus a bright attractive boy receives more favour, and thereby has more opportunities of getting on in life, than a dull and unpleasing one, but these advantages are not unmixed with drawbacks; attractiveness leads to social distractions, such as have ruined many promising careers. The amusing couplet of Henry Taylor is worth quoting:—"Me, God's mercy spared, from social snares with ease Saved by the gracious gift, ineptitude to please." Another instance of correlation is that the disposition to intellectual effort being heritable, a naturally studious boy is frequently brought up in a family whose influence and opportunities develop his natural bent; similarly as to natural scapegraces. But my returns here and elsewhere show that home influences are much less potent than might be supposed. Many correspondents speak of themselves as the only members of their family who had tastes like their own, and kinsfolk win distinction in many different directions. Moreover, a reaction against the monotony of home influences is often shown by those strong characters whose tastes are not in complete harmony with them. The correlation between natural aptitude and the circumstances favourable to success is consequently less strict than appears at first sight, and to the best of my judgment is not worth regarding in a rough inquiry.

The other assumption was that success is equal to the simple sum of natural ability and favouring circumstance. On the contrary, it must be some highly complex and discontinuous function of it. Still, the fact remains that a gifted child is more likely to succeed under conditions that are on the whole favourable to success than otherwise. The obvious objection that circumstances favourable to the development of one class of mind may be prejudicial to that of another is met by supposing a preliminary grouping of the men according to their dominant tendencies, scientific, scholastic, artistic, devotional, militant, and so forth, and treating these groups separately, each with its appropriate classification of circumstance. Little more is asked for than that natural ability and circumstance, as reasonably interpreted, shall be considered *cumulative*, in a broad and general sense, in their power of leading to success. It follows from this that any "exceptionality" of natural ability will, on the average, be roughly proportional but inferior to the exceptionality of the accompanying success. Also that the two will agree in direction, good ability going with high success, poor ability with the reverse. Rare exceptions do not invalidate general conclusions, any more than the fact of one boy in a class of schoolmates dying very early or very late invalidates the expectation of life at school ages as calculated by actuaries.

Exceptionally Gifted Families.—The diagram would assure us, even if we had no other grounds for assurance, that exceptionally gifted families must exist, whose race is a valuable asset to the nation. A few of these have been indicated by the present returns; they well deserve, and will probably receive, a full description hereafter. It must suffice for the present to mention the existence of at least nine gifted families connected with fellows of the Royal Society, two or three of whom are exceptionally gifted. I will conclude with the remark that the experience gained through this inquiry has strongly confirmed an opinion expressed in my lecture on Eugenics before the Sociological Society, of which an abstract appeared in these columns (vol. lxx. p. 82), namely, that it would be both feasible and advantageous to make a register of gifted families. I have now better hope of being able to carry some such design into effect.

FRANCIS GALTON.

THE HEALTH CONGRESS AT GLASGOW.

AT the congress of the Sanitary Institute recently held at Glasgow, a large number of sanitary officials, delegates from sanitary authorities, and others interested in public health matters assembled, and a busy four days of discussions were relieved by a generous programme of local entertainments. Glasgow is an excellent centre for such a meeting. The hospitality of the city is proverbial, and the enlightened enterprise of the corporation and its officials in dealing with the sanitary needs of "The Second City in the Empire" is generally recognised. The city abounds in interest to those who appreciate what a far-sighted and energetic civic management of affairs has achieved in the direction of solving the many public health problems which present themselves in every large industrial community. An enlightened municipality has provided an excellent system of electric trams, and acquired its own water supply and lighting; four public abattoirs have been established, and private slaughter-houses abolished; and hospital accommodation amounting to $1\frac{1}{3}$ beds to every 1000 of the population has been provided for the infectious sick. But the energy and wisdom which have characterised the civic management of affairs is in no respect better evidenced than by the circumstance that in comparatively recent years no fewer than fifteen parks or open spaces, together amounting to more than 1000 acres in area, have been procured as lungs for the city. There is, indeed, no form of municipal enterprise in the interest of public health, however recent or advanced, which has not been adopted and put to the test in Glasgow; and hence the attractiveness of the city to the hygienist and to the earnest municipal representative. Model lodgings for the poor and labourers' dwellings now replace some of the insanitary property which has been demolished; the corporation owns a municipal infants' milk depot, reception houses for the temporary detention of those who have been in close contact with certain of the infectious diseases, municipal chemical and bacteriological laboratories, public baths and wash-houses, and it has recently had the courage to demand the closing of the public houses at 10 p.m. Drunkenness is very prevalent in Glasgow, and the more drunkenness can be reduced the easier does the solution become of most public health problems.

Despite all this good work, the conditions under which so many of the poor are still housed in Glasgow continue to demand the exercise of much energy and enterprise on the part of the local authority. A tremendous amount of "spade-work" still remains to be done, and it is not easy to contemplate the state of things which would now exist if the corporation had shown less wisdom and vigour in dealing with the poorer section of the community in the past, for few, if any, cities of Great Britain have stood more in need of enlightened administration. Glasgow is essentially a manufacturing and trading community. A city cannot be this and beautiful at the same time. It has an atmosphere in which poverty, dirt, and intemperance naturally take root and thrive. But the corporation has proved itself to be quite wide awake to the wants of Glasgow, and it is administering to those wants with no niggard hand. Would that it could deal effectively with those pernicious individuals who fatten on the poorest section of the community by the system of "farming" tenements, and would that it could succeed in abolishing that almost essentially Scotch custom of placing beds in air-stagnant recesses in the walls of living rooms, for it is not easy to exaggerate the harmful effect the custom must have upon the public health.

It is, of course, impossible within the limits of a short article to deal adequately with the extensive programme of work performed at the congress. Figuring most prominently among the more important subjects which came under discussion were those of the milk supply, the disposal of sewage, the housing of the poor, infant feeding, school hygiene, the hospital isolation of infectious disease, and disinfection.

Dissatisfaction was generally expressed at the lack of suitable precautions to guard our milk supply from contamination, and there was a general conviction that this circumstance was responsible for much preventable infantile mortality. The same unanimity was not accorded to the subject of the value of hospital isolation of scarlet fever patients, and this was responsible for a lengthy discussion at the conference of medical officers of health. There is a considerable body of expert opinion opposed to the present wholesale and indiscriminate hospital isolation of this disease, which now generally assumes so mild a type. Hospital isolation seems incapable of materially reducing the attack rate among the community, and so few children escape attack altogether that the good obtained is disproportionate to the enormous expense entailed, and therefore the restriction of the number of cases admitted to hospital to those who cannot possibly be nursed at home without great risks, is advocated by many. This restriction, strictly enforced, would reduce the number of admissions by some 50 per cent. in many large towns, and the money thus saved could be spent with far greater effect upon other public health measures.

Many of the papers contributed to the congress dealt with controversial subjects, and contained nothing of scientific value; these contributions, however, serve a most useful purpose at such meetings, for the adoption or otherwise of administrative measures of public health importance is largely determined by the trend of the general discussions which they evoke.

Reference may be made to one or two of the more practical papers which were of general interest.

In a paper read by Dr. R. H. Crowley upon the spread of diphtheria in schools, it was pointed out with reference to a school outbreak of this disease in Bradford that whereas the throats of ninety-three scholars gave no clinical evidence of diphtheria, in forty-two instances diphtheria bacilli were present; and the importance of such an examination and the necessity of isolating scholars who, though apparently healthy, contain the germ on their throats during such outbreaks were emphasised.

Dr. Louis Cobbett, in another paper, concludes from the result of his experience in the Chelmsford and Cambridge outbreaks of the disease that diphtheria bacilli in healthy persons are only to be found among such as have come into contact with cases of diphtheria, and possibly also in those who have come into contact with healthy people who harbour the bacilli, and he advocates that all sanitary authorities should have at their disposal the services of a skilled bacteriologist.

Dr. A. Greenwood brought before the notice of the congress the results of his examination of the air of certain school class-rooms in Blackburn. He found that the average amount of carbon dioxide (CO_2) present in the air of Blackburn was 4·37 per 10,000, whereas that of the air of Blackburn schools was 9·69. This amount of vitiation of the air in the class-rooms of schools is doubtless very general, and improved means of ventilation are demanded in the interest of scholars.

Dr. H. Wright Thompson gave the results of his examination of the eyes of 750 Glasgow school children. He found that 34·2 per cent. of the 600 Christian children were in need of medical ophthalmic treatment, and that 47·6 per cent. of the 150 Jewish children required such treatment. So far as eyesight is concerned, Glasgow children are in a worse condition than those in either Edinburgh or Aberdeen.

Mr. W. C. Tyndale and Lieut.-Colonel Davies, R.A.M.C., in a paper recording valuable experimental work (including suitable bacteriological experiments), conclude that when the surface of a chalk formation is deluged with sewage, traces of sewage, as evidenced bacteriologically, may penetrate to a considerable depth, but that when sewage is applied in an ordinary and reasonable way over the surface no such contamination of the subsoil takes place.

Prof. Kenwood and Dr. Allan, in dealing with practical disinfection, furnished the results of experiments upon the disinfecting action of certain disinfectants after being exposed for four weeks to the air. The results show a considerable loss of power in most instances, even in the case of carbolic acid.

A rather sensational paper was read by the chief sanitary inspector for Glasgow, Mr. Peter Fyfe, upon the result of the examination of certain flock material taken from mattresses. This material is sometimes made from rags and cast-off clothing sorted from ash-pits, &c., and the bacteriological examination of the flock taken from some recently purchased mattresses disclosed an amount of un-

cleanliness in the form of live potential dirt that is unpleasant to contemplate, and is not without its dangers. The results of the examination revealed a state of affairs which calls for remedial action.

The usual exhibition of sanitary apparatus and appliances was held in association with the congress, and a new feature, which certainly met with an encouraging amount of success, was the delivery, each evening, of free popular lectures upon different items of general hygiene.

INDIAN IRRIGATION AND ITS RELATION TO FAMINES.

IN the summer of 1901 the Governor-General of India in Council decided on the formation of a special commission to report on the irrigation of India as a protection against famine.[1]

The commissioners appointed were Sir T. Higham, M.I.C.E., Inspector-General of Irrigation; the Hon. Denzil C. J. Ibbetson, Chief Commissioner of the Central Provinces; the Hon. J. W. P. Muir Mackenzie, Secretary to the Government of Bombay; Diwan Bahadur Mudaliar, member of the Legislative Council of Madras; with Sir Colin Scott Moncrieff as president, and Mr. W. B. Gordon, M.I.C.E., as secretary. Their first meeting was held at Lahore on October 29, 1901. Two years were spent in inspecting all the principal irrigation works, and their report was presented to Parliament a short time ago in the form of a Blue-book.

About the same time the Department of the Interior United States Geological Survey sent Mr. Herbert M. Wilson, one of their staff, to India to investigate the method of irrigation as carried out there, and to obtain such information as might be of use to the department charged with the irrigation works in the western States and the reclamation service of the American Geological Survey.

His report, entitled "Irrigation in India,"[2] was published in 1903. Largely as the result of the renewed activity in irrigation in America, the first edition of the report was soon exhausted, and a second edition revised up to date has been issued.

India stands preeminent in the gigantic engineering undertakings carried out for irrigation purposes. No other country has so vast and so fertile an expanse of territory with such convenient slopes for the construction of canals, and at the same time such an abundant though varied water supply.

The main factors determining the use and value of irrigation are the rainfall, the character of the soil, and the class of crop best suited to the special conditions prevailing.

In India the zone of heaviest rainfall lies along the western coast of the main peninsula, where the monsoon striking the western Ghats precipitates on their outer slopes an average annual rainfall of 100 to 250 inches. On the outer ranges of the Himalayas the annual rainfall amounts to 461 inches. Over the greater part of India, however, the rainfall is below 40 inches. In the extreme south of the peninsula it is scanty and precarious, and in some of the States of the north-west the average annual fall is as low as 5 inches. Where the annual rainfall is below from 10 to 12 inches cultivation is practically impossible without irrigation. Where it is abundant and exceeds 70 inches the chance of the failure of the crops may be regarded as so remote as to make irrigation unnecessary. Between these two extremes lies a vast tract of nearly a million square miles of which, in the absence of irrigation, no part can be deemed absolutely secure against the uncertainties of the season and the scourge of famine.

On the irrigated lands two crops can be taken in the year, one of which is sown in the early spring and gathered in the autumn, and the other sown in the autumn and gathered in the spring. The summer crop depends little on irrigation for its maturing, as this is growing during the monsoon or rainy season. The autumn crop consists of millet, pulses and rice, and the spring crop of wheat, barley, linseed and grain. The crops mainly dependent on irrigation to ensure a full return are wheat, barley, sugar cane, garden crops, and cotton where it grows on the black soil. The area under wheat covers more than 16 million acres, and that on which cotton is grown $8\frac{1}{3}$ million acres. Rice is an extensively cultivated crop, but is principally limited to the delta lands of the Orissa, Godaveri and Bengal; 80 per cent. of the crops raised in such regions are rice. Millet and oil seeds also are important crops. All kinds of vegetables and fruit are produced, these being the chief food of the natives. Jute is very extensively grown, the largest imports to this country coming from India. Indigo is also largely grown by the natives, and poppies for the production of opium. Tobacco and coffee are only grown in small quantities. Tea is extensively grown in Assam, where it is indigenous, and also in Darjeeling.

Irrigation has been practised in India from time immemorial. Many of the large tanks or storage reservoirs date back to the eighth and ninth centuries. The Grand Anicut in Madras is supposed to have been made in the second century. A canal on the banks of the Jumna made by the former rulers was restored in 1814, and the experience gained in this work led to the construction of the great Ganges Canal, a work which in magnitude and boldness has not been surpassed by any irrigation work.

The total length of the Government irrigation canals, including branches, is 36,000 miles, and they can discharge more than 100,000 cubic feet of water a second, and irrigate annually 19 million acres. There are also 7000 miles of minor protection works and storage reservoirs with a capacity of 25,000 million cubic feet.

The total area in India irrigated is estimated at 44 million acres, of which 42 per cent. is supplied with water from State works, $15\frac{1}{2}$ millions being from canals, and 3 millions from reservoirs. Of the private works, covering $25\frac{1}{2}$ million acres, 2·8 per cent. is from canals, 11·8 from tanks, 29·2 from wells, and 14 from other sources.

The capital outlay on the thirty-nine canals and major works up to the end of 1901 was more than $36\frac{1}{2}$ millions of pounds (counting a lakh of rupees as equal to 10,000*l.*). The annual revenue after paying all working expenses was 7·1 per cent. The works in the Punjab yield a net revenue of $10\frac{1}{2}$ per cent.; those in Bombay and Bengal do not earn enough revenue to cover interest charges on capital outlay.

The value of the crops irrigated in a single year is about equal to the whole capital cost of the works, and in time of famine the produce of the irrigated area being largely available for transport to distressed districts becomes an important item in the general food supply of the country. The irrigation works have also been largely instrumental in relieving congested districts. Some of the great canals in the North-West Provinces and the Punjab were undertaken in districts that were sparsely inhabited; within ten years from their construction the country became fully populated.

With regard to the value of irrigation works in mitigating the horrors and cost of famines, in the Sholapur district, where four famines have occurred since 1846, and where the cost to the State of the last two famines in 1896 and 1899 was equal to 1,150,000*l.*, the estimated loss is reckoned at 50,000*l.* a year, which, capitalised at 4 per cent., amounts to $1\frac{1}{4}$ millions of pounds as the limit of unproductive expenditure that might be incurred for the sake of avoiding the future cost of famine relief for this district alone. During the terrible famine of 1876, for which a large relief fund was raised in this country, $5\frac{1}{2}$ million of lives were lost, although the Indian Government expended 11 millions of pounds in relief.

Many of the great works already undertaken have been the direct outcome of famines. The great famine of 1837 in Bengal led to the project of the Ganges Canal, which has now 5500 miles of main canal and branches; the famine which desolated Orissa and the north of India in 1864, when a million of the inhabitants lost their lives by starvation, notwithstanding the expenditure of upwards of $6\frac{1}{4}$ millions of pounds in combating the famine, and also more than 3 millions in works of irrigation, resulted in the policy since adopted of systematically carrying out extraordinary public works and expending half a million a year in developing

[1] Report of the Indian Irrigation Commission, 1901–3. Part i. General. (Eyre and Spottiswoode). Price 1*s.* 4*d.*

[2] "Irrigation in India." By Herbert M. Wilson. (Washington: Government Printing Office.)

irrigation for the purpose of preventing the recurrence of these terrible disasters.

As the result of its investigation, the commission found that in the several districts it visited a programme of works had been prepared for work in such proportion of the population as is likely to be affected by famine, and that it was claimed that most of these works would be of a useful character; but the commissioners were of opinion that the degree of utility likely to be attained must for the present be regarded as uncertain, many of the works having been hurriedly selected. In addition to irrigation, the works included roads and railways.

The commissioners also recommended a very extensive programme of protective irrigation works to be constructed as rapidly as may be practicable in the tracts that are most likely to suffer from famine. They also endorse the recommendation of the Famine Commission of 1901, that greater reliance should be placed in future on village works as a means of employing relief labour than has been the practice in recent famines. They, however, advise the use of caution, and express the opinion that no relief labour can be more useless than that expended on works which, however useful if eventually completed, will probably remain as a famine folly, incomplete for ever.

They strongly recommend that a central board should be constituted, and invested with the responsibility of regularly watching and reporting progress as to works set out in the programme laid down, and of guarding against material deviations from the working plans of each province being made without the express sanction of the Government.

For the prosecution of their programme of new State irrigation works, it is pointed out that a large and permanent increase will have to be made in the strength of the engineering establishment.

The general conclusion arrived at is that there is a wide but not unlimited field in which the engineers and civil officers can work together for the protection of the country from famine, partly by the construction of new State irrigation works, and partly by encouraging and stimulating the extension of irrigation by means of private works. Both methods will involve heavy expenditure on the part of the State, upon which there may not be any direct return, although it may be justified by the value of the protection afforded. While the whole of India can never be protected from famine by irrigation alone, yet much can be done to restrict the area and to mitigate the intensity of famine. Any enduring success of works carried out will depend no less on their effect in evolving a spirit of self-help and thrift among the people than in their efficiency in securing crops from drought.

Mr. Wilson's report is of considerable value to engineers engaged in irrigation works, as it contains a great deal of information relating to constructive works, such as weirs, sluices, and dams, and also descriptions, accompanied by illustrations, of many of the principal irrigation works carried out in India.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The following re-appointments for three years have been made:—Dr. A. J. Herbertson, to be lecturer in regional geography and curator of the School of Geography; Dr. G. B. Grundy, to be lecturer on ancient geography; Mr. C. R. Beazley, to be lecturer on the history of geography.

DR. REGINALD BULLER, lecturer on botany in the University of Birmingham, has been appointed professor of botany in the University of Manitoba.

THE Salters' fellowship of the Pharmaceutical Society has again been conferred on Mr. J. Stuart Hills, who since October, 1903, has devoted himself entirely to research work.

DR. A. W. CROSSLEY, lecturer in chemistry at St. Thomas's Hospital Medical School, has been appointed to succeed Prof. W. P. Wynne, F.R.S., in the chair of chemistry in the School of Pharmacy of the Pharmaceutical Society of Great Britain, and the following demonstrators have also been appointed in the latter school:—Mr. F. G. C. Walker in chemistry, Mr. J. T. Cart in pharmaceutics, and Mr. T. G. Hill in botany.

THE Drapers' Company has discharged the debt of University College, London, to the bankers to the amount of 30,000*l*. The treasurer has received from Messrs. Wernher, Beit and Co. their cheque for 10,000*l*., promised to promote the incorporation of the college in the university. For the completion of the incorporation scheme, there yet remains the sum of 18,000*l*. to be raised. Prof. Oliver has been re-appointed to the Quain chair of botany. Dr. F. J. Poynton has been appointed sub-dean of the faculty of medicine in succession to Prof. G. D. Thane, resigned. The session 1904–5 will begin, in the faculties of arts and laws and of science, on Tuesday, October 4, and in the faculty of medicine on Monday, October 3. The introductory lecture will be given by Prof. J. Norman Collie, F.R.S., on October 3, at 4 o'clock.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 2.—"The Advancing Front of the Train of Waves Emitted by a Theoretical Hertzian Oscillator." By A. E. H. **Love**, F.R.S., Sedleian Professor of Natural Philosophy in the University of Oxford.

The waves emitted by Hertz's oscillator have been identified with those due to a vibrating electric doublet. The field due to a variable doublet is expressed by equations of the form

$$\left.\begin{aligned}(X, Y, Z) &= \left(\frac{\partial^2}{\partial x \partial z}, \ \frac{\partial^2}{\partial y \partial z}, \ -\frac{\partial^2}{\partial x^2}-\frac{\partial^2}{\partial y^2}\right)\frac{\psi(ct-r)}{r} \\ (\alpha, \beta, \gamma) &= \frac{1}{c}\left(\frac{\partial^2}{\partial y \partial t}, \ -\frac{\partial^2}{\partial x \partial t}, \ 0\right)\frac{\psi(ct-r)}{r}\end{aligned}\right\}$$

in which c is the velocity of radiation, and $\psi(ct)$ is the moment of the doublet at time t. When there is damping ψ has the form

$$\psi = Ae^{-\frac{\nu}{\lambda}(ct-r)} \sin \frac{2\pi}{\lambda}(ct-r+\epsilon),$$

where λ is the wave-length, A a constant depending upon the amplitude of the vibrations, ϵ a constant expressing the phase, and ν a constant expressing the damping. According to the experiments of Bjerknes, ν may be taken to be about 0·4 when the wave-length λ is about 10 m. The constant ϵ is determined by the conditions which hold at the front of the waves ($r=ct$). The field outside

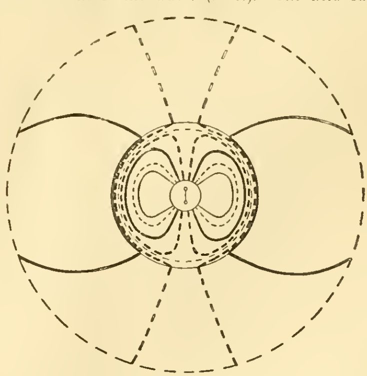


FIG. 1.

this surface is that which is established at the instant when the vibrations begin. At this instant the brass balls of the oscillator are so highly charged that the electric strength of the air between them gives way. The initial field is that due to the charges at this instant, so that it can most appropriately be represented as the electrostatic field of a fixed doublet.

It is shown that the moment of the initial doublet is the maximum moment of the vibrating doublet, and that ϵ is given by $\tan\frac{2\pi\epsilon}{\lambda}=\frac{2\pi}{\nu}$.

The effect of the introduction of the phase-constant ϵ is discussed in detail, and the advance of the waves through the pre-established electrostatic field is illustrated by a number of figures. For example, Fig. 1 here shows the lines of electric force after an interval of (0·51) of a period from the beginning of the vibrations, the fine continuous circle representing the front of the waves. Fig. 2 shows

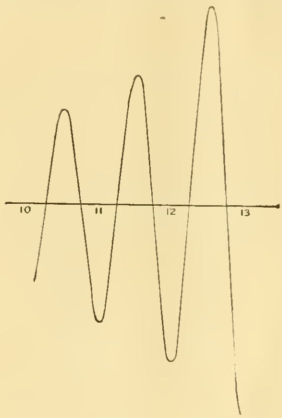

FIG. 2.

the transverse electric force at distances between 10 and 13 wave-lengths from the doublet at the end of 13 periods. Outside the front of the waves, when this front has travelled so far, the electric force is extremely small. Hence the marked discontinuity of the figure at $r = 13\lambda$.

June 16.—"The Absorption and Thermal Evolution of Gases Occluded in Charcoal at Low Temperatures." By James **Dewar**, M.A., D.Sc., LL.D., F.R.S.

"The Direct Separation of the most Volatile Gases from Air without Liquefaction." By James **Dewar**, M.A., D.Sc., LL.D., F.R.S.

PARIS.

Academy of Sciences, August 1.—M. Mascart in the chair.—The general organisation of solar researches. The continuous registration of the variable elements of the sun: H. **Deslandres**. The author summarises the actual position at the present time of researches on the sun, systematically carried out, and suggests further organisation of the work.—The synthesis of several alcohols in the cyclohexane series: Paul **Sabatier** and Alph. **Mailhe**. Starting with cyclohexane, which can be readily prepared in quantity by the method previously described, this is converted into the monochloroderivative, and this made to react with magnesium. By acting upon this magnesium compound with various aldehydes and ketones, and decomposing the resulting product with water, several new alcohols have been isolated.—The characteristics of anachoropteridian leaf traces: C. Eg. **Bertrand** and F. **Cornaille**.—Observations of the sun made at the Lyons Observatory with the Brünner 16 cm. equatorial during the first quarter of 1904: J. **Guillaume**. The results are given in three tables showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—On the zeros of integral functions: Pierre **Boutroux**.—On the indirect measurement of the real velocity of aërial vessels: Paul **Renard**. The absolute velocity of an airship, U, is the resultant of the velocity of the wind, V, and the real speed, W. A new method of estimating the latter is given.—On the theory of helices capable of supporting a weight: Edgar **Taffoureau**.—On the coefficient of rectilinear diameters: E. **Mathias**.—On the index of refraction of solutions: C. **Chéneveau**. A reply to the criticisms of Edmond Van Aubel on a former paper of the author.—On the mercury thermal ammeter: C. **Camichel**. The method employed consists in heating for one minute, by a continuous current, a mercury resistance placed in the inside of the bulb of a mercury thermometer, the latter radiating to a surrounding vessel maintained at the melting point of ice. The apparatus described gave a displacement of 145·3 divisions with a current of 1·588 amperes. Under these conditions, an increase in the intensity of the current of 0·01 ampere produced a rise of two divisions on the scale.—The action of ammonia upon boron bromide and on phosphorus trichloride: A. **Joannis**. The action of ammonia upon boron bromide depends upon the temperature, an amide being obtained at $-78°$ C., the imide at $-10°$ C. Phosphorus trichloride at $-78°$ C. gives a mixed amido-imide, possibly $NH{=}P{-}NH_2$.—The estimation of bismuth by electrolysis: A. **Hollard** and L. **Bertiaux**. Details are given of a method for separating small quantities of bismuth electrolytically in the presence of considerable quantities of copper or lead. Test experiments show the degree of accuracy obtainable.—On the existence of three kinds of phagocytic cells in normal Amphipoda: L. **Bruntz**.—On the urns of *Sipunculus nudus*: F. **Ladreyt**. These are not phagocytes nor parasites, but are detached from the body of the animal.—On a hemogregarian of *Psammodromus algirus*: H. **Soulié**.—On the structure of the crystalline medium: G. **Friedel**.—On the Callovian layers of the Morocco frontier: Louis **Gentil** and Paul **Lemoine**.—On the eruptive rocks described by the Niger-Bénoué-Tchad mission: Henry **Hubert**.—New observations on the alteration of level of the Mediterranean: Ph. **Negris**. From a study of an ancient bridge at Leucade the author concludes that the level of the Mediterranean is at present about 3 metres higher than it was at the time of the Romans, or about 2000 years ago.—Researches on animal lactase: H. **Bierry** and M. **Gmo-Salazar**.

Supplement to "Nature" August 18 1904

Rayleigh

THURSDAY, AUGUST 18, 1904.

SCIENTIFIC WORTHIES.

XXXIV.—LORD RAYLEIGH.

LORD RAYLEIGH'S investigations have covered so wide a field, and the advances he has made in every direction have been so marked, that it is no easy task to give an account of them in a short notice.

He has left his impress on all branches of physical research, an impress distinguished by the thoroughness and completeness of his work, by his skilful adaptation of means to ends, by a keen insight into the essentials of a problem, and by a strong grasp of the fundamental principles required for its solution.

Whether it be in his early work before the days when he held the Cavendish professorship, in the series of electrical measurements that marked his short tenure of that post, or in the discoveries made more recently in his own laboratory at Terling, these distinctive features stand out; the simplest means are selected, the devices nearest to hand adopted, but the whole procedure is directed to solving, as accurately as the conditions of the work will allow, the problem in view.

The four splendid volumes recently issued by the Cambridge University Press are a striking monument of his ability; these, with the "Theory of Sound," contain his contributions to the advancement of natural knowledge, and with their help it becomes possible to give some idea of his work.

Born on November 12, 1842, the son of the second Lord Rayleigh, he was educated at Trinity College, Cambridge, which he entered in October, 1861.

Some three years later, January, 1865, he took his degree as senior wrangler. In 1866 he was elected to a fellowship, which he held until his marriage in 1871.

The first paper in his collected works is dated 1869. His latest contribution to science was read before the Mathematical Society in June of the present year, and deals with Poisson's solution of the differential equation of wave motion.

The earlier papers are miscellaneous in character. One of the most important, on the theory of resonance (*Phil. Trans.*, 1870), appears again in an altered form as an important section of the "Theory of Sound," while a series of optical papers in the *Philosophical Magazine* for 1871, dealing with the colour of the sky, the scattering of light by small particles, double refraction, and the reflection of light from transparent matter, have long been classical.

In the first of these he proved that the intensity of the light reflected from small particles varies inversely as the fourth power of the wave-length; the third paper discusses the properties of an incompressible æolotropic ether, in which the inertia is a function of the direction, while the forces are the same as those in an isotropic medium; it appears that in such an ether the wave surface would not be that of Fresnel; it has since been shown that if the medium be not incompressible, but be such that the forces resisting compression are zero, then the wave surface is Fresnel's, but the motion is no longer in the wave front. The fourth paper of this series puts in a clear and definite manner the strict theory of reflection of waves in an elastic solid as developed by Green, distinguishing clearly between his results and those of other writers less rigid in their demonstrations.

Another series of optical papers of great importance was published in the *Philosophical Magazine* nine years later, in 1880.

These dealt with the theory of certain optical instruments, especially with regard to their separating or resolving power. In the first of these is established the fundamental law that a double line, when viewed through a telescope, cannot be fairly resolved unless its components subtend an angle exceeding that subtended by the wave-length of light at a distance equal to the horizontal aperture, and the principles leading to this law, applicable to a telescope, have been extended to the case of a microscope in more recent papers published in the *Philosophical Magazine* in 1896, and in the *Journal* of the Royal Microscopical Society, 1903.

Lord Rayleigh's contributions to optics are, however, best summed up in his article on wave theory in the ninth edition of the "Encyclopædia Britannica," and in themselves constitute a claim to the highest distinction.

Clerk Maxwell died in the autumn of 1879, and Lord Rayleigh, in response to an influential memorial, expressed his willingness to carry on the work at the Cavendish Laboratory. He was of course elected, and for the next five years devoted himself to the duties of the chair. The collected papers show us how fruitful those years were; moreover, in addition to original research, there was much to be done in organising the teaching and practical work in the laboratory. On his appointment pupils were few, and organised instruction hardly existed. Maxwell had collected a number of graduate students and inspired them with a keen love for research and investigation, but the practical classes which in Lord Rayleigh's time became so prominent a feature of the laboratory had almost to be formed. In 1879 the natural science tripos contained twenty-five names; in 1884 there were eighty successful candidates, very many of whom obtained a large portion of their training at the laboratory.

The researches of this period include the well known series of investigations into the fundamental electrical units. These were determined with an accuracy which it is difficult even after twenty years' experience of similar measurements to surpass, and have formed the foundation for the legal standards of resistance, current, and electromotive force throughout the world.

Allusion should be made to a short paper in the *Philosophical Magazine* for 1892 on a comparison of the methods for the determination of resistance in absolute

R

measure, which, as a recent writer in these columns, in reviewing the collected papers, July 30, 1903, observed, "exhibits in a marked degree Lord Rayleigh's great capacity for seeing distinctly the essential point of an experiment or a measurement and keeping that clearly in view throughout. This indeed is a distinguishing feature of his experimental work, a main factor in his success. Those who knew the Cavendish Laboratory when the electrical measurements were going on, or have since visited the laboratory at Terling, from which no less important work is continually being published, have sometimes been astonished at the makeshift character of much of the apparatus. Contrivances of wood and wire and wax do duty where most men would use apparatus elaborated with a quite unnecessary care; but in Lord Rayleigh's case, while the essential instrument on which the accuracy of the investigation really depends is as perfect as the skill of the workman can make it, and in addition has been thought out in all its details so as to fit it best for the purpose immediately in view, for the rest the arrangement which comes first to hand is utilised without regard to appearances."

The Cambridge period came to an end in 1884, but previously to this, in his address as president of the mathematical and physical section of the British Association in 1882, Lord Rayleigh had indicated what the next series of experiments were to be. He referred on that occasion to the supposed relation between the atomic weights of the chemical elements as a subject inviting investigation, and continued, "The time has perhaps come when a redetermination of the densities of the principal gases may be desirable—an undertaking for which I have made some preparations." Two years later, when president of the association at Montreal, speaking of the value of the study of electrolysis as affording a deeper insight into the nature of chemical reaction, he remarked, "And if I might without presumption venture a word of recommendation it would be in favour of a more minute study of the simpler chemical phenomena."

From this time forward Lord Rayleigh has devoted much of his time to the work thus indicated, publishing papers in 1887 and 1889 respectively on the relative densities of hydrogen and oxygen and on the composition of water in which results are given bearing on Prout's hypothesis.

The first article in the fourth volume of the collected papers is a letter to this Journal, which begins:—"I am much puzzled by some recent results as to the density of nitrogen, and shall be much obliged if any of your chemical readers can offer suggestions as to the cause. According to two methods of preparation I obtain quite distinct values. The relative difference, amounting to about 1/1000 part, is small in itself"—the difference ultimately found was 1/200—"but it lies entirely outside the errors of experiment, and can only be attributed to a variation in the character of the gas"; and his paper concludes, "Is it possible that the difference is independent of impurity, the nitrogen being in a different (dissociated) state?" This, which was published in 1892, was the first indication of the discovery of argon.

In the following year, 1893, Lord Rayleigh communicated to the Royal Society a paper on the densities of the principal gases, containing absolute determinations with all the precautions that recent physical experience or theory could suggest. Here again he points out that nitrogen prepared from ammonia is lighter than atmospheric nitrogen by something of the order of one-half per cent.; he excludes the possibility of contamination by any known substance, which suggests, as before, that an explanation is to be looked for in a dissociated state of the nitrogen itself. In April, 1894, he returned to the problem by way of further assuring himself by experiments on actual measured contamination of the absence of known impurities, and as against the dissociation hypothesis ascertained that keeping the lighter nitrogen for eight months did not increase its density. Chemical nitrogen was shown to differ from atmospheric nitrogen. As it appeared that the impurity could not be removed by known processes, and could hardly be in the chemical nitrogen, the next step was to remove the nitrogen from the atmospheric gas. This was essayed by Lord Rayleigh by combination of the nitrogen through the agency of the electric discharge, and by Sir William Ramsay, who had become associated in the work, by passing it over heated magnesium. Both workers were able to announce to the British Association at Oxford the discovery of a residue constituting a new gaseous constituent of atmospheric air. Then followed the joint memoir of Rayleigh and Ramsay on the isolation and properties of argon.

This physico-chemical work has been since continued in various forms, the physical properties of argon and of other gases have been investigated, and in particular attention has been given to the accuracy with which Boyle's law is satisfied at the ordinary temperature. This investigation has been extended from pressures of 0·01 mm. of mercury up to 150 mm., and the research is still in progress.

In addition to this physical work, numerous mathematical papers, chiefly on problems relating to wave motion and vibrations, should be mentioned.

Meanwhile, wide as has been the field of pure science covered by Lord Rayleigh's activities, he has found time to spare for the promotion of the application of science to industry and commerce. He was a prominent member of the Board of Trade Committee on Electrical Standards, to which we owe the legal definitions of the ohm, the ampere, and the volt. He presided over the Treasury Committee which recommended the establishment of the National Physical Laboratory, and for the past five years has been chairman of the executive committee of the laboratory. To his wise counsels and guidance much of its success is due. Recently he has been a member of a Board of Trade Committee on methods of testing gas, while

he is chairman of the Ordnance Committee of the War Office.

For some time he held the distinguished position of one of the secretaries of the Royal Society.

Throughout his life the search of truth in nature has been his main endeavour.

"The works of the Lord are great
Sought out of all them that have pleasure therein"

is the motto he has prefixed to his collected papers. His friends and pupils throughout the world hope that for many years to come he may continue as their guide in that search which he has already made so fruitful.

PHYSIQUE AND EDUCATION.

Physical Deterioration, its Causes and the Cure. By A. Watt Smyth. Pp. xv+318. (London: John Murray, 1904.) Price 6s. net.

Les Exercises physiques et le Développement intellectuel. By Angelo Mosso. Pp. 294. (Paris: Félix Alcan, 1904.) Price 6 francs.

MRS. WATT SMYTH'S book performs good service in directing the attention of that larger public who imagine Blue-books to be dull, and who avoid the study of health reports, to the national health. Those great weaknesses and injuries that beset the infant citizen have hitherto caused quite insufficient concern. Most of the drawbacks to healthy living here set out were proclaimed by the International Congress of Hygiene in 1891; so slow has been the progress in remedying them that we must hope these chapters will be more widely read than those transactions have been. Evidently many good sources of evidence have been carefully searched; even the sociologist may seek here for references, and while the frequent change of theme has necessitated brevity, the most salient facts and features receive due prominence.

So manifest and so important is the prevalence of physical unfitness in children, as observed first by Dr. Francis Warner, as recently reported on by a Royal Commission (making a striking contrast between the children of Aberdeen and those of Edinburgh), and as now under consideration by a Departmental Committee, that the causes and cure thereof call for this volume, whether or no a "general deterioration" be proved. The argument that excessive urban infant death rate is evidence of deterioration of survivors when illustrated by the annual mortality table of the whole of England (where up to the last decennium such mortality has declined) is an argument against so many individuals deteriorating as formerly. So "Individual Physical Deterioration" would seem a more appropriate title for this work. In any case, the comparison of the present day low expectation of life at Southwark (thirty-six years) with Hampstead (fifty years) is far more important than the consideration of the wretchedness of sixty years ago, when Whitechapel had an expectation of only thirty-one years.

Here are well told the many wants on which unfitness depends. First, in the mother, want of knowledge and want of means; in the infant, want of natural or of proper food; in the pupil, want of sufficient food. Next comes want of air, overcrowding (insufficiently defined), want of school and bedroom ventilation. Further, rest is wanting to the mother, and still more wanting to those children who labour; recreation is wanting to the children, and in the long unbroken hours of school work. Exercise is needed along with recreation.

Such are the causes of physical unfitness; cure lies in their removal. In general, two means of remedy are proposed—legislative measures and increase of instruction and knowledge. Perhaps the legislative proposals of the book evince warm-hearted suggestion rather than practical statesmanship; if there be not in these measures danger of relieving parents of their responsibility, one may yet say with Dr. Bulstrode, the State cannot move except in response to a decisively expressed public opinion, and to load the machinery of public health administration with unpopular measures is, as has been amply exemplified in the history of public health, a futile and eminently unscientific proceeding. To take a current instance; existing powers of making and enforcing by-laws on the overcrowding in the east of London are not carried out, and have not been thoroughly tried.

We welcome in this book a beginning of the other means of remedy—increased knowledge and instruction. A spread of the information here given may render possible in future legislative measures for which the nation is not yet ripe.

We agree with the writer that "the root of the national unfitness lies in the health of the mother during pregnancy and the feeding of infants during their earliest years"; and we read, "out of the children (Sheffield) under two years who had died during the summer of diarrhœa, death in 21 per cent. resulted from the inexperience or ignorance of the mothers."

The better health and physical development (and lower infantile death rate) of Jewish children Dr. Hall "attributes mainly to the fact that Jewish women are better nourished during pregnancy, are more anxious to suckle their children, are more attentive to them in early childhood and feed them with more intelligence." The Royal Commission on Alien Immigration was similarly told, "the difference in the death rate is due to the better care the inhabitants take of themselves and their mode of life," and an appendix shows death rate of infants, Whitechapel 144, Limehouse 204, Whitechapel having nearly double the overcrowding, but 31 per cent. aliens as compared to 3 per cent. in the Limehouse population. Further, while for ten years the aliens and overcrowding had been increasing in Whitechapel, infant deaths had fallen 15 per cent. In Limehouse, with no such increases, deaths had risen 7 per cent. The explanation of these striking figures lies in the fact that the overcrowding of Whitechapel is caused by aliens—for the most part Jews. No laws will remedy ignorance; let us first take the mote out of our own eye and learn a lesson from the Jewess.

Mrs. Watt Smyth has convinced us that the teaching of girls is the key of the position, and her vivid

portrayal of domestic subjects reminds us how peculiarly they are a woman's province.

If all elder girls are taught that the air, food, clothing, washing, rest, and exercise of a baby must, to ensure its health, conform to lessons of experience, if this teaching be based upon reasoned explanations, not only will babies benefit, but young mothers will not discontinue to use their reasoning for the wants of the growing child.

The more liberal views recently adopted by the Board of Education should expedite this reform.

Boys would welcome any teaching that explained how they can best gain and keep strength, and if incidentally they are taught that the habit of drinking more than a pint of beer a day may entail a penalty on health, even if a long-deferred penalty, they will have learnt a fact not one working man in twenty is conscious of to-day. The recent actuarial evidence of the United Kingdom Provident Institution proves that the duration of an abstainer's life, age thirty, is 11 per cent. longer than that of the ordinary temperate insurer.

Teaching will also probably do more for a pure milk supply and for the benefit of a rural population than legislation. Neglect of all subjects bearing on rural occupation in rural school teaching is in itself a lesson to the rustic to ignore such study. How many farmers have heard of cooperative credit, or even know the meaning of the word tuberculosis?

It is pleasant to read how some attempts at amelioration are commencing in the vivid descriptions of the teaching of domestic subjects, the out of school recreation classes, the different systems of physical education, and the practice of physical culture in elementary schools.

Knowledge of the health of the growing child should, we agree, be gained by genuine and efficient observation; as Dr. Bulstrode writes:—"if an officer were appointed to test sight and hearing, detect deformity and reduce the hours of working of the physically and mentally unfit, the harvest would speedily be so abundant that further action would follow in a similar direction."

It is to be hoped this useful and interesting work may come out in a cheaper form, so that it may instruct a wider circle.

Prof. Mosso has long taught us the principles of physical education in his work upon "Fatigue," and in 1893 he published a brief comparative study of the practices in vogue among Continental nations and in England. The present work extends over a wider field. Its nucleus consists of three lectures, part of a course of lectures upon physical education recently instituted in Turin for teachers of gymnastics; they are "Origines et Decadence de l'Agonistique et de la Gymnastique," "L'Agonistique moderne," "L'Éducation physique dans les Universités," and chapters have been added upon the training in ancient Rome, State control, "pédagogie," on the physique of the scholar, and on women's education in America.

Prof. Mosso is an entertaining writer; he sees equally the picturesque side of physical education whether in the palæstra of ancient Greece or at Wellesley College among American girls. In many countries has he travelled, made inquiries on the spot and studied their literature. Accordingly, a broad-minded attitude prevails in this book, and the problems of physical education are viewed from a multiplicity of aspects; but the theme of his title is not systematically developed.

One gathers generally that the early days of Greece and Rome with the American student of to-day represent the best combinations of physique and intellect.

Games in the open air are to be encouraged rather than exercises in a hall; the former will include more moral and intellectual improvement. For these games Prof. Mosso adopts the term "agonistique," which has hitherto been applied to the rivalry of athletic sports rather than to the larger congregation who should join in the recreative game. The change of meaning in this hitherto little used word is to be deprecated.

It is pointed out that the word recreation may convey its literal sense if one recognises that those same cells of psychomotor centres which have been engaged in thought and inhibiting motor impulses are re-animated by recreative exercise after study. In devoting themselves to motor activities, the reaction is one that regenerates these nerve cells.

The book affords a pleasant general discussion upon the physical side of education.

Hugh R. Beevor.

FISH-PASSES AND FISH-PONDS.

Fischwege und Fischteiche. Die Arbeiten des Ingenieurs zum nutzen der Fischerei. By Paul Gerhardt. Pp. 147; 142 woodcuts in text. (Leipzig: Wilhelm Engelmann; London: Williams and Norgate, 1904.) Price 5s. net.

It is a strange thing that in the articles upon river engineering in the latest edition of the "Encyclopædia Britannica" there is no reference to the construction of fish ladders, nor is there, we believe, any comprehensive work upon this subject which has been produced in Britain. The present work is intended primarily for the purpose of instructing engineers in that branch of fresh-water engineering which concerns fishery matters.

The author rightly insists upon the necessity of engineers who propose to undertake the planning and building of fish passes or ponds knowing the habits of the fishes concerned, and in his "Einleitung" of nineteen pages sets out concisely the necessary information in this direction. His statements in some cases, however, for example with regard to the habits of the salmon in the sea and in the river, appear to us somewhat too "cut and dried" considering the speculative condition of our knowledge upon the subject.

The second part of the book deals with fishways, and after a general dissertation upon their importance

the various forms of fish pass are considered the pool fishway, the oblique pass, queen's gap, and the various forms of fish ladders. The various forms are described, but are quite insufficiently criticised. The oblique groove, "Schrägpasse" (under which, by the way, is included the queen's gap pass, "Wehreinschnitt") is dealt with at some length, although it, *i.e.* the oblique groove, was years ago considered utterly useless in Britain, where it was chiefly tried.

The information upon fish ladders is arranged under headings "Fischtreppen mit Stegen," "Fischtreppen mit Sperren u. Einschnitten," and "Lachstreppen mit Sperren u. Schlupfoffnungen," no distinction being drawn between step fishways and inclined fishways, although, in Britain and America at any rate, the latter form has been considered vastly superior to the former.

Seeing that the author in his preface undertakes the consideration of foreign fishways as well as of German ones, we should have expected to see more fish ladders described and discussed, especially those of this country and America, where this branch of engineering has had plenty of scope. The "Smith's Ladder" at the lower falls on the Ballysadare River is described and figured, but no mention is made of the ladder at the Collooney Falls on the same river, which is a combination of Cail's and Smith's inventions. The first Smith's pass, and one of the most successful in Scotland—that at Deanstone, on the Teith—surely deserved mention, as did the inventor. The "queen's gap" at Poolquay Weir, on the Severn, is described in detail, although the weir was washed away in 1881, and has never been rebuilt.

Part iii. is devoted to fish-ponds. There is only one reference to an English fish farm, and none of the numerous American hatcheries, where pond construction has been carefully studied, are mentioned.

Much of this part of the book is of less value from the British fish culturist's or engineer's point of view, because in Germany coarse fish, such as the carp, are a staple food, and are reared in large numbers, whereas most of our fish culture is concerned with the Salmonidæ. As the author says:—

"Der Karpfen ist derjenige Fisch, der sich am besten für die Teichwirtschaft eignet. Er ist ein Edelfisch, leicht zu ziehen und schnellwüchsig, so dass er gute Erträge liefert,"

and this section of the book is written very much from this point of view.

Much of the information as to the construction of ponds and their inlets and outflows is, of course, ancient, and can be found in such books as the "History of Howietoun," by the late Sir R. Gibson-Maitland.

The book is doubtless a useful exposition of some of the existing fish passes and ponds, but in such a work we should have expected to find fuller criticisms and summaries, for instance, as to the value of one form of pass compared with another.

On the whole, we think a more useful book could be written from a British engineer's point of view.

FRANK BALFOUR BROWNE.

OUR BOOK SHELF.

Photographic Chemicals and How to Make Them. By W. Taylor. Pp. 107. (London: Iliffe and Sons, Limited.) Price 1*s*.

This small volume of a hundred pages consists of explanatory remarks on various chemical operations, such as filtering, weighing, boiling, and so on, and concise instructions for the preparation of twenty-one substances that are in common use by photographers. The author considers that "the processes may form a pleasant variation upon ordinary photographic methods." He adds that "it must not be supposed that there will be a saving of cost," but "the pleasure and amusement afforded by the manipulations, to say nothing of their value educationally, if followed out with due care, should do far more than compensate for the trifling increase in expense." The instructions given are clear and correct, and are illustrated by several good figures of really practical apparatus, but, as is often the case in such volumes, the style is uneven. If the book is intended for those who will profit by being told how to test with litmus paper and how to bend a glass tube, and need to have figures to show what kind of things a pestle and mortar, an evaporating dish and a pair of tongs are, then the descriptions of processes are far too lacking in detail. They are more of the character of instructions that might be given to a student of chemistry who has had experience in a well appointed laboratory. We very much doubt whether the author or anyone else has boiled away sulphuric acid "in an empty grate"—of an ordinary room, presumably. The open air is suggested as an alternative place for the performance of this and many other operations which would very speedily render it impossible to live in any room where they were going on. The risk of accidents or desirable precautions might have been set forth a little more prominently in case the volume should fall into the hands of those who know nothing of chemistry. However, there are many young people who have "done" a little chemistry at school, and these will no doubt find it useful. It may be noted that the method described for preparing anhydrous sodium acetate is not efficient; it is necessary to fuse the dried salt.

Dictionnaire des Engrais et des Produits chimiques agricoles. By E. S. Bellenoux. Pp. x + 158. (Paris: Schleicher Frères et Cie., 1904.)

This is meant to be a handy book of reference for the farmer and the agricultural student, in which any material used in agriculture may be looked up and information obtained as to its nature, use, adulteration and the like. The arrangement is alphabetical under such heads as "analysis of the soil," "ash," "nitrogen," "purchase of manures"; the treatment is popular, and though results of experiments are occasionally given, there are no references. The scheme of the book causes a good deal of overlapping, and we doubt if the same end of easy reference would not be better attained by a good index to an ordinary book covering the same ground. The information provided is not very well selected nor always correct; for example, we read, "le sulfate d'ammoniaque a, au contraire, la propriété de remonter des profondeurs du sol où l'eau peut l'avoir entrainé et de revenir à la surface: c'est un sel *grimpant*, ainsi qu'on l'a dénommé, et c'est cette propriété spéciale qui le fait employer avant l'hiver afin que les pluies le fassent pénétrer jusqu'aux racines. Si on l'emploie au printemps, il faut l'enfouir par un labour et ne jamais le répandre en couverture. . . . L'azote du sulfate d'ammoniaque est directement assimilable par les plantes."

Actualités scientifiques. By Max de Nansouty. Pp. 329. (Paris: Schleicher Frères et Cie., 1904.) Price 3.50 francs.

THIS collection of short popular essays on scientific subjects is likely to appeal to a wide circle of readers. The questions selected for treatment are those pertaining to recent discoveries which have been given prominence in the Press. To name a few of the titles is enough to show the character of the book, especially when it is added that a subject is rarely given more than four pages by way of explanation:—Radium and radio-activity, wireless telegraphy, captive balloons, electric cookery, and so on. The book may prove of service in this country to young people fond of science who are learning French.

LETTERS TO THE EDITOR.

An Optical Phenomenon.

A SHORT time ago, when experimenting with a cubical mirror, I noticed the following peculiar phenomenon:—

Diffused daylight from a near window fell on the mirror, and was reflected towards the observer. Now, the mirror was made to revolve slowly. A succession of flashes of white light was thrown at the observer as the different faces passed before the eye. When the rate of about two revolutions per second was reached, instead of the white flashes, a display of various colours, resembling interference colours, was observed, and this effect continued until about six revolutions per second were made, when the colours disappeared, and a uniform grey light was reflected. The experiment was repeatedly made, and always with the same effect.

The exact moment of appearance and disappearance of the colour effect could only be determined approximately, nor is there, apparently, a definite order in which the colours succeed each other. At least, I was unable to distinguish a strict order, but this may have been due to the imperfect way of turning the mirror, viz., by hand power, means of obtaining an absolutely uniform rate not being available. As a rule, several colours appear at the same time, one near the other. On the whole, however, it may be said that green tints predominate, whilst yellow hardly appears. Bluish tints seem to predominate at the beginning and towards the end of the colour range.

The experiment may also be varied in the following manner:—Place the mirror so that the direct sunlight strikes it. Then turning the mirror, observe the path of reflected light on the wall. In this path, not far from the mirror, fasten a piece of white paper to the wall. When the mirror is then turned at the above-named rate, the colours will be seen on the paper.

To secure a quick perception of the colours, it is well, in both cases, to start with a high speed of rotation, and then to slacken it gradually.

I would like to know whether this phenomenon has already been observed by others, and also how it may be explained. FRED J. HILLIG.

St. John's College, Toledo, Ohio, U.S.A.

The Celtic Pony.

AT a sale of Icelandic and Welsh ponies held at Gateshead on July 14, I observed a small black Welsh stallion which had the essential characteristics of the Celtic pony (*Equus caballus celticus*) lately described by Prof. Ewart. There was no trace of a callosity on either hind leg, and the tail had a very well marked caudal fringe or tail-lock, while in most other respects this pony conformed to the Celtic type. I believe that this is the first instance on record of a Welsh pony resembling the Celtic variety in all the main points. The other Welsh ponies at the sale, so far as I noticed, possessed hock callosities, but the majority of these resembled the Celtic pony in having a more or less distinct caudal fringe.

The occurrence of "Celtic" characters in Welsh and other ponies which usually differ from *E. caballus celticus*, as pointed out by Mr. Annandale and myself in a paper on Færöe and Icelandic ponies (*Proc.* Camb. Phil. Soc., vol. xii., 1904), is in no way inconsistent with the view we put forward that the present distribution of the Celtic pony is related to the Viking migration. This view receives confirmation in Dr. Stejneger's statement that there is a Norwegian breed called the "fjordhest" which is closely allied to if not identical with the Celtic pony. But though the purest representatives of the Celtic pony at the present day seem to be generally restricted to certain (usually isolated) parts of north-west Europe, it would appear that there are traces elsewhere of the primitive small-headed horse (the probable ancestor of the Celtic pony, according to Prof. Ewart) which had a wider distribution. The Welsh and other ponies which sometimes show Celtic characters, as well as certain of the smaller Arabs, probably represent such traces (see Ewart, "The Multiple Origin of Horses and Ponies," *Trans.* Highland and Agric. Society of Scotland, 1904).

Out of sixty Icelandic ponies which I examined at the Gateshead sale, I found fourteen without hock callosities, a rather unusually high proportion. All colours were represented, but the commonest and probably the most typical colour with the Icelandic ponies was light dun with a dark line down the centre of the back.

FRANCIS H. A. MARSHALL.

Monksfield, Freshwater Bay, Isle of Wight, August 10.

THE NEEDS OF ANTHROPOLOGY AT CAMBRIDGE.

AT first sight it does not strike one as a particularly edifying spectacle to see an appeal for funds made by a department of an ancient university, but after all it is a hopeful sign, as it indicates normal expansion or growth along new lines. It is a common mistake to regard the Universities of Oxford and Cambridge as well endowed; the wealth, such as it is—or rather such as it was—belongs to the colleges and not to the university, and as these universities are not endowed with public funds, they have to rely solely upon ancient and recent benefactions in addition to fees received from students. Consequently, when old subjects expand rapidly, or new subjects arise, there are insufficient funds to meet their needs; especially is this the case for scientific subjects, as, in addition to the lecturers, class-rooms, and books of the older subjects, these require demonstrators, laboratories, apparatus, and specimens. Museums, which are a necessity to many branches of science, are expensive institutions to erect, maintain, and increase. They are a relatively new feature in university education, and, though they are at present regarded by some with suspicion and by more with dismay, they are essential alike to teaching and research, and it is safe to predict that their value will become increasingly recognised. The chief reasons why museums are so generally misunderstood are because they are too small or too badly constructed to display their contents; they are understaffed and starved in funds for cases and additions, and, finally, they are not properly arranged. The last count is very largely dependent upon the previous conditions, for only those who have had experience can fully realise the impossibility of orderly and educative installation when every department of the museum is overcrowded and new specimens or collections are continually coming in. It is usually extremely difficult for a curator to keep pace with the new material in addition to the ordinary routine work of a museum, and as scarcely any museum has any-

thing like an adequate staff, it is inevitable that something must be left undone. It is certainly the first duty of a curator to take care of his specimens, and thus it naturally happens that what is left to a more convenient season is the educational arrangement and descriptive labelling of the specimens; as it is these deficiencies that cause museums to be condemned as uninteresting or uninstructive, so it is difficult to get out of that vicious circle which is so well described by the proverb, "the destruction of the poor is their poverty."

A circular, signed by the Disney professor of archæology and the curator of the Museum of Archæology and Ethnology at Cambridge, has been issued directing attention to the congested state of the museum and the inability even to store the existing specimens; the nineteenth annual report of the antiquarian committee, which accompanies the appeal, gives a long list of additions to the museum for the year 1903, which proves that it is rapidly and symmetrically growing. Valuable collections have to be stored out of sight, and so are unavailable for purposes of study. The university has assigned a fine site for the proposed new museum, but as the subscriptions hitherto raised only amount to about 3300*l.*, no steps can be taken towards erecting the building.

Not only do the collections require space and cases for them to be seen by the public, and to enable them to be used for purposes of instruction and research, but rooms are required for the teaching staff, and where research and demonstrations can be carried on. The present teaching staff, of subjects connected with the museum, consists of one professor and a lecturer, both with absurdly small stipends. The circular estimates that for the proper development of the department a new museum must be provided, at a cost of 25,000*l.*, in addition to an adequate annual income for maintenance and for the increase of the stipends of the curatorial and teaching staff.

The circular concludes by pointing out that no better centre than the University of Cambridge can be found for the study of anthropology or for the development of a museum of the best kind; many of her students are led for purposes of research, or in the discharge of professional duties, or for pleasure, to divers quarters of the globe, and not a few among these have enriched the museum with valuable collections. The opportunities for the study of primitive society, and for the formation of collections illustrative of its various phases, are rapidly vanishing before the advance of European civilisation. The funds of the university have been strained to their utmost of late years to keep even the older scientific departments abreast of the times. It is therefore necessary to appeal for outside help in order to raise the funds required for the erection, equipment, and endowment of a museum of anthropology which shall be worthy of the university.

BRITISH ASSOCIATION MEETING AT CAMBRIDGE.

In the issues of Nature for July 21 and August 4, articles giving general accounts of the local arrangements and of the main items in the sectional programmes were published. At the time of writing this article the sectional committees had not met, so that the programme of technical papers to be read before the sections cannot be fully announced. The meetings begin to-day, but already the reception room at the Guildhall has been opened, and a very large number of members have applied for reserved seats at the first general meeting, when the president will deliver his address. An exceptionally large number of tickets have already been sold, so that there is every probability that the Cambridge meeting will see one of the largest attendances the Association has known during recent years. The unusual number of foreign guests who will be present, and the many leading men of science of Great Britain who have accepted invitations will make the meeting a thoroughly representative one in all branches of science. An interesting memento of the meeting is a book of lithographed signatures of the members of the Association who were present at the first meeting in Cambridge in 1833. There are only a few of these books, and they will be on sale in the reception room during the present meeting.

The arrangements of the reception room and general rooms at the Guildhall are very complete, and now that the somewhat unexpected rush at opening is over the attendants will be able to cope easily with the large amount of business that is to be done. A word should be said about the postal arrangements. A temporary post office has been established in the general reception room, where all postal business can be transacted. For the convenience of members a special box has been provided in which notes for members of the Association may be placed unstamped; these will be sorted and delivered with ordinary letters at the post office in the reception room. One of the new features of the general arrangements is the establishment of a Press Bureau. At this office information will be collected from sectional secretaries and will be available for the Press, so that full information can be obtained without the difficulty of finding the sectional secretaries. It is hoped that this arrangement will facilitate reports of sectional and other meetings, and lead to a more satisfactory account of the Association's proceedings in the Press.

A weather forecast will be supplied by Dr. Shaw from the Meteorological Office twice a day during the meeting. This will be posted in the general reception room.

At present we can only give the titles of a few of the papers which have not appeared in earlier articles. In Section A it is expected that there will be a discussion on *n*-rays. Prof. Lummer and probably Prof. Rubens will take part in the discussion of this most debated question. Mr. Burke, who is one of the few Englishmen who have made experiments on these rays, is also expected to contribute to the discussion. Dr. Rotch, the director of the Blue Hill Observatory, is to read a paper on the temperature of air in cyclones and anticyclones as shown by kite-flights at Blue Hill Observatory, U.S.A. Prof. W. Wien will read a paper on experiments to determine whether the ether moves with the earth or not.

In Section A this year is included as a subsection the department of cosmical physics. Under this subsection is the committee appointed by the International Meteorological Committee at Southport in 1903 to combine and discuss meteorological observations from the point of view of their relations with solar physics. The members of this committee who will attend are, so far as is known at present, Sir J. Eliot, Sir Norman Lockyer, M. A. Angot, Prof. Riccò, Prof. Knut Ångstrom, Prof. Birkeland, Dr. W. J. S. Lockyer, Dr. W. N. Shaw, Mr. Axsel S. Steen, and Prof. S. P. Langley.

In Section B twenty-nine papers are to be communicated. Eleven of these papers are by Cambridge chemists, and a most interesting meeting is looked forward to. The greatest interest perhaps centres round the paper by Dr. Lowry on dynamic isomerism, and the discussion of the report to be presented by Mr. H. O. Jones on the stereo-

chemistry of nitrogen. In this discussion it is expected that Prof. Aschan, of Helsingfors, Prof. Pope, Prof. Kipping, and Prof. Wedekind will take part. In connection with this section the apparatus of Messrs. Heycock and Neville will be on view, and in the University Chemical Laboratory Prof. Liveing has set up an echelon spectroscope with which the Zeeman effect and other interesting phenomena in spectroscopy will be exhibited.

In Section I, devoted to physiology, in addition to the communications already announced, Mr. Hankin, pathologist at Agra, will on Saturday morning deliver a lecture on the spread of plague. Thursday afternoon will be devoted to the heart. Communications from Prof. Sherrington and Miss Sowton on the action of chloroform on the heart, from Dr. W. E. Dixon on the action of alcohol on the heart, and from Dr. G. A. Gibson on the disturbance of cardiac rhythm will be made. Tuesday will be devoted to physiological chemistry. Prof. Macallum, of Toronto, will read a paper on the distribution of potassium in animal and vegetable cells, and a communication will be received from Prof. Kossel and Mr. Dakin on protamines and a general discussion on the nature of proteids. On Friday and Saturday afternoons this section will hold no meetings, but the Physiological and Psychological Societies will meet on these days, so that members of the Association who desire can attend these meetings without missing any of the papers communicated to the Association. On Monday afternoon Prof. Schäfer, of Edinburgh, will give an account of methods of artificial respiration with a special view to the restoration of the apparently drowned. This should be a specially interesting demonstration in view of Prof. Schäfer's new method for producing artificial respiration. The rest of Monday afternoon will be devoted to other demonstrations. The physiological laboratory will be open for inspection by members of the Association during the meetings.

In the Cavendish Laboratory an exhibition of apparatus and objects of scientific interest will be open during the session. Of special interest is the exhibition of geometrical models under Section A, and of models made at various schools under the education section. Among the more interesting of the models under Section A may be mentioned a plaster model of the general cubic surface with its twenty-seven lines drawn on it; and a model of Sir Robert Ball's cylindroid. The Cambridge Scientific Instrument Company is exhibiting a collection of scientific instruments, among which an oscillograph will be shown in action at certain times during the session. The Cambridge University Press is exhibiting a large number of books. Mr. C. E. S. Phillips will exhibit a new automatic vacuum pump, and Prof. J. A. Fleming will show an instrument for measuring wave-lengths used in wireless telegraphy.

Dr. W. N. Shaw will show the "microbarograph" which he and Mr. Dines have recently invented. This instrument is for measuring and recording small and rapid variations of atmospheric pressure, while slow changes are allowed to escape. Various forms of self-recording meteorological instruments will be shown by Messrs. Lander and Smith. A temperature recording instrument is set up at the entrance to the Guildhall by the Cambridge Scientific Instrument Company. In addition to the room used for the main part of the exhibition, the Cavendish and other laboratories will be open for inspection during the session, where members can see the ordinary apparatus in use and study the methods of scientific teaching adopted in the university.

INAUGURAL ADDRESS BY THE RIGHT HON. A. J. BALFOUR, D.C.L., LL.D., M.P., F.R.S., CHANCELLOR OF THE UNIVERSITY OF EDINBURGH, PRESIDENT OF THE ASSOCIATION.

Reflections suggested by the New Theory of Matter.

THE meetings of this great Society have for the most part been held in crowded centres of population, where our surroundings never permit us to forget, were such forgetfulness in any case possible, how close is the tie that binds modern science to modern industry, the abstract researches of the student to the labours of the inventor and the mechanic. This, no doubt, is as it should be. The interdependence of theory and practice cannot be ignored without inflicting injury on both; and he is but a poor friend to either who undervalues their mutual cooperation.

Yet, after all, since the British Association exists for the advancement of science, it is well that now and again we should choose our place of gathering in some spot where science rather than its applications, knowledge, not utility, are the ends to which research is primarily directed.

If this be so, surely no happier selection could have been made than the quiet courts of this ancient University. For here, if anywhere, we tread the classic ground of physical discovery. Here, if anywhere, those who hold that physics is the true *Scientia Scientiarum*, the root of all the sciences which deal with inanimate nature, should feel themselves at home. For, unless I am led astray by too partial an affection for my own University, there is nowhere to be found, in any corner of the world, a spot with which have been connected, either by their training in youth, or by the labours of their maturer years, so many men eminent as the originators of new and fruitful physical conceptions. I say nothing of Bacon, the eloquent prophet of a new era; nor of Darwin, the Copernicus of Biology; for my subject to-day is not the contributions of Cambridge to the general growth of scientific knowledge. I am concerned rather with the illustrious line of physicists who have learned or taught within a few hundred yards of this building—a line stretching from Newton in the seventeenth century, through Cavendish in the eighteenth, through Young, Stokes, Maxwell, in the nineteenth, through Kelvin, who embodies an epoch in himself, down to Rayleigh, Larmor, J. J. Thomson, and the scientific school centred in the Cavendish laboratory, whose physical speculations bid fair to render the closing years of the old century and the opening years of the new as notable as the greatest which have preceded them.

Now what is the task which these men, and their illustrious fellow-labourers out of all lands, have set themselves to accomplish? To what end led these "new and fruitful physical conceptions" to which I have just referred? It is often described as the discovery of the "laws connecting phenomena." But this is certainly a misleading, and in my opinion a very inadequate, account of the subject. To begin with, it is not only inconvenient, but confusing, to describe as "phenomena" things which do not appear, which never have appeared, and which never can appear, to beings so poorly provided as ourselves with the apparatus of sense perception. But apart from this, which is a linguistic error too deeply rooted to be easily exterminated, is it not most inaccurate in substance to say that a knowledge of Nature's laws is all we seek when investigating Nature? The physicist looks for something more than what, by any stretch of language, can be described as "co-existences" and "sequences" between so-called "phenomena." He seeks for something deeper than the laws connecting possible objects of experience. His object is physical reality: a reality which may or may not be capable of direct perception; a reality which is in any case independent of it; a reality which constitutes the permanent mechanism of that physical universe with which our immediate empirical connection is so slight and so deceptive. That such a reality exists, though philosophers have doubted, is the unalterable faith of science; and were that faith *per impossibile* to perish under the assaults of critical speculation, science, as men of science usually conceive it, would perish likewise.

If this be so, if one of the tasks of science, and more particularly of physics, is to frame a conception of the physical universe in its inner reality, then any attempt to

compare the different modes in which, at different epochs of scientific development, this intellectual picture has been drawn cannot fail to suggest questions of the deepest interest. True, I am precluded from dealing with such of these questions as are purely philosophical by the character of this occasion; and with such of them as are purely scientific by my own incompetence. But some there may be sufficiently near the dividing line to induce the specialists who rule by right on either side of it to view with forgiving eyes any trespasses into their legitimate domain which I may be tempted, during the next few minutes, to commit.

Let me, then, endeavour to compare the outlines of two such pictures, of which the first may be taken to represent the views prevalent towards the end of the eighteenth century; a little more than a hundred years from the publication of Newton's "Principia," and, roughly speaking, about midway between that epoch-making date and the present moment. I suppose that if at that period the average man of science had been asked to sketch his general conception of the physical universe, he would probably have said that it essentially consisted of various sorts of ponderable matter, scattered in different combinations through space, exhibiting most varied aspects under the influence of chemical affinity and temperature, but through every metamorphosis obedient to the laws of motion, always retaining its mass unchanged, and exercising at all distances a force of attraction on other material masses, according to a simple law. To this ponderable matter he would (in spite of Rumford) have probably added the so-called "imponderable" heat, then often ranked among the elements; together with the two "electrical fluids," and the corpuscular emanations supposed to constitute light.

In the universe as thus conceived, the most important form of action between its constituents was action at a distance; the principle of the conservation of energy was, in any general form, undreamed of; electricity and magnetism, though already the subjects of important investigation, played no great part in the Whole of things; nor was a diffused ether required to complete the machinery of the universe.

Within a few months, however, of the date assigned for these deliverances of our hypothetical physicist came an addition to this general conception of the world, destined profoundly to modify it. About a hundred years ago Young opened, or re-opened, the great controversy which finally established the undulatory theory of light, and with it a belief in an interstellar medium by which undulations could be conveyed. But this discovery involved much more than the substitution of a theory of light which was consistent with the facts for one which was not; since here was the first authentic introduction [1] into the scientific world-picture of a new and prodigious constituent—a constituent which has altered, and is still altering, the whole balance (so to speak) of the composition. Unending space, thinly strewn with suns and satellites, made or in the making, supplied sufficient material for the mechanism of the heavens as conceived by Laplace. Unending space filled with a continuous medium was a very different affair, and gave promise of strange developments. It could not be supposed that the ether, if its reality were once admitted, existed only to convey through interstellar regions the vibrations which happen to stimulate the optic nerve of man. Invented originally to fulfil this function, to this it could never be confined. And accordingly, as everyone now knows, things which, from the point of view of sense perception, are as distinct as light and radiant heat, and things to which sense perception makes no response, like the electric waves of wireless telegraphy,[2] intrinsically differ, not in kind, but in magnitude alone.

This, however, is not all, nor nearly all. If we jump over the century which separates 1804 from 1904, and attempt to give in outline the world-picture as it now presents itself to some leaders of contemporary speculation, we shall find that in the interval it has been modified, not merely by such far-reaching discoveries as the atomic and molecular composition of ordinary matter, the kinetic theory of gases, and the laws of the conservation and dissipation of energy, but by the more and more important part which electricity and the ether occupy in any representation of ultimate physical reality.

Electricity was no more to the natural philosophers in the year 1700 than the hidden cause of an insignificant phenomenon.[1] It was known, and had long been known, that such things as amber and glass could be made to attract light objects brought into their neighbourhood; yet it was about fifty years before the effects of electricity were perceived in the thunderstorm. It was about 100 years before it was detected in the form of a current. It was about 120 years before it was connected with magnetism; about 170 years before it was connected with light and ethereal radiation.

But to-day there are those who regard gross matter, the matter of everyday experience, as the mere appearance of which electricity is the physical basis; who think that the elementary atom of the chemist, itself far beyond the limits of direct perception, is but a connected system of monads or sub-atoms which are not electrified matter, but are electricity itself; that these systems differ in the number of monads which they contain, in their arrangement, and in their motion relative to each other and to the ether; that on these differences, and on these differences alone, depend the various qualities of what have hitherto been regarded as indivisible and elementary atoms; and that while in most cases these atomic systems may maintain their equilibrium for periods which, compared with such astronomical processes as the cooling of a sun, may seem almost eternal, they are not less obedient to the law of change than the everlasting heavens themselves.

But if gross matter be a grouping of atoms, and if atoms be systems of electrical monads, what are these electrical monads? It may be that, as Prof. Larmor has suggested, they are but a modification of the universal ether, a modification roughly comparable to a knot in a medium which is inextensible, incompressible and continuous. But whether this final unification be accepted or not, it is certain that these monads cannot be considered apart from the ether. It is on their interaction with the ether that their qualities depend; and without the ether an electric theory of matter is impossible.

Surely we have here a very extraordinary revolution. Two centuries ago electricity seemed but a scientific toy. It is now thought by many to constitute the reality of which matter is but the sensible expression. It is but a century ago that the title of an ether to a place among the constituents of the universe was authentically established. It seems possible now that it may be the stuff out of which that universe is wholly built. Nor are the collateral inferences associated with this view of the physical world less surprising. It used, for example, to be thought that mass was an original property of matter, neither capable of explanation nor requiring it; in its nature essentially unchangeable, suffering neither augmentation nor diminution under the stress of any forces to which it could be subjected; unalterably attached to, or identified with, each material fragment, howsoever much that fragment might vary in its appearance, its bulk, its chemical or its physical condition.

But if the new theories be accepted these views must be revised. Mass is not only explicable, it is actually explained. So far from being an attribute of matter considered in itself, it is due, as I have said, to the relation between the electrical monads of which matter is composed and the ether in which they are bathed. So far from being unchangeable, it changes, when moving at very high speeds, with every change in its velocity.

Perhaps, however, the most impressive alteration in our picture of the universe required by these new theories is to be sought in a different direction. We have all, I suppose, been interested in the generally accepted views as to the origin and development of suns with their dependent planetary systems; and the gradual dissipation of the energy which during this process of concentration has largely taken the form of light and radiant heat. Follow out the theory to its obvious conclusions, and it becomes plain that the stars now visibly incandescent are those in mid-journey between the nebulæ from which they sprang and the frozen

[1] The hypothesis of an ether was, of course, not new. But before Young and Fresnel it cannot be said to have been established.

[2] First known through the theoretical work of Maxwell and the experiments of Herz.

[1] The modern history of electricity begins with Gilbert, but I have throughout confined my observations to the post-Newtonian period.

darkness to which they are predestined. What, then, are we to think of the invisible multitude of the heavenly bodies in which this process has been already completed? According to the ordinary view, we should suppose them to be in a state where all possibilities of internal movement were exhausted. At the temperature of interstellar space their constituent elements would be solid and inert; chemical action and molecular movement would be alike impossible, and their exhausted energy could obtain no replenishment unless they were suddenly rejuvenated by some celestial collision, or travelled into other regions warmed by newer suns.

This view must, however, be profoundly modified if we accept the electric theory of matter. We can then no longer hold that if the internal energy of a sun were as far as possible converted into heat either by its contraction under the stress of gravitation or by chemical reactions between its elements, or by any other inter-atomic force; and that, were the heat so generated to be dissipated, as in time it must be, through infinite space, its whole energy would be exhausted. On the contrary, the amount thus lost would be absolutely insignificant compared with what remained stored up within the separate atoms. The system in its corporate capacity would become bankrupt—the wealth of its individual constituents would be scarcely diminished. They would lie side by side, without movement, without chemical affinity; yet each one, howsoever inert in its external relations, the theatre of violent motions, and of powerful internal forces.

Or, put the same thought in another form. When the sudden appearance of some new star in the telescopic field gives notice to the astronomer that he, and perhaps, in the whole universe, he alone, is witnessing the conflagration of a world, the tremendous forces by which this far-off tragedy is being accomplished must surely move his awe. Yet not only would the members of each separate atomic system pursue their relative course unchanged, while the atoms themselves were thus riven violently apart in flaming vapour, but the forces by which such a world is shattered are really negligible compared with those by which each atom of it is held together.

In common, therefore, with all other living things, we seem to be practically concerned chiefly with the feebler forces of Nature, and with energy in its least powerful manifestations. Chemical affinity and cohesion are on this theory no more than the slight residual effects of the internal electrical forces which keep the atom in being. Gravitation, though it be the shaping force which concentrates nebulæ into organised systems of suns and satellites, is trifling compared with the attractions and repulsions with which we are familiar between electrically charged bodies; while these again sink into insignificance beside the attractions and repulsions between the electric monads themselves. The irregular molecular movements which constitute heat, on which the very possibility of organic life seems absolutely to hang, and in whose transformations applied science is at present so largely concerned, cannot rival the kinetic energy stored within the molecules themselves. This prodigious mechanism seems outside the range of our immediate interests. We live, so to speak, merely on its fringe. It has for us no promise of utilitarian value. It will not drive our mills; we cannot harness it to our trains. Yet not less on that account does it stir the intellectual imagination. The starry heavens have from time immemorial moved the worship or the wonder of mankind. But if the dust beneath our feet be indeed compounded of innumerable systems, whose elements are ever in the most rapid motion, yet retain through uncounted ages their equilibrium unskaken, we can hardly deny that the marvels we directly see are not more worthy of admiration than those which recent discoveries have enabled us dimly to surmise.

Now, whether the main outlines of the world-picture which I have just imperfectly presented to you be destined to survive, or whether in their turn they are to be obliterated by some new drawing on the scientific palimpsest, all will, I think, admit that so bold an attempt to unify physical nature excites feelings of the most acute intellectual gratification. The satisfaction it gives is almost æsthetic in its intensity and quality. We feel the same sort of pleasurable shock as when from the crest of some melancholy pass we first see far below us the sudden glories of plain, river, and mountain. Whether this vehement sentiment in favour of a simple universe has any theoretical justification I will not venture to pronounce. There is no *a priori* reason that I know of for expecting that the material world should be a modification of a single medium, rather than a composite structure built out of sixty or seventy elementary substances, eternal and eternally different. Why, then, should we feel content with the first hypothesis and not with the second? Yet so it is. Men of science have always been restive under the multiplication of entities. They have eagerly noted any sign that the chemical atom was composite, and that the different chemical elements had a common origin. Nor, for my part, do I think such instincts should be ignored. John Mill, if I rightly remember, was contemptuous of those who saw any difficulty in accepting the doctrine of "action at a distance." So far as observation and experiment can tell us, bodies *do* actually influence each other at a distance. And why should they not? Why seek to go behind experience in obedience to some *a priori* sentiment for which no argument can be adduced? So reasoned Mill, and to his reasoning I have no reply. Nevertheless, we cannot forget that it was to Faraday's obstinate disbelief in "action at a distance" that we owe some of the crucial discoveries on which both our electric industries and the electric theory of matter are ultimately founded; while at this very moment physicists, however baffled in the quest for an explanation of gravity, refuse altogether to content themselves with the belief, so satisfying to Mill, that it is a simple and inexplicable property of masses acting on each other across space.

These obscure intimations about the nature of reality deserve, I think, more attention than has yet been given to them. That they exist is certain; that they modify the indifferent impartiality of pure empiricism can hardly be denied. The common notion that he who would search out the secrets of Nature must humbly wait on experience, obedient to its slightest hint, is but partly true. This may be his ordinary attitude; but now and again it happens that observation and experiment are not treated as guides to be meekly followed, but as witnesses to be broken down in cross-examination. Their plain message is disbelieved, and the investigating judge does not pause until a confession in harmony with his preconceived ideas has, if possible, been wrung from their reluctant evidence.

This proceeding needs neither explanation nor defence in those cases where there is an apparent contradiction between the utterances of experience in different connections. Such contradictions must of course be reconciled, and science cannot rest until the reconciliation is effected. The difficulty really arises when experience apparently says one thing and scientific instinct persists in saying another. Two such cases I have already mentioned; others will easily be found by those who care to seek. What is the origin of this instinct, and what its value; whether it be a mere prejudice to be brushed aside, or a clue which no wise man would disdain to follow, I cannot now discuss. For other questions there are, not new, yet raised in an acute form by these most modern views of matter, on which I would ask your indulgent attention for yet a few moments.

That these new views diverge violently from those suggested by ordinary observation is plain enough. No scientific education is likely to make us, in our unreflective moments, regard the solid earth on which we stand, or the organised bodies with which our terrestrial fate is so intimately bound up, as consisting wholly of electric monads very sparsely scattered through the spaces which these fragments of matter are, by a violent metaphor, described as "occupying." Not less plain is it that an almost equal divergence is to be found between these new theories and that modification of the common-sense view of matter with which science has in the main been content to work.

What was this modification of common sense? It is roughly indicated by an old philosophic distinction drawn between what were called the "primary" and the "secondary" qualities of matter. The primary qualities, such as shape and mass, were supposed to possess an existence quite independent of the observer; and so far the theory agreed with common sense. The secondary qualities, on the other hand, such as warmth and colour, were thought to have no such independent existence, being, indeed, no more than the resultants due to the action of the primary

qualities on our organs of sense-perception; and here, no doubt, common sense and theory parted company.

You need not fear that I am going to drag you into the controversies with which this theory is historically connected. They have left abiding traces on more than one system of philosophy. They are not yet solved. In the course of them the very possibility of an independent physical universe has seemed to melt away under the solvent powers of critical analysis. But with all this I am not now concerned. I do not propose to ask what proof we have that an external world exists, or how, if it does exist, we are able to obtain cognisance of it. These may be questions very proper to be asked by philosophy; but they are not proper questions to be asked by science. For, logically, they are antecedent to science, and we must reject the sceptical answers to both of them before physical science becomes possible at all. My present purpose requires me to do no more than observe that, be this theory of the primary and secondary qualities of matter good or bad, it is the one on which science has in the main proceeded. It was with matter thus conceived that Newton experimented. To it he applied his laws of motion; of it he predicated universal gravitation. Nor was the case greatly altered when science became as much preoccupied with the movements of molecules as it was with those of planets. For molecules and atoms, whatever else might be said of them, were at least pieces of matter, and, like other pieces of matter, possessed those "primary" qualities supposed to be characteristic of all matter, whether found in large masses or in small.

But the electric theory which we have been considering carries us into a new region altogether. It does not confine itself to accounting for the secondary qualities by the primary, or the behaviour of matter in bulk by the behaviour of matter in atoms; it analyses matter, whether molar or molecular, into something which is not matter at all. The atom is now no more than the relatively vast theatre of operations in which minute monads perform their orderly evolutions; while the monads themselves are not regarded as units of matter, but as units of electricity; so that matter is not merely explained, but is explained away.

Now the point to which I desire to direct attention is not to be sought in the great divergence between matter as thus conceived by the physicist and matter as the ordinary man supposes himself to know it, between matter as it is perceived and matter as it really is, but to the fact that the first of these two quite inconsistent views is wholly based on the second.

This is surely something of a paradox. We claim to found all our scientific opinions on experience; and the experience on which we found our theories of the physical universe is our *sense-perception* of that universe. That *is* experience; and in this region of belief there is no other. Yet the conclusions which thus profess to be entirely founded upon experience are to all appearance fundamentally opposed to it; our knowledge of reality is based upon illusion, and the very conceptions we use in describing it to others, or in thinking of it ourselves, are abstracted from anthropomorphic fancies, which science forbids us to believe and Nature compels us to employ.

We here touch the fringe of a series of problems with which inductive logic ought to deal, but which that most unsatisfactory branch of philosophy has systematically ignored. This is no fault of men of science. They are occupied in the task of making discoveries, not in that of analysing the fundamental presuppositions which the very possibility of making discoveries implies. Neither is it the fault of transcendental metaphysicians. Their speculations flourish on a different level of thought; their interest in a philosophy of nature is lukewarm; and howsoever the questions in which they are chiefly concerned be answered, it is by no means certain that the answers will leave the humbler difficulties at which I have hinted either nearer to or further from a solution. But though men of science and idealists stand acquitted, the same can hardly be said of empirical philosophers. So far from solving the problem, they seem scarcely to have understood that there was a problem to be solved. Led astray by a misconception to which I have already referred; believing that science was concerned only with (so-called) "phenomena," that it had done all that it could be asked to do if it accounted for the sequence of our individual sensations, that it was concerned only with the "laws of Nature," and not with the inner character of physical reality; disbelieving, indeed, that any such physical reality does in truth exist;—it has never felt called upon seriously to consider what are the actual methods by which science attains its results, and how those methods are to be justified. If anyone, for example, will take up Mill's logic, with its "sequences and co-existences between phenomena," its "method of difference," its "method of agreement," and the rest; if he will then compare the actual doctrines of science with this version of the mode in which those doctrines have been arrived at,—he will soon be convinced of the exceedingly thin intellectual fare which has been hitherto served out to us under the imposing title of Inductive Theory.

There is an added emphasis given to these reflections by a train of thought which has long interested me, though I acknowledge that it never seems to have interested anyone else. Observe, then, that in order of logic sense-perceptions supply the premisses from which we draw all our knowledge of the physical world. It is they which tell us there *is* a physical world; it is on their authority that we learn its character. But in order of causation they are effects due (in part) to the constitution of our organs of sense. What we see depends not merely on what there is to be seen, but on our eyes. What we hear depends not merely on what there is to hear, but on our ears. Now, eyes and ears, and all the mechanism of perception, have, as we know, been evolved in us and our brute progenitors by the slow operation of Natural Selection. And what is true of sense-perception is of course also true of the intellectual powers which enable us to erect upon the frail and narrow platform which sense-perception provides, the proud fabric of the sciences.

Now Natural Selection only works through utility. It encourages aptitudes useful to their possessor or his species in the struggle for existence, and, for a similar reason, it is apt to discourage useless aptitudes, however interesting they may be from other points of view, because, being useless, they are probably burdensome.

But it is certain that our powers of sense-perception and of calculation were fully developed ages before they were effectively employed in searching out the secrets of physical reality—for our discoveries in this field are the triumphs but of yesterday. The blind forces of Natural Selection, which so admirably simulate design when they are providing for a present need, possess no power of prevision, and could never, except by accident, have endowed mankind, while in the making, with a physiological or mental outfit adapted to the higher physical investigations. So far as natural science can tell us, every quality of sense or intellect which does not help us to fight, to eat, and to bring up children, is but a by-product of the qualities which do. Our organs of sense-perception were not given us for purposes of research; nor was it to aid us in meting out the heavens or dividing the atom that our powers of calculation and analysis were evolved from the rudimentary instincts of the animal.

It is presumably due to these circumstances that the beliefs of all mankind about the material surroundings in which it dwells are not only imperfect but fundamentally wrong. It may seem singular that down to, say, five years ago, our race has, without exception, lived and died in a world of illusions; and that its illusions, or those with which we are here alone concerned, have not been about things remote or abstract, things transcendental or divine, but about what men see and handle, about those "plain matters of fact" among which common sense daily moves with its most confident step and most self-satisfied smile. Presumably, however, this is either because too direct a vision of physical reality was a hindrance, not a help, in the struggle for existence; because falsehood was more useful than truth; or else because with so imperfect a material as living tissue no better results could be attained. But, if this conclusion be accepted, its consequences extend to other organs of knowledge besides those of perception. Not merely the senses, but the intellect, must be judged by it; and it is hard to see why evolution, which has so lamentably failed to produce trustworthy instruments for obtaining the raw material of experience, should be credited with a larger measure of success in its provision of the physiological

arrangements which condition reason in its endeavours to turn experience to account.

Considerations like these, unless I have compressed them beyond the limits of intelligibility, do undoubtedly suggest a certain inevitable incoherence in any general scheme of thought which is built out of materials provided by natural science alone. Extend the boundaries of knowledge as you may; draw how you will the picture of the universe; reduce its infinite variety to the modes of a single space filling ether; retrace its history to the birth of existing atoms; show how under the pressure of gravitation they became concentrated into nebulæ, into suns, and all the host of heaven; how, at least in one small planet, they combined to form organic compounds; how organic compounds became living things; how living things, developing along many different lines, gave birth at last to one superior race; how from this race arose, after many ages, a learned handful, who looked round on the world which thus blindly brought them into being, and judged it, and knew it for what it was:—perform, I say, all this, and, though you may indeed have attained to science, in nowise will you have attained to a self-sufficing system of beliefs. One thing at least will remain, of which this long-drawn sequence of causes and effects gives no satisfying explanation; and that is knowledge itself. Natural science must ever regard knowledge as the product of irrational conditions, for in the last resort it knows no others. It must always regard knowledge as rational, or else science itself disappears. In addition, therefore, to the difficulty of extracting from experience beliefs which experience contradicts, we are confronted with the difficulty of harmonising the pedigree of our beliefs with their title to authority. The more successful we are in explaining their origin, the more doubt we cast on their validity. The more imposing seems the scheme of what we know, the more difficult it is to discover by what ultimate criteria we claim to know it.

Here, however, we touch the frontier beyond which physical science possesses no jurisdiction. If the obscure and difficult region which lies beyond is to be surveyed and made accessible, philosophy, not science, must undertake the task. It is no business of this Society. We meet here to promote the cause of knowledge in one of its great divisions; we shall not help it by confusing the limits which usefully separate one division from another. It may perhaps be thought that I have disregarded my own precept—that I have wilfully overstepped the ample bounds within which the searchers into Nature carry on their labours. If it be so, I can only beg your forgiveness. My first desire has been to rouse in those who, like myself, are no specialists in physics, the same absorbing interest which I feel in what is surely the most far-reaching speculation about the physical universe which has ever claimed experimental support; and if in so doing I have been tempted to hint my own personal opinion that as natural science grows it leans more, not less, upon an idealistic interpretation of the universe, even those who least agree may perhaps be prepared to pardon.

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY PROF. HORACE LAMB, LL.D., D.SC., F.R.S., PRESIDENT OF THE SECTION.

THE losses sustained by mathematical science in the past twelvemonth have perhaps not been so numerous as in some years, but they include at least one name of world-wide import. Those of us who were students of Mathematics thirty or forty years ago will recall the delight which we felt in reading the geometrical treatises of George Salmon, and the brilliant contrast which they exhibited with most of the current text-books of that time. It was from him that many of us first learned that a great mathematical theory does not consist of a series of detached propositions carefully labelled and arranged like specimens on the shelves of a museum, but that it forms an organic whole, instinct with life, and with unlimited possibilities of future development. As systematic expositions of the actual state of the science, in which enthusiasm for what is new is tempered by a due respect for what is old, and in which new and old are brought into harmonious relation with each other, these treatises stand almost unrivalled. Whether in the originals, or in the guise of translations, they are accounted as classics in every university of the world. So far as British universities are concerned, they have formed the starting-point of a whole series of works conceived in a similar spirit, though naturally not always crowned by the same success. The necessity for this kind of work grows, indeed, continually; the modern fragmentary fashion of original publication and the numerous channels through which it takes place make it difficult for anyone to become initiated into a new scientific theory unless he takes it up at the very beginning and follows it diligently throughout its course, backwards and forwards, over rough ground and smooth. The classical style of memoir, after the manner of Lagrange, or Poisson, or Gauss, complete in itself and deliberately composed like a work of art, is continually becoming rarer. It is, therefore, more and more essential that from time to time some one should come forward to sort out and arrange the accumulated material, rejecting what has proved unimportant, and welding the rest into a connected system. There is perhaps a tendency to assume that such work is of secondary importance, and can be safely left to subordinate hands. But in reality it makes severe demands on even the highest powers; and when these have been available the result has often done more for the progress of science than the composition of a dozen monographs on isolated points. For proof one need only point to the treatises of Salmon himself, or recall (in another field) the debt which we owe to such books as the "Treatise on Natural Philosophy" and the "Theory of Sound," whose authors are happily represented amongst us.

A modest but most valuable worker has passed away in the person of Prof. Allman. His treatise on the history of Greek Geometry, full of learning and sound mathematical perception, is written with great simplicity, and an entire absence of pedantry or dogmatism. It ranks, I believe, with the best that has been done in the subject. It is to be regretted that, as an historian, he leaves so few successors among British mathematicians. We have amongst us, as a result of our system of university education, many men of trained mathematical faculty and of a scholarly turn of mind, with much of the necessary linguistic equipment, who feel, however, no special vocation for the details of recent mathematical research. Might not some of this ability be turned to a field, by no means exhausted, where the severity of mathematical truth is tempered by the human interest attaching to the lives, the vicissitudes, and even the passions and the strife of its devotees, who through many errors and perplexities have contrived to keep alive and trim the sacred flame, and to hand it on burning ever clearer and brighter?

In another province we have to record the loss of Dr. Isaac Roberts, a distinguished example of the class of non-professional investigators who have left so deep a mark on British science and on Astronomy in particular. Few of us can be unaware of his long and enthusiastic devotion to celestial photography, of the beauty and delicacy of the results which he achieved, or of the wealth of unsuspected detail which they brought to light.

Finally, we have to lament the death, within the last few days, of Prof. Everett, whose name will always be associated with one of the most successful tasks which the British Association has taken in hand, viz., the promotion of a uniform system of dynamical and electrical units. He acted as Reporter to the Committee entrusted with the question, and by his handbook on "Units and Physical Constants," he has done more, perhaps, than anyone else to popularise and establish its recommendations. He was well known to most of us as a bright and genial presence at these meetings, and contributed numerous interesting papers on optical and other subjects. He was happy in retaining his scientific faculties undimmed to the last, and was engaged at the time of his death on some problems of a mathematical kind, on point-assemblages, suggested by a study of the recent speculations of Prof. Osborne Reynolds.

Of the various subjects which fall within the scope of this Section there is no difficulty in naming that which at the present time excites the widest interest. The phenomena of Radio-activity, Ionisation of Gases, and so on, are not only startling and sensational in themselves, they

have suggested most wonderful and far-reaching speculations, and, whatever be the future of these particular theories, they are bound in any case deeply to influence our views on fundamental points of chemistry and physics. No reference to this subject would, I think, be satisfactory without a word of homage to the unsurpassed patience and skill in the devising of new experimental methods to meet new and subtle conditions which it has evoked. It will be felt as a matter of legitimate pride by many present that the University of Cambridge has been so conspicuously associated with this work. It would therefore have been natural and appropriate that this Chair should have been occupied, this year above others, by one who could have given us a survey of the facts as they at present stand, and of their bearing, so far as can be discerned, on other and older branches of physics. Whether from the experimental or from the more theoretical and philosophical standpoint, there would have been no difficulty in finding exponents of unrivalled authority. But it has been otherwise ordered, and you and I must make the best of it. If the subject cannot be further dealt with for the moment, we have the satisfaction of knowing that it will in due course engage the attention of the Section, and that we may look forward to interesting and stimulating discussions, in which we trust the many distinguished foreign physicists who honour us by their presence will take an active part.

It is, I believe, not an unknown thing for your President to look up the records of previous meetings in search of inspiration, and possibly of an example. I have myself not had to look very far, for I found that when the British Association last met in Cambridge, in the year 1862, this Section was presided over by Stokes, and, moreover, that the Address which he gave was probably the shortest ever made on such an occasion, for it occupies only half a page of the report, and took, I should say, some three or four minutes to deliver. It would be to the advantage of the business of the meeting, and to my own great relief, if I had the courage to follow so attractive a precedent; but I fear that the tradition which has since established itself is too strong for me to break without presumption. I will turn, therefore, in the first instance, to a theme which, I think, naturally presents itself—viz., a consideration of the place occupied by Stokes in the development of Mathematical Physics. It is not proposed to attempt an examination or appreciation of his own individual achievements; this has lately been done by more than one hand, and in the most authoritative manner. But it is part of the greatness of the man that his work can be reviewed from more than one standpoint. What I specially wish to direct attention to on this occasion is the historical or evolutionary relation in which he stands to predecessors and followers in the above field.

The early years of Stokes's life were the closing years of a mighty generation of mathematicians and mathematical physicists. When he came to manhood, Lagrange, Laplace, Poisson, Fourier, Fresnel, Ampère, had but recently passed away. Cauchy alone of this race of giants was still alive and productive. It is upon these men that we must look as the immediate intellectual ancestors of Stokes, for, although Gauss and F. Neumann were alive and flourishing, the interaction of German and English science was at that time not very great. It is noteworthy, however, that the development of the modern German school of mathematical physics, represented by Helmholtz and Kirchhoff, in linear succession to Neumann, ran in many respects closely parallel to the work of Stokes and his followers.

When the foundations of Analytical Dynamics had been laid by Euler and d'Alembert, the first important application was naturally to the problems of Gravitational Astronomy; this formed, of course, the chief work of Laplace, Lagrange, and others. Afterwards came the theoretical study of Elasticity, Conduction of Heat, Statical Electricity, and Magnetism. The investigations in Elasticity were undertaken mainly in relation to Physical Optics, with the hope of finding a material medium capable of conveying transverse vibrations, and of accounting also for the various phenomena of reflection, refraction, and double refraction. It has often been pointed out, as characteristic of the French school referred to, that their physical speculations were largely influenced by ideas transferred from Astronomy; as, for instance, in the conception of a solid body as made up of discrete particles acting on one another at a distance with forces in the lines joining them, which formed the basis of most of their work on Elasticity and Optics. The difficulty of carrying out these ideas in a logical manner was enormous, and the strict course of mathematical deduction had to be replaced by more or less precarious assumptions. The detailed study of the geometry of a continuous deformable medium which was instituted by Cauchy was a first step towards liberating the theory from arbitrary and unnecessary hypothesis; but it was reserved for Green, the immediate predecessor of Stokes among English mathematicians, to carry out this process completely and independently, with the help of Lagrange's general dynamical methods, which here found their first application to questions of physics outside the ordinary Dynamics of rigid bodies and fluids. The modern school of English physicists, since the time of Green and Stokes, have consistently endeavoured to make out, in any given class of phenomena, how much can be recognised as a manifestation of general dynamical principles, independent of the particular mechanism which may be at work. One of the most striking examples of this was the identification by Maxwell of the laws of Electromagnetism with the dynamical equations of Lagrange. It would, however, be going too far to claim this tendency as the exclusive characteristic of English physicists; for example, the elastic investigations of Green and Stokes have their parallel in the independent though later work of Kirchhoff; and the beautiful theory of dynamical systems with latent motion which we owe to Lord Kelvin stands in a very similar relation to the work of Helmholtz and Hertz.

But perhaps the most important and characteristic feature in the mathematical work of the later school is its increasing relation to and association with experiment. In the days when the chief applications of Mathematics were to the problems of Gravitational Astronomy, the mathematician might well take his materials at second hand; and in some respects the division of labour was, and still may be, of advantage. The same thing holds, in a measure, of the problems of ordinary Dynamics, where some practical knowledge of the subject-matter is within the reach of everyone. But when we pass to the more recondite phenomena of Physical Optics, Acoustics, and Electricity, it hardly needs the demonstrations which have involuntarily been given to show that the theoretical treatment must tend to degenerate into the pursuit of mere academic subtleties unless it is constantly vivified by direct contact with reality. Stokes, at all events, with little guidance or encouragement from his immediate environment, made himself from the first practically acquainted with the subjects he treated. Generations of Cambridge students recall the enthusiasm which characterised his experimental demonstrations in Optics. These appealed to us all; but some of us, I am afraid, under the influence of the academic ideas of the time, thought it a little unnecessary to show practically that the height of the lecture-room could be measured by the barometer, or to verify the calculated period of oscillation of water in a tank by actually timing the waves with the help of the image of a candle-flame reflected at the surface.

The practical character of the mathematical work of Stokes and his followers is shown especially in the constant effort to reduce the solution of a physical problem to a quantitative form. A conspicuous instance is furnished by the labour and skill which he devoted, from this point of view, to the theory of the Bessel's Function, which presents itself so frequently in important questions of Optics, Electricity, and Acoustics, but is so refractory to ordinary methods of treatment. It is now generally accepted that an analytical solution of a physical question, however elegant it may be made to appear by means of a judicious notation, is not complete so long as the results are given merely in terms of functions defined by infinite series or definite integrals, and cannot be exhibited in a numerical or graphical form. This view did not originate, of course, with Stokes; it is clearly indicated, for instance, in the works of Fourier and Poinsot, but no previous writer had, I think, acted upon it so consistently and thoroughly.

We have had so many striking examples of the fruitfulness of the combination of great mathematical and experi-

mental powers that the question may well be raised, whether there is any longer a reason for maintaining in our minds a distinction between mathematical and experimental physics, or at all events whether these should be looked upon as separate provinces which may conveniently be assigned to different sets of labourers. It may be held that the highest physical research will demand in the future the possession of both kinds of faculty. We must be careful, however, how we erect barriers which would exclude a Lagrange on the one side or a Faraday on the other. There are many mansions in the palace of physical science, and work for various types of mind. A zealous, or over-zealous, mathematician might indeed make out something of a case if he were to contend that, after all, the greatest work of such men as Stokes, Kirchhoff, and Maxwell was mathematical rather than experimental in its complexion. An argument which asks us to leave out of account such things as the investigation of Fluorescence, the discovery of Spectrum Analysis, and the measurement of the Viscosity of Gases, may seem audacious; but a survey of the collected works of these writers will show how much, of the very highest quality and import, would remain. However this may be, the essential point, which cannot, I think, be contested, is this, that if these men had been condemned and restricted to a mere book knowledge of the subjects which they have treated with such marvellous analytical ability, the very soul of their work would have been taken away. I have ventured to dwell upon this point because, although I am myself disposed to plead for the continued recognition of mathematical physics as a fairly separate field, I feel strongly that the traditional kind of education given to our professed mathematical students does not tend to its most effectual cultivation. This education is apt to be one-sided, and too much divorced from the study of tangible things. Even the student whose tastes lie mainly in the direction of pure mathematics would profit, I think, by a wider scientific training. A long list of instances might be given to show that the most fruitful ideas in pure mathematics have been suggested by the study of physical problems. In the words of Fourier, who did so much to fulfil his own saying, "L'étude approfondie de la nature est la source la plus féconde des découvertes mathématiques. Non seulement cette étude, en offrant aux recherches un but déterminé, a l'avantage d'exclure les questions vagues et les calculs sans issue; elle est encore un moyen assuré de former l'analyse elle-même, et d'en découvrir les éléments qu'il nous importe le plus de connaître, et que cette science doit toujours conserver: ces éléments fondamentaux sont ceux qui se reproduisent dans tous les effets naturels."

Another characteristic of the applied mathematics of the past century is that it was, on the whole, the age of linear equations. The analytical armoury fashioned by Lagrange, Poisson, Fourier, and others, though subject, of course, to continual improvement and development, has served the turn of a long line of successors. The predominance of linear equations, in most of the physical subjects referred to, rests on the fact that the changes are treated as infinitely small. The electric theory of light forms at present an exception; but even here the linear character of the fundamental electrical relations is itself remarkable, and possibly significant. The theory of small oscillations, in particular, runs as a thread through a great part of the literature of the period in question. It has suggested many important analytical results, and it still gives the best and simplest intuitive foundation for a whole class of theorems which are otherwise hard to comprehend in their various relations, such as Fourier's theorem, Laplace's expansion, Bessel's functions, and the like. Moreover, the interest of the subject, whether mathematical or physical, is not yet exhausted; many important problems in Optics and Acoustics, for example, still await solution. The general theory has in comparatively recent times received an unexpected extension (to the case of "latent motions") at the hands of Lord Kelvin; and Lord Rayleigh, by his continual additions to it, shows that, in his view, it is still incomplete.

When the restriction to infinitely small motions is abandoned, the problems become of course much more arduous. The whole theory, for instance, of the normal modes of vibration which is so important in Acoustics, and even in Music, disappears. The researches hitherto made in this direction have, moreover, encountered difficulties of a less patent character. It is conceivable that the modern analytical methods which have been developed in Astronomy may have an application to these questions. It would appear that there is an opening here for the mathematician; at all events, the numerical or graphical solution of any one of the various problems that could be suggested would be of the highest interest. One problem of the kind is already classical—the theory of steep water-waves discussed by Stokes; but even here the point of view has perhaps been rather artificially restricted. The question proposed by him, the determination of the possible form of waves of permanent type, like the problem of periodic orbits in Astronomy, is very interesting mathematically, and forms a natural starting-point for investigation; but it does not exhaust what is most important for us to know in the matter. Observation may suggest the existence of such waves as a fact; but no reason has been given, so far as I know, why free water-waves should tend to assume a form consistent with permanence, or be influenced in their progress by considerations of geometrical simplicity.

I have tried to indicate the kind of continuity of subject-matter, method, and spirit which runs through the work of the whole school of mathematical physicists of which Stokes may be taken as the representative. It is no less interesting, I think, to examine the points of contrast with more recent tendencies. These relate not so much to subject-matter and method as to the general mental attitude towards the problems of Nature. Mathematical and physical science have become markedly introspective. The investigators of the classical school, as it may perhaps be styled, were animated by a simple and vigorous faith; they sought as a matter of course for a mechanical explanation of phenomena, and had no misgivings as to the trustiness of the analytical weapons which they wielded. But now the physicist and the mathematician alike are in trouble about their souls. We have discussions on the principles of mechanics, on the foundations of geometry, on the logic of the most rudimentary arithmetical processes, as well as of the more artificial operations of the Calculus. These discussions are legitimate and inevitable, and have led to some results which are now widely accepted. Although they were carried on to a great extent independently, the questions involved will, I think, be found to be ultimately very closely connected. Their common nexus is, perhaps, to be traced in the physiological ideas of which Helmholtz was the most conspicuous exponent. To many minds such discussions are repellent, in that they seem to venture on the uncertain ground of philosophy. But, as a matter of fact, the current views on these subjects have been arrived at by men who have gone to work in their own way, often in entire ignorance of what philosophers have thought on such subjects. It may be maintained, indeed, that the mathematician or the physicist, as such, has no special concern with philosophy, any more than the engineer or the geographer. Nor, although this is a matter for their own judgment, would it appear that philosophers have very much to gain by a special study of the methods of mathematical or physical reasoning, since the problems with which they are chiefly concerned are presented to them in a much less artificial form in the circumstances of ordinary life. As regards the present topic I would put the matter in this way, that between Mathematics and Physics on the one hand and Philosophy on the other there lies an undefined borderland, and that the mathematician has been engaged in setting things in order, as he is entitled to do, on his own side of the boundary.

Adopting this point of view, it would be of interest to trace in detail the relationships of the three currents of speculation which have been referred to. At one time, indeed, I was tempted to take this as the subject of my Address; but, although I still think the enterprise a possible one, I have been forced to recognise that it demands a better equipment than I can pretend to. I can only venture to put before you some of my tangled thoughts on the matter, trusting that some future occupant of this Chair may be induced to take up the question and treat it in a more illuminating manner.

If we look back for a moment to the views currently entertained not so very long ago by mathematicians and

physicists, we shall find, I think, that the prevalent conception of the world was that it was constructed on some sort of absolute geometrical plan, and that the changes in it proceeded according to precise laws; that, although the principles of mechanics might be imperfectly stated in our text-books, at all events such principles existed, and were ascertainable, and, when properly formulated, would possess the definiteness and precision which were held to characterise, say, the postulates of Euclid. Some writers have maintained, indeed, that the principles in question were finally laid down by Newton, and have occasionally used language which suggests that any fuller understanding of them was a mere matter of interpretation of the text. But, as Hertz has remarked, most of the great writers on Dynamics betray, involuntarily, a certain *malaise* when explaining the principles, and hurry over this part of their task as quickly as is consistent with dignity. They are not really at their ease until, having established their equations somehow, they can proceed to build securely on these. This has led some people to the view that the laws of Nature are merely a system of differential equations; it may be remarked in passing that this is very much the position in which we actually stand in some of the more recent theories of Electricity. As regards Dynamics, when once the critical movement had set in, it was easy to show that one presentation after another was logically defective and confused; and no satisfactory standpoint was reached until it was recognised that in the classical Dynamics we do not deal immediately with real bodies at all, but with certain conventional and highly idealised representations of them, which we combine according to arbitrary rules, in the hope that if these rules be judiciously framed the varying combinations will image to us what is of most interest in some of the simpler and more important phenomena. The changed point of view is often associated with the publication of Kirchhoff's lectures on Mechanics in 1876, where it is laid down in the opening sentence that the problem of Mechanics is to describe the motions which occur in Nature completely and in the simplest manner. This statement must not be taken too literally; at all events, a fuller, and I think a clearer, account of the province and the method of Abstract Dynamics is given in a review of the second edition of Thomson and Tait, which was one of the last things penned by Maxwell, in 1879 (Nature, vol. xx. p. 213; *Scientific Papers*, vol. ii. p. 776). A "complete" description of even the simplest natural phenomenon is an obvious impossibility; and, were it possible, it would be uninteresting as well as useless, for it would take an incalculable time to peruse. Some process of selection and idealisation is inevitable if we are to gain any intelligent comprehension of events. Thus, in Astronomy we replace a planet by a so-called material particle—*i.e.*, a mathematical point associated with a suitable numerical coefficient. All the properties of the body are here ignored except those of position and mass, in which alone we are at the moment interested. The whole course of physical science and the language in which its results are expressed have been largely determined by the fact that the ideal images of Geometry were already at hand at its service. The ideal representations have the advantage that, unlike the real objects, definite and accurate statements can be made about them. Thus two lines in a geometrical figure can be pronounced to be equal or unequal, and the statement is in either case absolute. It is no doubt hard to divest oneself entirely of the notion conveyed in the Greek phrase ἀεὶ ὁ θεὸς γεωμετρεῖ, that definite geometrical magnitudes and relations are at the back of phenomena. It is recognised indeed that all our measurements are necessarily to some degree uncertain, but this is usually attributed to our own limitations and those of our instruments rather than to the ultimate vagueness of the entity which it is sought to measure. Everyone will grant, however, that the distance between two clouds, for instance, is not a definable magnitude; and the distance of the earth from the sun, and even the length of a wave of light, are in precisely the same case. The notion in question is a convenient fiction, and is a striking testimony to the ascendency which Greek Mathematics have gained over our minds, but I do not think that more can be said for it. It is, at any rate, not verified by the experience of those who actually undertake physical measurements. The more refined the means employed, the more vague and elusive does the supposed magnitude become; the judgment flickers and wavers, until at last in a sort of despair *some* result is put down, not in the belief that it is exact, but with the feeling that it is the best we can make of the matter. A practical measurement is in fact a classification; we assign a magnitude to a certain category, which may be narrowly limited, but which has in any case a certain breadth.

By a frank process of idealisation a logical system of Abstract Dynamics can doubtless be built up, on the lines sketched by Maxwell in the passage referred to. Such difficulties as remain are handed over to Geometry. But we cannot stop in this position; we are constrained to examine the nature and the origin of the conceptions of Geometry itself. By many of us, I imagine, the first suggestion that these conceptions are to be traced to an empirical source was received with something of indignation and scorn; it was an outrage on the science which we had been led to look upon as divine. Most of us have, however, been forced at length to acquiesce in the view that Geometry, like Mechanics, is an applied science; that it gives us merely an ingenious and convenient symbolic representation of the relations of actual bodies; and that, whatever may be the *a priori* forms of intuition, the science as we have it could never have been developed except for the accident (if I may so term it) that we live in a world in which rigid or approximately rigid bodies are conspicuous objects. On this view the most refined geometrical demonstration can be resolved into a series of imagined experiments performed with such bodies, or rather with their conventional representations.

It is to be lamented that one of the most interesting chapters in the history of science is a blank; I mean that which would have unfolded the rise and growth of our system of ideal Geometry. The finished edifice is before us, but the record of the efforts by which the various stones were fitted into their places is hopelessly lost. The few fragments of professed history which we possess were edited long after the achievement.

It is commonly reckoned that the first rude beginnings of Geometry date from the Egyptians. I am inclined to think that in one sense the matter is to be placed much further back, and that the dawn of geometric ideas is to be traced among the prehistoric races who carved rough but thoroughly artistic outlines of animals on their weapons. I do not know whether the matter has attracted serious speculation, but I have myself been led to wonder how men first arrived at the notion of an outline drawing. The primitive sketches referred to immediately convey to the experienced mind the idea of a reindeer or the like; but in reality the representation is purely conventional, and is expressed in a language which has to be learned. For nothing could be more unlike the actual reindeer than the few scratches drawn on the surface of a bone; and it is of course familiar to ourselves that it is only after a time, and by an insensible process of education, that very young children come to understand the meaning of an outline. Whoever he was, the man who first projected the world into two dimensions, and proceeded to fence off that part of it which was reindeer from that which was not, was certainly under the influence of a geometrical idea, and had his feet in the path which was to culminate in the refined idealisations of the Greeks. As to the manner in which these latter were developed, the only indication of tradition is that some propositions were arrived at first in a more empirical or intuitional, and afterwards in a more intellectual way. So long as points had size, lines had breadth, and surfaces thickness, there could be no question of exact relations between the various elements of a figure, any more than is the case with the realities which they represent. But the Greek mind loved definiteness, and discovered that if we agree to speak of lines *as if* they had no breadth, and so on, exact statements became possible. If any one scientific invention can claim pre-eminence over all others, I should be inclined myself to erect a monument to the inventor of the mathematical point, as the supreme type of that process of abstraction which has been a necessary condition of scientific work from the very beginning.

It is possible, however, to uphold the importance of the part which Abstract Geometry has played, and must still play, in the evolution of scientific conceptions, without committing ourselves to a defence, on all points, of the

traditional presentment. The consistency and completeness of the usual system of definitions, axioms, and postulates have often been questioned; and quite recently a more thorough-going analysis of the logical elements of the subject than has ever before been attempted has been made by Hilbert. The matter is a subtle one, and a general agreement on such points is as yet hardly possible. The basis for such an agreement may perhaps ultimately be found in a more explicit recognition of the empirical source of the fundamental conceptions. This would tend, at all events, to mitigate the rigour of the demands which are sometimes made for logical perfection.

Even more important in some respects are the questions which have arisen in connection with the applications of Geometry to purposes of graphical representation. It is not necessary to dwell on the great assistance which this method has rendered in such subjects as Physics and Engineering. The pure mathematician, for his part, will freely testify to the influence which it has exercised in the development of most branches of Analysis; for example, we owe to it all the leading ideas of the Calculus. Modern analysts have discovered, however, that Geometry may be a snare as well as a guide. In the mere act of drawing a curve to represent an analytical function we make unconsciously a host of assumptions which are difficult not merely to prove, but even to formulate precisely. It is now sought to establish the whole fabric of mathematical analysis on a strictly arithmetical basis. To those who were trained in an earlier school, the results so far are in appearance somewhat forbidding. If the shade of one of the great analysts of a century ago could revisit the glimpses of the moon, his feelings would, I think, be akin to those of the traveller to some mediæval town, who finds the buildings he came to see obscured by scaffolding, and is told that the ancient monuments are all in process of repair. It is to be hoped that a good deal of this obstruction is only temporary, that most of the scaffolding will eventually be cleared away, and that the edifices when they reappear will not be entirely transformed, but will still retain something of their historic outlines. It would be contrary to the spirit of this Address to undervalue in any way the critical examination and revision of principles; we must acknowledge that it tends ultimately to simplification, to the clearing up of issues, and the reconciliation of apparent contradictions. But it would be a misfortune if this process were to absorb too large a share of the attention of mathematicians, or were allowed to set too high a standard of logical completeness. In this particular matter of the "arithmetisation of Mathematics" there is, I think, a danger in these respects. As regards the latter point, a traveller who refuses to pass over a bridge until he has personally tested the soundness of every part of it is not likely to go very far; something must be risked, even in Mathematics. It is notorious that even in this realm of "exact" thought discovery has often been in advance of strict logic, as in the theory of imaginaries, for example, and in the whole province of analysis of which Fourier's theorem is the type. And it might even be claimed that the services which Geometry has rendered to other sciences have been almost as great in virtue of the questions which it implicitly begs as of those which it resolves.

I would venture, with some trepidation, to go one step further. Mathematicians love to build on as definite a foundation as possible, and from this point of view the notion of the integral number, on which (we are told) the Mathematics of the future are to be based, is very attractive. But, as an instrument for the study of Nature, is it really more fundamental than the geometrical notions which it is to supersede? The accounts of primitive peoples would seem to show that, in the generality which is a necessary condition for this purpose, it is in no less degree artificial and acquired. Moreover, does not the act of enumeration, as applied to actual things, involve the very same process of selection and idealisation which we have already met with in other cases? As an illustration, suppose we were to try to count the number of drops of water in a cloud. I am not thinking of the mere practical difficulties of enumeration, or even of the more pertinent fact that it is hard to say where the cloud begins or ends. Waiving these points, it is obvious that there must be transitional stages between a more or less dense group of molecules and a drop, and in the case of some of these aggregates it would only be by an arbitrary exercise of judgment that they would be assigned to one category rather than to the other. In whatever form we meet with it, the very notion of counting involves the highly artificial conception of a number of objects which for some purposes are treated as absolutely alike, whilst yet they can be distinguished.

The net result of the preceding survey is that the systems of Geometry, of Mechanics, and even of Arithmetic, on which we base our study of Nature, are all contrivances of the same general kind: they consist of series of abstractions and conventions devised to represent, or rather to symbolise, what is most interesting and most accessible to us in the world of phenomena. And the progress of science consists in a great measure in the improvement, the development, and the simplification of these artificial conceptions, so that their scope may be wider and the representation more complete. The best in this kind are but shadows, but we may continually do something to amend them.

As compared with the older view, the function of physical science is seen to be much more modest than was at one time supposed. We no longer hope by levers and screws to pluck out the heart of the mystery of the universe. But there are compensations. The conception of the physical world as a mechanism, constructed on a rigid mathematical plan, whose most intimate details might possibly some day be guessed, was, I think, somewhat depressing. We have been led to recognise that the formal and mathematical element is of our own introduction; that it is merely the apparatus by which we map out our knowledge, and has no more objective reality than the circles of latitude and longitude on the sun. A distinguished writer not very long ago speculated on the possibility of the scientific mine being worked out within no distant period. Recent discoveries seem to have put back this possibility indefinitely; and the tendency of modern speculation as to the nature of scientific knowledge should be to banish it altogether. The world remains a more wonderful place than ever; we may be sure that it abounds in riches not yet dreamed of; and although we cannot hope ever to explore its innermost recesses, we may be confident that it will supply tasks in abundance for the scientific mind for ages to come.

One significant result of the modern tendency is that we no longer with the same obstinacy demand a mechanical explanation of the phenomena of Light and Electricity, especially since it has been made clear that if one mechanical explanation is possible, there will be an infinity of others. Some minds, indeed, revelling in their new-found freedom, have attempted to disestablish ordinary or "vulgar" matter altogether. I may refer to a certain treatise which, by some accident, does not bear its proper title of "Æther and *no* Matter," and to the elaborate investigations of Prof. Osborne Reynolds, which present the same peculiarity, although the basis is different. Speculations of this nature have, however, been so recently and (if I may say it) so brilliantly dealt with by Prof. Poynting before this Section that there is little excuse for dwelling further on them now. I will only advert to the question whether, as some suggest, physical science should definitely abandon the attempt to construct mechanical theories in the older sense. The question would appear to be very similar to this, whether we should abandon the use of graphical methods in analysis. In either case we run the risk of introducing extraneous elements, possibly of a misleading character; but the gain in vividness of perception and in suggestiveness is so great that we are not likely altogether to forego it, by excess of prudence, in one case more than in the other.

We have travelled some distance from Stokes and the mathematical physics of half a century ago. May I add a few observations which might perhaps have claimed his sympathy? They are in substance anything but new, although I do not find them easy to express. We have most of us frankly adopted the empirical attitude in physical science; it has justified itself abundantly in the past, and has more and more forced itself upon us. We have given up the notion of causation, except as a convenient phrase; what were once called laws of Nature are now simply rules by which we can tell more or less

accurately what will be the consequences of a given state of things. We cannot help asking, How is it that such rules are possible? A rule is invented in the first instance to sum up in a compact form a number of past experiences; but we apply it with little hesitation, and generally with success, to the prediction of new and sometimes strange ones. Thus the law of gravitation indicates the existence of Neptune; and Fresnel's wave-surface gives us the quite unsuspected phenomenon of double refraction. Why does Nature make a point of honouring our cheques in this manner, or, to put the matter in a more dignified form, how comes it that, in the words of Schiller,[1]

> "Mit dem Genius steht die Natur im ewigen Bunde,
> Was der eine verspricht, leistet die andre gewiss"?

The question is as old as science, and the modern tendencies with which we have been occupied have only added point to it. It is plain that physical science has no answer; its policy, indeed, has been to retreat from a territory which it could not securely occupy. We are told in some quarters that it is vain to look for an answer anywhere. But the mind of man is not wholly given over to physical science, and will not be content for ever to leave the question alone. It will persist in its obstinate questionings, and, however hopeless the attempt to unravel the mystery may be deemed, physical science, powerless to assist, has no right to condemn it.

I would like, in conclusion, to read to you a characteristic passage from that Address of Stokes in 1862 which has formed the starting-point of this discourse:—

"In this Section, more, perhaps, than in any other, we have frequently to deal with subjects of a very abstract character, which in many cases can be mastered only by patient study, at leisure, of what has been written. The question may not unnaturally be asked, If investigations of this kind can best be followed by quiet study in one's own room, what is the use of bringing them forward in a Sectional meeting at all? I believe that good may be done by public mention, in a meeting like the present, of even somewhat abstract investigations; but whether good is thus done, or the audience merely wearied to no purpose, depends upon the judiciousness of the person by whom the investigation is brought forward."

It might be urged that these remarks are as pertinent now as they were forty years ago, but I will leave them on their own weighty authority. I will not myself attempt to emphasise them, lest some of my hearers should be tempted to retort that the warning might well be borne in mind, not only in the ordinary proceedings of the Section, but in the composition of a Presidential Address!

SECTION B.

CHEMISTRY.

Opening Address by Prof. Sydney Young, D.Sc., F.R.S., President of the Section.

The researches of Hermann Kopp on the molecular volumes and boiling-points of chemical compounds extended over half a century, beginning with his inaugural dissertation on the densities of oxides in 1838, and concluding in 1889 with a review of the whole of the work done on the subject. In his second paper Kopp considered the molecular volumes of solid compounds, and arrived at the conclusion that truly isomorphous substances have the same atomic or molecular volume, but that in other cases the volumes are usually different. Schröder also made the same observation at about the same time.

Now, isomorphous substances have analogous chemical formulæ, and are usually of similar chemical character, and it is interesting to notice that at this early date the fact was recognised that close chemical relationship is associated with similarity in physical properties.

For about the first six years Kopp was engaged in the consideration of the results obtained by other observers, and from these results he deduced the most important of his generalisations.

As regards boiling-points, Kopp, in 1842, concluded that a constant difference in chemical composition is accompanied by a constant difference in boiling-point, and he adopted the value 18° as the rise due to the replacement of the methyl by the ethyl group in organic compounds, although the observed differences varied between 11°·0 and 24°·8. Two years later he found in sixteen comparisons differences varying from 8° to 33°; but he doubted the correctness of the extreme values, and took 19° as the true value; he further suggested that this is the constant difference for an addition of CH_2 in any homologous series, and he pointed out that the observed difference was most regular in the case of the fatty acids.

Kopp was also of opinion that isomeric compounds with the same composition and the same vapour density have the same boiling-point.

The paucity of experimental data and the wide discrepancies between the results obtained by different observers induced Kopp to undertake the determination of the boiling-points of various compounds, and, later, their molecular volumes at a series of temperatures, and it is interesting to note the comparative crudeness of his first attempts and the increasing attention which he paid to the purification of his compounds and to the elimination of thermometric and other errors. He first examined three pairs of esters in order to find whether isomeric compounds have really the same boiling-points. But he employed only calcium chloride as a dehydrating agent, and this would remove neither water nor the alcohol completely; he was much troubled by the "bumping" of the liquids, and the temperatures he actually observed—with the thermometer bulb in the liquid—fluctuated considerably, and he could only, in most cases, take the lowest temperature observed as the most probable boiling-point. By so doing, and by making a fairly liberal allowance for residual errors, Kopp arrived at the erroneous conclusion that the boiling-points of isomers were the same in the three cases examined, and therefore, probably, in all cases.

The boiling-point of methyl alcohol was of great interest to Kopp, because, taking that of ethyl alcohol—about which there was general agreement—as correct, it should, according to his law, be $78° - 19° = 59°$, while the temperatures actually observed varied from 60° to 66°. Kopp prepared a specimen of methyl alcohol, and found that it boiled at about 65°; but he had more faith in his law than in his experimental result, and he concluded that the methods of determining boiling-points were not sufficiently accurate to give results correct to within even 1° or 2°.

In 1854 he discussed the corrections which should be applied to thermometer readings, giving a table of corrections for the unheated column of mercury, and adopting the value 27 mm. per degree as the value of dp/dt for all substances, in order to reduce the observed boiling-point to that at normal pressure. He pointed out, also, that the height of the barometer should be reduced to 0° C. Taking advantage of Delff's improved method of preparing and purifying methyl alcohol, Kopp made a fresh specimen from methyl oxalate and dried it with lime; but while Delff observed the boiling-point to be 60°, Kopp obtained the value 65°·2 – 65°·8. He was still, however, inclined to think that, owing to bumping, the observed boiling-point was too high and that the true temperature should be about 60°.

Meanwhile, in 1847 Kopp had examined sixteen liquids, including water, two alcohols, three fatty acids, and seven esters, and in 1854, as a result of his further determinations, he was able to compare the boiling-points—and also the molecular volumes—of a large number of substances, most of which were either alcohols, acids, or esters, and he at first adhered to his previous value of 19° for the rise of boiling-point due to the addition of CH_2. Later in the same year, however, taking a wider survey and including hydrocarbons and their halogen derivatives, ethers, sulphides, and other compounds, he was obliged to admit that the difference is in some cases higher, in others lower, than 19°, but he still regarded these cases merely as exceptions to the law. In 1867 Kopp admitted that isomeric aromatic hydrocarbons have not always the same boiling-point, and that the difference for an addition of CH_2 was not always 19°; but he still believed that the difference for CH_2 was constant in any really homologous series—for example, 20°·5 for homologues of toluene, 18°·5 for those of xylene, and 16°·5 for those of trimethylbenzene. He also recognised the fact that isomeric alcohols have widely different boiling-points.

Kopp published no later papers on the boiling-points of

[1] Applied by Herschel to the discovery of Neptune.

organic compounds, although he dealt fully with the question of molecular volumes in his final communication in 1889.

As a pioneer, Kopp had very great difficulties to contend against when he began his researches; data were scanty and far from accurate, and the substances which could be most easily obtained and, it was thought, readily purified were, unfortunately, those which were the least likely to lead to normal generalisations. Water, the alcohols, and the organic acids all contain a hydroxyl group, and we now know that the physical properties of these substances are abnormal in nearly all respects, owing, probably, to the fact that their molecules tend to associate together; moreover, the esters, which are formed by the interaction of acids and alcohols, do not behave quite normally, and there is probably molecular association, though to a much smaller extent than with the hydroxyl compounds.

There can be little doubt that if Kopp had been able, in the first place, to obtain a considerable number of pure substances of normal behaviour, such as the paraffins or their halogen derivatives, he would not have been led to the erroneous conclusions which he defended with such vigour for so many years. If we take the normal paraffins as the simplest class of organic compounds, we find that, instead of the boiling-points rising by equal intervals as the series is ascended, the rise, which is very large for the lowest numbers, becomes smaller and smaller as the molecular weight increases. This fact is, of course, now well known, and various formulæ have been suggested to reproduce these boiling-points. Thus Walker has proposed the formula $T=aM^b$, where T is the boiling-point on the absolute scale of temperature, M is the molecular weight, and a and b are constants. Ramage has this year suggested that this formula applies only to the CH_2 chain linkage, and that the influence of the terminal hydrogen atoms is considerable in the case of the lowest members, but diminishes as the chain lengthens, and becomes eventually either constant or negligible. In other words, the lower members of the series cannot be regarded as truly homologous, and that is a point which is, I think, important to bear in mind. Ramage suggests a new formula, $T=a[M(1-2^{-n})]^{\frac{1}{2}}$, where a is Walker's constant, 37·3775, and n is the number of carbon atoms in the molecule. He assumes, however, a constant difference for CH_2 in the case of the alcohols, the aldehydes, and the ketones, but I doubt whether the boiling-points of the last two classes of compounds are yet sufficiently well established to allow of any certain conclusions being drawn from them.

I am inclined to think that it may be useful to regard the value of Δ (the rise of B.P. for an increment of CH_2) as being mainly a function of the absolute temperature, and I would provisionally suggest the formula $\Delta = \frac{144{\cdot}86}{T^{0{\cdot}0148\sqrt{T}}}$, where Δ is the difference between the boiling-point, T, of any paraffin and that of its next higher homologue. Taking the boiling-point of methane as 106°·75 abs., the values for the higher members agree better with the observed temperatures than those given by Ramage's formula, as will be seen by the first table on the next column.

I do not wish, however, to lay much stress on the actual form of the equation, or on the particular values of the constants; the chief point I wish to direct attention to is that Δ may be regarded as a function of the temperature.

Suppose that we replace a terminal atom of hydrogen in each normal paraffin by chlorine, so as to form the homologous series of primary alkyl chlorides. The boiling-points of these chlorides are much higher, and the differences, Δ, are much smaller than for the corresponding paraffins, but the gradual fall in the values of Δ as the series is ascended is unmistakable. The same remarks apply to the bromides and iodides, the boiling-points being still higher and the values of Δ smaller.

But the point of chief interest appears to me to be this: if the values of Δ for the halogen derivatives are plotted against the absolute temperatures, the points for the most part fall near the curve constructed for the paraffins, and represented by the formula $\Delta = \frac{144{\cdot}86}{T^{0{\cdot}0148\sqrt{T}}}$. The first value of Δ is decidedly low in each case (average deviation from curve 2°·7); the later ones are rather high in nearly every case (average deviation 0°·86). Similar results are in

In the great majority of cases the deviations are greatest for the lowest members of a series, the calculated values of Δ being almost invariably higher than the observed, and this may perhaps be explained in the manner suggested by Ramage. I have, therefore, divided each series into two groups, the first ending and the second beginning with the lowest member of the series which contains a CH_2 group linked to two carbon atoms. Thus, of the alkyl chlorides, the first group contains CH_3Cl, CH_3CH_2Cl, and $CH_3-CH_2-CH_2Cl$, and the second group begins with

propyl chloride, so that all its members contain one or more $C-CH_2-C$ groups.

In the case of the ethers, esters, and other compounds which contain two alkyl radicals, a series is regarded as homologous when one radical remains unaltered and the other increases by stages of CH_2. The variable radical only is considered in dividing the series into the two groups; thus, although propionic acid contains a $C-CH_2-C$ group, it remains unchanged in the propionic esters, the first group of which consists of methyl, ethyl, and propyl propionate, the second beginning with the last-named ester.

Of the seventeen series of non-associating substances there are only five for which the mean difference between the calculated and observed values of Δ for the higher members exceeds 1°·5.

1. The *m*-xylene series. Here there is only one value, which, I think, is doubtful.

2. The olefines, $H_2C=CHR$. Here two of the three individual differences are less than 1°·5; the temperatures are all below 0°, and are somewhat uncertain.

3. The polymethylenes. The difference for pentamethylene and hexamethylene differs by less than 1° from the calculated value. The B.P. of heptamethylene appears very doubtful.

4. The amines. Differences somewhat erratic; three within 1°·5 and two within 0°·5. Octylamine and nonylamine clearly incorrect and not included.

5. The esters. Although Ramsay and Shields include these substances as non-associating, there is, I think, reason to suspect slight association.

It will be seen that the differences are greater for associating than for non-associating substances; also that they are greatest for the alcohols and least for the acids, although the factor of association is very high for both these series. In order to arrive at an explanation of these facts the effect of replacing hydrogen by chlorine may first be considered.

The boiling-point of hydrogen chloride is not yet known accurately, but it must be about −80°. Thus, by replacing an atom of hydrogen in the hydrogen molecule by chlorine the boiling-point is raised from 20°·4 abs. to about 193° abs., or about 173°. On replacing an atom of hydrogen in methane by chlorine the rise of boiling-point is from 108°·3 to 249°·3, or 141°. Ascending the series of paraffins the rise of boiling-point due to the replacement of hydrogen by chlorine diminishes rapidly at first, and then more slowly, being only 58°·5 in the case of octane. Thus the influence of the chlorine atom becomes relatively smaller as the formula weight of the alkyl group increases.

Consider, now, the effect of replacing a hydrogen atom by a hydroxyl group. In the formation of water from hydrogen gas the boiling-point is raised no less than 352°·6, from 20°·4 abs. to 373° abs., or in the ratio of 1 : 18·3; in the case of methane the rise is 221°·8, from 108°·3 to 337°·7, or in the ratio of 1 : 3·12; with octane the rise is 65°·4, from 398°·6 to 464°; and with hexdecane it is only 56°·5, from 560°·5 to 617°, the ratio being 1 : 1·10.

It will be seen that in the case of hydrogen the influence of the hydroxyl is enormously greater, and in the case of methane very much greater, than that of chlorine in raising the boiling-point, but that on ascending the series of paraffins to octane the influence of the hydroxyl group diminishes until it is little greater than that of the chlorine atom, and it is quite probable that with hexdecane it would be somewhat less. This is, no doubt, to be explained by the fact that the molecules of water and of the lower alcohols are highly associated in the liquid, but not in the gaseous state, and therefore, in order to vaporise the liquids, this molecular attraction must be overcome, and the temperature must therefore be raised. The molecular association diminishes, however, as the series of alcohols is ascended, and is probably slight in the case of octyl alcohol. If so, it would appear that the effect of the hydroxyl group—apart from association—in raising the boiling-point is not very different from, and is probably somewhat less than, that of the chlorine atom, and that the difference between the boiling-points of the lower alcohols and of the corresponding chlorides is entirely due to molecular association in the liquid state.

With the acids there is association in the gaseous as well as the liquid state, and since, according to the tables given by Ramsay and Shields, the factor of association for a liquid fatty acid at its boiling-point is rarely greater, and in most cases is somewhat smaller, than for the corresponding liquid alcohol, the molecular attraction to be overcome on vaporisation must be considerably less for the acid than for the corresponding alcohol, and the resulting rise of boiling-point above the normal value must be less. An explanation of the very low values of Δ for the alcohols and the moderately low values for the acids is thus afforded.

It would take up far too much time and space to give full details of the boiling-points of all the compounds considered, with the observed and calculated values of Δ; but it may, I think, be stated that the difference between the boiling-point of any non-associating organic compound which contains at least one $C-CH_2-C$ group, and that of its next higher homologue (at any rate up to temperatures of about 300° C.), may be calculated with an error rarely exceeding 1°·5, and generally under 1°, by means of the formula $\Delta = \frac{144 \cdot 86}{T^{0 \cdot 0148\sqrt{T}}}$. The formula seems also to be applicable to any ester which contains at least five atoms of carbon in the variable alkyl or acyl group (the mean error for 40 values of Δ is +0°·93), and with smaller error when the number of carbon atoms is still larger;[1] it is probably also applicable to the higher fatty acids, cyanides, ketones, and nitro-compounds.

Comparison of Molecular Volumes.

The fundamental idea on which both Kopp and Schröder based their methods of calculating the molecular volumes of organic compounds from the atomic volumes of the component elements was the constancy of the increase in molecular volume for each addition of CH_2. With regard to this point the question was greatly discussed whether the comparison should be made at the same temperature, say 0° C., or at the boiling-points of the compounds under the same pressure. Later, when Van der Waals brought forward his conception of corresponding states, it was thought probable that the comparison should be made at *corresponding* or equal *reduced* temperatures; that is to say, at temperatures which bear the same ratio to the critical temperatures. If the generalisations of Van der Waals were strictly true, the boiling-points under corresponding pressures would be corresponding temperatures, but that is not usually the case. The comparison may, therefore, be made either at equal reduced temperatures or at the boiling-points under equal reduced pressures; or, lastly, it may be made at the critical points themselves, and, thanks to the law of Cailletet and Mathias, the critical volumes can be ascertained with a great degree of accuracy.

In order to find whether the difference in molecular volume for each addition of CH_2 is really constant it is best to examine such perfectly normal substances as the paraffins, and the data for four consecutive members of the series—*n*-pentane, *n*-hexane, *n*-heptane, and *n*-octane—are fortunately available.

In the table below the molecular volumes and the

Paraffin	A		B		C		D		E	
	M. Vol.	Δ	M. Vol.	Δ	M. Vol.	Δ	M. Vol.	Δ	M. Vol.	Δ
n-Pentane ...	111·33		117·80		116·13		116·13		309·3	
		15·44		22·13		20·09		21·66		56·8
n-Hexane ...	126·77		139·93		136·22		137·19		366·1	
		15·69		22·63		20·18		21·49		60·2
n-Heptane ...	142·46		162·56		156·40		158·68		426·3	
		15·88		23·70		20·54		21·83		62·6
n-Octane	158·34		186·26		176·94		180·51		488·9	

[1] Thus the observed B.P. of *n*-hexyl formate is 153°·6, and the value of Δ calculated from the formula is 22·8, giving 176°·4 as the B.P. of the next higher homologue. This agrees very well with the observed B.P. of *n*-heptyl formate, 176°·7, but not with that of *n*-hexyl acetate, 169°·2. Again, the observed B.P. of methyl caproate (hexoate) is 149°·6, and the calculated value of Δ is 23°·0, giving 172°·6 as the B.P. of the next homologue. The observed B.P. of methyl œnanthylate (heptoate) is 172°·1, but that of ethyl caproate is only 166°·6.

differences, Δ, for an addition of CH_2 are given under the following conditions :[1]—

A. At 0° C.

B. At the respective boiling points under 1 atm. pressure.

C. At equal reduced temperatures (0·6396).

D. At the respective boiling-points under equal reduced pressures (0·02241).

E. At the respective critical points.

It will be seen that in every case there is a decided rise in the value of Δ as the series is ascended, but that the rise is relatively smallest when the comparison is made at the particular reduced temperature chosen. At higher reduced temperatures, however, it would be relatively much greater, since it is very marked at the critical point, where the reduced temperature = 1. The rise is also comparatively small at the common temperature 0°, but the comparison would not be satisfactory if a higher common temperature, say 150°, were chosen, because the coefficients of expansion differ considerably; at 150° the values of Δ would be 8·75, 13·45, and 15·38 respectively.

In the case of nine of the lower esters the values of Δ are by no means constant, whether the comparison be made at 0°, at the boiling-point, or at the critical point. The eleven values of Δ vary in the three methods between 16·34 and 18·21, 20·84 and 23·42, 54·3 and 61·7 respectively; but there is not a regular rise with increase of molecular weight.

Both Kopp and Schröder compared the molecular volumes of compounds at their boiling-points under normal pressure, but they deduced quite different values for the atomic volumes of carbon and hydrogen; it is clear, however, that as Δ varies considerably no values whatever for C and H could give accurate results, even in the case of true homologues.

Traube makes the comparison at a common temperature, usually 15°, and takes into consideration both the actual volumes of the molecules and the co-volume, which he assumes to have the same value, 24·5 $(1+at)$, where $a = 1/273$, for all substances. He calculates definite values for the atomic volumes of C and H at a given temperature; thus, at 15°, C = 9·9 and H = 3·1, or $CH_2 = 16·1$, so that here again the difference for CH_2 at a given temperature should be constant.

It does not appear to me that the problem has yet been completely solved, although Traube's method of calculation generally gives much better results than those of Kopp and Schröder.

Comparison of Boiling-points at a Series of Equal Pressures.

The results of this comparison are often exceedingly simple if the two substances compared are very closely related, and if there is no molecular association in either case. Taking, for example, chlorobenzene and bromobenzene, it is found that the ratio of the boiling-points (on the absolute scale of temperature) under equal pressures is constant whatever the pressure may be, or

$$\frac{T_A}{T_B} = \frac{T'_A}{T'_B} = 1·0590.$$

A similar result is obtained with the other halogen derivatives of benzene, with ethyl bromide and ethyl iodide, with ethyl acetate and propyl acetate, and some other pairs of esters; but in some cases of close relationship—for example, with ethyl formate and ethyl acetate—the ratio is not quite constant, and the formula becomes

$$\frac{T_A}{T_B} = \frac{T'_A}{T'_B} + c(T_B - T'_B),$$

where c has a very low value [0·0000417 for these two esters]. When there is no close relationship, but the molecules are not associated, the value of c is usually larger—for example, 0·000185 for carbon disulphide and ethyl bromide.

Lastly, when there is no close relationship and the molecules of one or both substances are associated, the formula

$$\frac{T_A}{T_B} = \frac{T'_A}{T'_B} + c(T_B - T'_B)$$

may no longer hold, and a third term may be required, thus:

$$\frac{T_A}{T_B} = \frac{T'_A}{T'_B} + c(T_B - T'_B) + d(T_B - T'_B)^2;$$

or, in any case, the value of c becomes much higher, as with benzene and ethyl alcohol [c = 0·0008030] or sulphur and carbon disulphide [c = 0·000645].

Behaviour of Liquids when Mixed Together.

There are three points to consider when two liquids are brought together—(1) their miscibility, whether infinite, partial, or inappreciable; (2) the relative volumes of the mixture and of the components; (3) the heat evolved or absorbed.

Liquids which are classed as non-miscible rarely, if ever, bear any close chemical relationship. Thus water is practically non-miscible with all hydrocarbons and with their halogen and many other derivatives; again, mercury, so far as I know, is not miscible with any liquid compound, organic or inorganic. It is true that the higher aliphatic alcohols are almost insoluble in water, although there may be said to be some chemical relationship between them, inasmuch as an alcohol may be regarded as an alkyl derivative of water. But the alcohols may also be looked upon as hydroxyl derivatives of the hydrocarbons, and, the higher the formula weight of the alkyl group, the greater is its influence, relatively to that of the hydroxyl, on the properties of the alcohol. Thus, while the lower alcohols show considerable resemblance to water—for example, in their behaviour with dehydrating agents, such as sodium, phosphoric anhydride, or lime, and in their power of uniting with metallic salts to form crystalline alcoholates corresponding to the hydrates—this resemblance diminishes as we ascend the series, and is generally not observable with the higher members.

On the other hand, the higher the molecular weight of the alcohol the closer is its resemblance to the hydrocarbon from which it is derived. This, as already mentioned, is well shown by the diminishing difference between the boiling-points of the alcohol and paraffin as the series is ascended; it may also be noted that methane was long classed as a permanent gas, while methyl alcohol is a liquid; whereas both hexdecane ($C_{16}H_{34}$) and cetyl alcohol ($C_{16}H_{33}OH$) are solids, the former melting at 18° and the latter at 50°.

It may, in fact, I think, be stated that the chemical relationship between water and methyl alcohol is fairly close, while that between water and cetyl alcohol is very distant. So, also, two adjacent members of a homologous series, such as methyl and ethyl alcohol, are more closely related than two members of widely different molecular weight, such as methyl and cetyl alcohol.

Adopting this view, it is, I believe, safe to state that liquids which are chemically closely related to each other are invariably miscible in all proportions.

As regards the relative volumes of a mixture and of its components at the same temperature, it is well known that inequality is the rule and equality the exception; and, further, that contraction is more frequently observed than expansion on admixture. So far, however, as experimental evidence is available, it appears that when the liquids are very closely related to each other the change of volume is exceedingly small. For example, with ethyl acetate and propionate in equimolecular proportions, +0·015 per cent.; toluene and ethyl benzene, −0·034 per cent.; n-hexane and n-octane, −0·053 per cent.; methyl and ethyl alcohol, +0·004 per cent.; chlorobenzene and bromobenzene, no change.

When the relationship is less close the changes are usually, but not invariably, larger, and are in some cases positive, in others negative; and it is rarely possible, in the present state of our knowledge, to predict from the nature of the substances—unless one is basic and the other acidic in character—whether contraction or expansion is to be expected. Thus, when methyl alcohol is mixed with water considerable contraction occurs, although the relationship is less close than between methyl and ethyl alcohol, which expand to a minute extent on mixing.

All we can say with regard to the alcohols is that, the higher the molecular weight—or, if isomeric alcohols are

[1] The atomic weights [C = 11·97, H = 1] employed in the original papers are retained.

included, the higher the boiling-point—the smaller, as a rule, is the contraction on mixing with water.

Very similar remarks apply to the heat changes which occur on mixing liquids. It appears that in the case of very closely related substances these changes are exceedingly small, or negligible, as is indicated by the very minute change of temperature which has been observed, thus: ethyl acetate and propionate, $-0^{\circ}\cdot02$; toluene and ethyl benzene, $+0^{\circ}\cdot05$; n-hexane and n-octane, $+0^{\circ}\cdot06$; methyl and ethyl alcohol, $-0^{\circ}\cdot10$; chlorobenzene and bromobenzene, $0^{\circ}\cdot00$.

It might be expected that in the case of less closely related substances contraction would be accompanied by evolution of heat and expansion by absorption of heat, but this is by no means invariably the case; for example, on mixing 40 gram-molecules of propyl alcohol with 60 gram-molecules of water there is a contraction of 1·42 per cent., but a fall of $1^{\circ}\cdot15$ in temperature was observed. Taking the alcohols as a group, it is found that, the higher the boiling-point, the smaller is the heat evolution or the greater the absorption on admixture with water.

Properties of Mixtures.

The behaviour of two non-miscible liquids when heated together is well known, and I need only refer to the fact that the vapour pressure is equal to the sum of the vapour pressures of the pure components at the same temperature; that the boiling-point is the temperature at which the sum of the vapour pressures of the components is equal to the pressure under which the liquid is being distilled, provided that evaporation is taking place freely and the vapour is not mixed with air; and, lastly, that the composition of the vapour is independent of that of the liquid (so long as both components are present in sufficient quantity), and is expressed by the equation $\frac{x_A}{x_B}=\frac{P_A D_A}{P_B D_B}$, where x_A and x_B are the relative weights of the two components in the vapour, P_A and P_B their vapour pressures at the observed boiling-point, and D_A and D_B their vapour densities.

The vapour pressure, boiling-point, and vapour composition, then, can be calculated for non-miscible liquids, and it has been stated that such liquids have never any close chemical relationship, and are usually not related at all.

On the other hand, it has been mentioned that when the chemical relationship is very close the liquids are invariably miscible in all proportions, and that there is very little, if any, volume or heat change on admixture.

So, also, the vapour pressure and boiling-point of a mixture of closely related liquids are easily ascertained from those of the pure components, and the composition of the vapour bears a simple relation to that of the liquid.

The vapour pressure of the mixture is given, at any rate with a very close approach to accuracy, by the equation

$$P=\frac{mP_A+(100-m)P_B}{100},$$

where P, P_A, and P_B are the vapour pressures of the mixture and of the components, A and B, at the observed boiling-point, and m is the molecular percentage of A.

Van der Waals concluded from theoretical considerations that this relation should be true when the critical pressures are equal and the molecular attractions agree with the formula proposed by Galitzine and by D. Berthelot, $a_{1\cdot2}=\sqrt{a_1 \cdot a_2}$, where $a_{1\cdot2}$ represents the attraction of the unlike molecules and a_1 and a_2 the respective attractions of the like molecules. That is certainly the case with chlorobenzene and bromobenzene, which, as already mentioned, show no heat or volume change on admixture, for the maximum difference between the observed and calculated pressure in three experiments was less than 0·1 per cent.

But the relation is, at any rate, very nearly true for closely related substances when the critical pressures are not equal, for in the case of methyl and ethyl alcohol the difference between the observed and calculated pressure was within the limits of experimental error, and with four other pairs of closely related substances the greatest mean difference (for three readings each) was only 0·6 per cent. It is not, however, as Speyers suggested, true for all non-associated substances, whether closely related or not; indeed, chemical relationship seems to be much more important than the state of molecular aggregation, for the relation is true for methyl and ethyl alcohol, while it is altogether untrue for benzene and hexane.

The boiling-point of a mixture of closely related liquids may be ascertained from the vapour pressures of the components, but not so simply as in the case of non-miscible liquids, because the boiling-point depends on the composition of the liquid.

In order to calculate the boiling-points of all mixtures of two closely related liquids under normal pressure we should require to know the vapour pressure of each substance at temperatures between their respective boiling-points under that pressure. Thus, chloroform boils at $132^{\circ}\cdot0$, and bromobenzene at $156^{\circ}\cdot1$, and we must be able to ascertain the vapour pressure of each substance between 132° and 156°.

The percentage molecular composition of mixtures which exert a vapour pressure of 760 mm. must then be calculated at a series of temperatures—say every two degrees—between these limits by means of the formula $m=100 \cdot \frac{P_B-P}{P_B-P_A}$, where, in this case, $P=760$.

Lastly, the molecular percentages of A, so calculated, must be mapped against the temperatures, and the curve drawn through the points will give us the required relation between boiling-point and molecular composition under normal pressure. In the case of six pairs of closely related liquids the greatest difference between the observed temperature and that read from the curve constructed as described was $0^{\circ}\cdot27$.

For liquids which are not closely related the differences are usually much greater, and particular mixtures of constant (minimum or maximum) boiling-point are not unfrequently met with, especially when the molecules of one or both substances are associated in the liquid state.

The formula for the composition of the vapour from a mixed liquid suggested independently by Berthelot and by Wanklyn, $\frac{x_A}{x_B}=\frac{W_A P_A D_A}{W_B P_B D_B}$, (where x_A and x_B, P_A and P_B, D_A and D_B, have the same meaning as in the equation for non-miscible liquids, and W_A and W_B are the relative weights of the two components in the liquid mixture), was shown by F. D. Brown to be incorrect, and he proposed the simpler formula, $\frac{x_A}{x_B}=c\frac{W_A}{W_B}$, where c is a constant which does not differ greatly from $\frac{P_A}{P_B}$. The subject was investigated mathematically by Duhem and by Margules, and experimentally and mathematically by Lehfeldt and by Zawidski. The two last-named observers deduced workable formulæ from the fundamental equation of Duhem and Margules, and it is noticeable that both Lehfeldt's and Zawidski's formulæ, in their simplest form, become identical with Brown's. Zawidski's, however, assumes the form $\frac{x_A}{x_B}=\frac{P_A}{P_B}\cdot\frac{W_A}{W_B}$. This formula is certainly not, as a rule, true for mixtures of liquids which are not closely related; but, on the other hand, in the very few cases examined the equation $\frac{x_A}{x_B}=c\cdot\frac{W_A}{W_B}$ appears to hold for those mixtures for which the equation

$$P=\frac{mP_A+(100-m)P^B}{100}$$

is true; that is to say, generally, for closely related liquids.

The question, however, whether $c=\frac{P_A}{P_B}$ is an open one; but it is interesting to remark that if this equality holds it should be possible in many cases to calculate the vapour pressure at any temperature, the boiling-point under any pressure, and the composition of the vapour, of any mixture of two very closely related liquids, if the boiling-point of one of them under any one pressure, and the vapour pressures of the other within sufficiently wide limits of temperature, are known. For the boiling-points on the absolute scale of the two liquids at the same pressure bear a constant ratio to

each other, or $\frac{T_A}{T_B} = \frac{T'_A}{T'_B}$; hence the vapour pressures or boiling-points of one substance can be calculated if those of the other are known. Again, from the vapour pressures of the pure substances we can calculate the vapour pressures and the boiling-points of all mixtures; and, lastly, if $c = \frac{P_A}{P_B}$, we can make use of Brown's formula, $\frac{x_A}{x_B} = c\frac{W_A}{W_B}$, to calculate the composition of the vapour from all mixtures without carrying out special experiments to find the value of c. It is, therefore, a matter of considerable interest to ascertain whether c is really equal to $\frac{P_A}{P_B}$ or not.

When the equation

$$P = \frac{mP_A + (100 - m)P_B}{100}$$

does not hold good, a modification of Brown's formula, or that of Lehfeldt, or of Zawidski, must be employed to calculate the vapour composition, and the constants for those formulæ must first be determined experimentally.

Other physical properties, such as the refractive power of mixtures, might be considered, but I will only refer to the critical temperature and pressure. In 1882 Pawlewski stated that the critical temperature of a mixture could be calculated from those of the components by the formula

$$\theta = \frac{m\theta_A + (100 - m)\theta_B}{100},$$

where m is the percentage *by weight* of A; and G. C. Schmidt, in 1891, carried out experiments to test the correctness of the statement, purposely choosing substances of widely different physical properties. The differences between the calculated and observed temperatures were not, as a rule, very great, rarely exceeding 4°, and Schmidt considered that they might, to some extent, be accounted for by partial decomposition of one or other component.

Such determinations are, however, liable to serious errors. It is exceedingly difficult to fill a tube with the required amount of a liquid mixture of known composition quite free from air, and although the composition of the very small amount of liquid employed might be determined after the experiment from its specific refractive power, it would be necessary to know the specific refractive powers of the two components and of mixtures of them. Schmidt does not state how he prepared his mixtures and determined their composition.

Again, when a liquid mixture is heated in a sealed tube, fractionation goes on, so that the more volatile component tends to accumulate in the upper part of the tube, leaving the less volatile component in excess below, and unless a stirring arrangement, such as that devised by Kuenen, is employed, many hours would elapse before complete admixture by diffusion took place at the critical point.

By far the most important and accurate experiments on this subject have been carried out by past or present pupils of Prof. Kamerlingh Onnes, notably by Prof. Kuenen; and it is quite certain that the formula of Pawlewski cannot be generally true for mixed liquids, for, just as we may have mixtures of minimum or maximum boiling-point, so also, as Kuenen has shown, mixtures of minimum or maximum critical temperature may exist. Thus the critical temperature of carbon dioxide is 31°·1, and of ethane, 32°·0, but that of a mixture containing 30 molecules per cent. of carbon dioxide is 18°·8. The question remains, however, whether some such law as that proposed by Pawlewski may not hold good for closely related substances. In certain cases, when the relationship is very close (for example, C_6H_5Cl and C_6H_5Br), the critical pressures are equal, or very nearly so, and it seems probable that the critical pressure would be the same for any mixture as for the components. Such a case as this would be likely to give the simplest possible relation between the critical temperatures of a mixture and those of its components; and although the critical temperatures of these substances are inconveniently high, there are, no doubt, others which might be employed —perhaps ethyl chloride and bromide, or possibly carbon dioxide and carbon disulphide. I imagine, however, that Pawlewski's formula would be more likely to hold if m represented the *molecular percentage*, and not the percentage *by weight* of A.

In the case of homologous compounds, paraffins, ethers, esters, and so on, the critical pressures are not equal, and it would be necessary to find whether the critical pressures of mixtures are represented by the formula

$$P = \frac{mP_A + (100 - m)P_B}{100}$$

(where m is the molecular percentage of A), and also whether any such simple formula is applicable to the critical temperatures.

Kuenen has made some observations with mixtures of ethane and butane containing 2·5 and 5 molecules per cent. of butane, and at the conclusion of his paper he says: "If there was a simple law connecting the critical constants of mixtures with those of the constituents, we might calculate the constants for the second substance [those of the first being known]. But such is not the case. Pawlewski's law that the critical temperature is proportional to the composition, expressed in weight units, is very inaccurate, the deviations being sometimes considerable in both directions."

It would, I think, be of great interest if Prof. Kuenen could find time to carry out further experiments with mixtures of ethane and butane in order to settle this point, or, perhaps, with *n*-hexane and *n*-octane, both of which can be more easily obtained in a pure state.

From what has been said it may be concluded that, in order to ascertain the normal behaviour of pure substances under different conditions, or to find the simplest relations between the boiling-points, molecular volumes, or other physical constants of a series of substances, or, again, to ascertain the normal behaviour of substances when mixed together, and the properties of the mixtures as compared with those of the components, it is undoubtedly advisable—at first, at any rate—to confine our attention to substances of which the molecules show no signs of association in either the gaseous or liquid state.

In the case of mixtures it is also best to begin with substances which are chemically closely related to each other.

SECTION C.

GEOLOGY.

OPENING ADDRESS BY AUBREY STRAHAN, M.A., F.R.S., PRESIDENT OF THE SECTION.

It is forty-two years since the British Association last met in Cambridge, and we may turn with no little interest to the record of what was taking place at a date when the science of Geology was still in its infancy, and in a University where its promise of development was first recognised. Dr. John Woodward, the founder of the Woodwardian Chair, had been dead 176 years, but his bequest to the University had not long begun to bear fruit, for the determination to house suitably the collection of fossils and to provide for the reading of a systematic course of lectures was not arrived at until 1818. In that year Adam Sedgwick, on his appointment to the Woodwardian Chair, began a series of investigations into the geology of this country, which made one of the most memorable epochs in the history of British Geology. At the Cambridge meeting of 1862 he had therefore held the professorship for forty-four years, a period sufficient to spread his reputation throughout the civilised world as one of the pioneers of geological science.

Towards the close of his life Sedgwick gave expression to the objects which he had had in view when he accepted a professorship in a science to which he had not hitherto specially devoted his attention. "There were three prominent hopes," he writes, "which possessed my heart in the earliest days of my Professorship. First, that I might be enabled to bring together a Collection worthy of the University, and illustrative of all the departments of the Science it was my duty to study and to teach. Secondly, that a Geological Museum might be built by the University, amply capable of containing its future Collections; and lastly, that I might bring together a Class of Students who would listen to my teaching, support me by their sympathy, and help me by the labour of their hands."

We, visiting the scene of his labours more than thirty years after he wrote these words, witness the realisation of Sedgwick's hopes. The collection is not only worthy of the University, but has become one of the finest in the kingdom. It is housed in this magnificent memorial to the name of Sedgwick, on the completion of which I offer for myself, and I trust I may do so on behalf of this Section also, hearty congratulations to the Woodwardian Professor and his staff. Finally, I may remind you that at this moment the Directorship of the Geological Survey and the Presidential Chair of the Geological Society are held by Cambridge men; that the sister University has not disdained to borrow from the same source; and lastly, that it is upon Cambridge chiefly that we have learned to depend for recruiting the ranks of the Geological Survey, as proofs that Cambridge has maintained her place among the foremost of the British schools of Geology.

Though he had taken a leading part at former meetings of the Association, Sedgwick's advanced age in 1862 necessitated rest, and this Section was deprived to a great extent of the charm of his presence. It benefited, however, in the fact that the Presidential Chair was occupied by one of his most distinguished pupils. Jukes was one of those men the extent of whose knowledge is not readily fathomed. It has been my experience, and probably that of many others in this room, to find that some conclusion, formed after prolonged labour and perhaps fondly imagined to be new, has been arrived at years before by one of the old geologists. Such will be the experience of the man who follows Jukes's footsteps. Turning to his Address given to this Section in 1862, we find much of what is now written about earth-movement and earth-sculpture forestalled by him, with this difference, however, that whereas the custom is growing of using a phraseology which may sometimes be useful, but is generally far from euphonious, and not always intelligible, he states his arguments in plain, forcible English.

It may raise a smile to find that Jukes thought it necessary in 1862 to combat the view that deep and narrow valleys had originated as fissures in the crust of the earth, and that the Straits of Dover must have been formed in this way, because the strata correspond on its two sides. But we shall do well to remember that the smile will be at the public opinion of that day, and not at Jukes himself. In no branch of Geology have our views changed more than in the recognition of the potency of the agents of denudation. In 1862 it was necessary to present preliminary arguments and to draw inferences which in 1904 may be taken as granted.

The evidences of the prodigious movements to which strata have been subjected, and of the extent to which denudation has ensued, cannot fail to strike the most superficial observer. Both mountain and plain present in varying degree proof that sheets of sedimentary material originally horizontal are now folded and fractured. But after a momentary interest aroused by some example more striking than usual, glimpsed, it may be, from a train-window, the subject is probably dismissed with an impression that such phenomena are due to cataclysms of a past geological age, and have little concern for the present inhabitants of the globe. These stupendous disturbances, it might be argued, can only have taken place under conditions different from those which prevail now. We are familiar with mountain-ranges in which their effects are conspicuous; we have carried railways over or through them and have been troubled by no cataclysmic movements of the strata. Apparently the rocks have been fixed in their plicated condition, and are liable to no further disturbance. Parts of the world, it is true, are subject to earthquakes accompanied by fissuring and slight displacement of the crust, but not even in earthquake regions can we point to an example of such thrusting and folding of the strata being actually in progress as have taken place in the past. Nor, again, can volcanic activity be appealed to, for some of the most highly disturbed regions are devoid of igneous rocks. Volcanic eruptions are more probably the effect than the cause of the disturbances of the crust. Nowhere in the world therefore, it will be said, can we see strata undergoing such violent treatment as they have experienced in the past. How, then, can we dispute the inference that the forces by which the folding was produced have ceased to operate?

Before accepting a conclusion which would amount to admitting that the globe is moribund and that the forces by which land has been differentiated from sea have ceased to act, we shall do well to look more closely into the history of the earth-movements to which any particular region has been subjected. The investigation is one which calls for the most intimate knowledge of the geological structure, and, as time will admit of my dealing with a small area only, I shall confine my observations to England and Wales, selecting such facts as have been established beyond dispute.

At the outset of the investigation we find reason to conclude that the movements, so far as any one region is concerned, have been intermittent. Evidence of this fact is furnished wherever any considerable part of the geological column is laid open to view. Sheets of sediment, aggregating perhaps thousands of feet in thickness, have been laid down in conformable sequence, all bearing evidence of having been deposited in shallow seas. The inference is inevitable that that period of sedimentation was a period of uninterrupted subsidence. But sooner or later every such period came to an end. Compression and upheaval took the place of subsidence, and the strata lately deposited were plicated and brought within the reach of denudation. Illustrations of the recurrence of these movements abound, and I need dwell no further upon them than to remark that movements of subsidence and upheaval may be seen to have alternated wherever opportunity is afforded for observation.

On extending our observations we are led to infer that the movements of the crust were developed regionally, not universally. The areas of subsidence, for example, evidenced by the marine formations, had their limits, though those limits did not coincide with the shores of existing seas, nor has reason been found to believe that the proportion of land to sea has varied greatly in past times. The limits of the area affected by any one movement of upheaval are more difficult to determine, but the effects were manifested in the crumpling up of comparatively narrow belts of country, and are easy of recognition.

Further than this, we ascertain that the movements of one region were not necessarily contemporaneous with those of adjoining regions. The forces operating upon the crust of the earth came into activity in different places at different times, and, while some continental tracts have been but little disturbed from early geological times, there are parts of the globe which have been the scene, so to speak, of almost ceaseless strife. Among the latter we may include the British Isles.

These are commonplaces of Geology, and I mention them merely to emphasise the fact that the geological structure of these islands is the result of movement superimposed upon movement. Obviously, therefore, in order to gain a comprehensive view of the operations which were in progress in any one region during any one epoch, we have to find some means of distinguishing the movements of that epoch and of eliminating all which preceded or followed it. This, briefly, is the problem which has engaged the attention of geologists for many years past, and upon which I propose to touch.

The determination of the age of a disturbance is seldom easy, and among the older Palæozoic rocks is often impossible; but at the close of the Carboniferous period, during the great continental epoch which led to and followed upon the deposition of the Coal Measures, there came into action a set of movements of elevation and compression which generally can be distinguished both from those which preceded them and from those which have been superimposed upon them. The distinction depends upon the determination of the age of the rocks affected by the movements. For example, a movement by which the latest Carboniferous rocks have been tilted from their original horizontal position is obviously post-Carboniferous. On the other hand, if Permian rocks lie undisturbed upon those tilted Carboniferous rocks it is equally obvious that the movement was pre-Permian. Now it happens that earth-movements of the date alluded to were particularly active in the British Isles, and played an important part in shaping the platform on which the Permian and later rocks were laid down. Though they have been more completely explored than others in the working of coal, their further investigation is of the greatest economic importance. I have attempted, therefore, briefly to sketch out the principal lines along which earth-movements of that age came into operation in England,

premising, however, that by Permian I mean the Magnesian Limestone series, and not the "Permian of Salnpian type," which is now known to be partly of Triassic but principally of Carboniferous age. In the course of the investigation we shall find reason to conclude that several at least of the movements followed old axes of disturbance, lines of weakness dating from an early period in the history of the habitable globe; and, again, that some of the latest disturbances of which we have cognisance were but renewals of movement along the same general lines.

One of the most clearly proved examples of pre-Permian faulting in the Carboniferous rocks occurs in the Whitehaven Coalfield. The fault forms the south-eastern limit of the Coal Measures, and has been precisely located for a distance of six miles. In its course towards the south-west it passes under five outliers of Permian rocks, and finally is lost to sight under the Permian and Trias of St. Bees. The dislocation in the Carboniferous rocks amounts to about 400 yards, but the Permian rocks have not been even cracked; though broken and displaced by numerous faults of later date, they pass undisturbed over this great dislocation, the movement along it obviously having ceased before they were deposited. This fault forms part of the upheaval which brought the older rocks of Cumberland and Westmorland to the surface, and in that sense it may be said to form the north-western frontier of the Lake District.

On the north-eastern side also of the Lake District the Permian rocks rest upon uptilted Carboniferous strata, but the axis of upheaval runs in a north-north-westerly direction and defines what we may regard as the north-eastern frontier. Along this frontier much movement has taken place in post-Permian times, but the unconformable relations of the Permian and Carboniferous rocks enable us to distinguish that part of the tilting which intervened between the two periods. On the south-eastern frontier also the Carboniferous rocks had been upheaved and denuded before the Permian sandstones were laid down. A huge fault, along which Carboniferous rocks have been jammed from the east in a multitude of plications against Silurian, runs from Kirkby Stephen by Dent to Kirkby Lonsdale, and thence trends south-eastwards by Settle. It is highly probable, though it has not been proved, that this fault is of pre-Permian age. That the Pendle axis which upheaves the Lower Carboniferous rocks between Settle and Burnley is pre-Permian is placed beyond doubt by the fact that an outlier of Permian rests upon the denuded crest of the anticline near Clitheroe.

The south-western frontier is defined by a still more marked unconformable overlap by the Permian strata, which here pass over the edges of the lowest members of the Carboniferous series and come to rest upon the Lake District rocks.

We have thus defined the sides of an oblong tract which was upheaved in the period we are considering. The older rocks forming the northern part of that tract had already had imposed upon them a dominant north-easterly strike by a pre-Carboniferous movement of great energy. As a result also of that and other movements they had been subjected to vast denudation, not only in the Lake District, but throughout the north-west of England generally. But while it is doubtful whether any of the physical features then produced have survived, it seems to be beyond dispute that it was in consequence of the pre-Permian movements that the older rocks of the Lake District were freed from their Carboniferous covering, and that to this extent the district may be said to have been blocked out in pre-Permian times. The detailed sculpturing resulted from later movements, with which we are not now concerned.

During this same period there rose into relief that part of the Pennine axis which runs between Lancashire and Yorkshire. The doming up of the Lower Carboniferous rocks and the wildness of the moorlands which characterise their outcrops have impressed all who have had occasion to cross from the one populous coalfield to the other, and have gained the name of the "backbone of England" for this anticlinal axis. Whether, however, it can be regarded as one axis or as the result of several movements is doubtful, but not material for our present purpose. Regarded as a geological structure it is not continuous with that part of the Pennine axis which runs along the north-eastern frontier of the Lake District.

Passing westwards from the Pennine axis we cross the deep and broad Triassic basin of Cheshire, which may be regarded as the complement of the dome of elevation of Derbyshire. To the west of this, again, we reach a part of North Wales which was more or less shaped out by the earth-movements which came into action between the Carboniferous and Permian periods. Two leading faults traverse the district. The one runs in a north-north-westerly direction across Denbighshire and introduces that little bit of "Cheshire in Wales" known as the Vale of Clwyd. Though there has been some later movement along this fault, it was in the main pre-Triassic, which statement, in view of the perfect conformity between the Permian and Trias, amounts to saying that it was pre-Permian. The other passes across Wales in a north-easterly direction along the Dee Valley at Bala, and reaches the Triassic basin between Chester and Wrexham. The date of this fault has not been worked out in detail, but the fact that it is associated with a pre-Triassic anticline, where it reaches the Triassic margin, proves that it is in part at least of pre-Triassic age. In Anglesey also there has been strong post-Carboniferous folding in the same N.E.–S.W. direction.

It is to be noticed, further, that the Carboniferous rocks maintain their characters to their margins on the flanks of the Clwydian Hills and other ranges of Silurian rocks in North Wales. Both along the coast, and even in a little outlier preserved near Corwen by an accident of faulting, they show a persistence of type and of detail in sequence which could hardly have been maintained had the Silurian uplands existed in Carboniferous times. The inference that the uplands of Denbighshire and Flintshire are the result of post-Carboniferous upheaval is strengthened by the fact that the Carboniferous rocks reposing on their flanks are tilted at an angle which would carry them over their tops. This part of North Wales, therefore, presents a history corresponding in its main events with that of the Lake District. It had undergone elevation and denudation in pre-Carboniferous times on a scale so vast that rocks showing slaty cleavage and other indications of deep-seated metamorphism had been laid bare. But in both cases it was in consequence of the post-Carboniferous movements that the leading physical features as they exist to-day began to take shape.

In both these regions pre-Carboniferous movements had been extremely active. For example, an axis of compression and upheaval ranges from N.E. to S.W., involving the Lake District, the Isle of Man, and Anglesey. It belongs to the Caledonian system of disturbances which is developed on a large scale further north, and which sufficed here to cause slaty cleavage and presumably the extrusion of the Shap granite. I mention this pre-Carboniferous axis to point out that it offers an explanation of the direction taken by the post-Carboniferous disturbances of Whitehaven, Pendle, Anglesey, and possibly Bala. With the exception of the last-named they lie well within the region affected, and alone among the post-Carboniferous axes take that particular direction.

The Pennine axis ends as a physical feature in South Derbyshire and North Staffordshire on the margin of a deep channel filled with Triassic marl, which extends westwards from Nottingham into Shropshire. In this part of England there springs into existence a remarkable series of disturbances tending to radiate southwards. The westernmost of these is the great fault which forms the western boundary of the North Staffordshire Coalfield. Recent work by Mr. W. Gibson has shown that the vertical displacement of the Coal Measures amounts to no less than 900 yards, but that it is far less, though recognisable, in the Trias, proving that the disturbance was in the main pre-Triassic. The fault ranges from Macclesfield in a south-south-westerly direction, is lost to view under the Trias near Market Drayton, but it is recognisable further on in the great dislocation which passes along the western side of the Wrekin, and thence through Central Shropshire by Church Stretton to Presteign in Radnorshire, and thence into Brecknock.

The second is the Apedale Fault of the North Staffordshire Coalfield. In working the coal this disturbance has

been found to possess the structure of a broken monocline, a fold with fracture such as may be regarded as an early stage in the formation of an overthrust from the east. It runs through the coalfield in a direction slightly east of south, and then passing under the Trias of Stafford ranges for Wolverhampton and Stourbridge. This fault is mainly pre-Triassic, but what Mr. Gibson believes to be a continuation of it, following the same direction as far south as Hanbury, certainly effects a great movement in the Trias.

The third disturbance runs on the east of the Forest of Wyre Coalfield in a direction a little west of south. Here, as I learn from Mr. T. C. Cantrill, the thrust from the east is obvious, for Old Red Sandstone has been pushed from that direction against and even over Coal Measures, while the strata have been forced up into a vertical position for some miles. In South Staffordshire all the Carboniferous rocks, including the "Salopian Permian," are involved in this and the previously mentioned movement, proving that both disturbances were of post-Carboniferous date.

Traced southwards this disturbed belt leads to Abberley, and there connects itself with the well-known Malvernian axis. The broken belt known by that name runs north and south, and may be followed almost continuously from Worcestershire to Bristol. It presents evidence of having been a line of weakness through a large part of the world's history, as shown by Prof. Groom, and of having yielded repeatedly to earth-stresses; but there is seldom difficulty in distinguishing the movements which were effected during the period under consideration. For example, near and south of Abberley the Coal Measures are clearly involved in a thrust from the east, which was sufficiently energetic to turn over a great belt of Old Red Sandstone and other rocks beyond verticality for some miles. Further south, again, among repeated proofs of the ridging up of the old axis in several pre-Carboniferous periods, we find evidence of post-Carboniferous elevation along the same general line. Throughout this same region there has been also post-Triassic dislocation, which, however, is on a comparatively small scale. That the Carboniferous rocks were greatly disturbed before the Trias was laid down is proved by the great unconformity between the two formations.

The Malvernian axis continues southwards by Newent, but perhaps with diminishing intensity. On its west side a broad syncline rolls in the tract of Carboniferous rocks which underlies the Forest of Dean. The syncline trends north and south, and is shown to be of pre-Triassic age by the fact that the Triassic strata on the banks of the Severn do not share in the synclinal structure. Here we must leave the Malvernian axis for the present.

The fourth disturbance ranges along the Lickey Hills, which, diminutive as they are, tell a story of great geological significance. They range in a south-south-easterly direction, and in the fact that they are formed of extremely ancient rocks furnish evidence of immense upheaval. From the relations of these ancient formations to one another we may gather also that the upheaval was due to a recurrence of movement along the same axis at more than one geological date, but at the same time we find no difficulty in distinguishing that part of the movement which took place between Carboniferous and Triassic times, for the Coal Measures are tilted up on end along the flanks of the axis, while the Trias passes horizontally over all the tilted rocks. A clue to the southward extension of the axis under the Secondary rocks is furnished by some faulting as far as Redditch, here also there having been a renewal of movement on a small scale in post-Triassic times.

The fifth disturbance runs through Warwickshire, and includes the low ridge of ancient rocks which ranges through Atherstone and Nuneaton in a south-easterly direction. About fifteen miles to the north-east Archæan rocks form the parallel ridge or series of ridges of Charnwood Forest, while the intervening space is overspread by Trias, resting partly on Carboniferous and partly on older strata. The structure of the Carboniferous and older strata is dominated by what is known as the Charnian movement, which includes disturbances of several ages ranging in a south-easterly direction. That part of the movement which was post-Carboniferous is identifiable by the fact that Coal Measures are tilted on either side of the ridges of old rocks. They once overspread both ridges, but were removed by denudation as a consequence of upheaval before the Trias was deposited. It has been found also in working the coal, as I am informed by Mr. Strangways, that there are large faults having the south-eastward or Charnian direction which shift the Coal Measures, but do not break through the overlying Trias. The evidence, therefore, of a great Charnian movement having taken place during the period under consideration is conclusive. The disturbance ranges as a whole in the direction of Northampton, where in fact borings have reached the Charnwood rocks at no great depth.

The five great disturbances which I have briefly indicated tend to converge northwards, but their exact connection with the Pennine axis is not known. What may be only a part of that axis trends for Charnwood through a tract of Lower Carboniferous rocks exposed at Melbourne, between the Yorkshire and Leicestershire Coalfields, but the Triassic channel I have already mentioned intervenes, and the structure of the rocks underlying the red marl is unknown. The channel itself appears to be of Triassic age, for not only is the depth of marl in it suggestive of its having been a strait in the Triassic waters, but its northern margin has been found by Mr. Gibson to coincide with, and perhaps to have been determined by, faults known to be mainly of pre-Triassic age. One of these, with a downthrow of 400 yards to the south, runs from Trentham through Longton, and south of Cheadle, while another ranges from near Nottingham to the north of Derby.

We come now to the south-west of England, where we find striking proofs of a still more energetic movement than any yet mentioned having intervened between the Carboniferous and Triassic periods. The central part of the Armorican axis, as it has been called, after the ancient name of Brittany, trends nearly east and west, and keeps to the south of our South Coast; but we have opportunities in Devon and Cornwall of seeing some of the stupendous effects produced along its northern side. A belt of country measuring some 130 miles in width has been completely buckled up. Slaty cleavage was superimposed upon the intricate folds into which the strata were being thrown, while after or towards the close of these phenomena granite was extruded at several points along the belt of disturbance, a little north, however, of the line along which the oldest rocks were brought up to the surface. In Devon the Culm-measures are fully involved in the movement, but on the other hand the Permian strata, while containing fragments of the cleaved and metamorphosed rocks, are themselves wholly free from such structures. The age of the folding, cleavage, and extrusion of the granite is thus definitely fixed as having been subsequent to the deposition of the Culm-measures, but previous to that of the Permian rocks.

But we may fix the age still more closely. A broad syncline of Carboniferous rocks traverses Mid-Devon, and is succeeded northwards by an anticline and by an extrusion of granite at Lundy Island, the age of which, however, has not yet been definitely ascertained. Still further north in a series of folds and overthrusts which traverse the southern margin of South Wales we can recognise the last effects of the great Devonshire movement at a distance of not less than 130 miles from the central axis, the ground-swell, so to speak, subsiding as it receded from the distant storm-area. Here the higher Carboniferous rocks are involved, and thus prove that this part at least of the Armorican disturbance was of post-Carboniferous age.

In Dorset, Somerset, and Gloucestershire the Palæozoic rocks pass eastwards under Secondary formations, and are seen no more in the south of England. That the disturbance continues, however, is inferred from the fact that it has been traced across a large part of the continent of Europe in the one direction and across the south of Ireland in the other. The determination of its position therefore, and especially of the effects of its intersection with the Midland disturbances, is of the greatest importance in view of the possible occurrence of concealed coalfields under the Secondary rocks. One such intersection is open to observation.

The Malvern and Devonshire disturbances intersect in Somerset. On investigating their behaviour as they

approach we may notice in the first place that the subsidiary axes which form the northernmost part of the Devonshire disturbance in South Wales die away one after the other towards the east. Thus an east and west disturbance at Llanelly runs a few miles and disappears. The more important Pontypridd anticline, which traverses the centre of the coalfield, fades away near Caerphilly, while the coalfield itself terminates a little further east, its place on the same line of latitude being taken by the Usk anticline, which trends southwards and south-westwards. So far it might be inferred that the east and west folds die away on approaching the north and south Malvernian axis. But the Cardiff anticline, which lies south of and was more energetic than those mentioned, crosses the Bristol Channel and, emerging on the other side in a complicated region near Clevedon and Portishead, passes to the north of Bristol and holds its course right across the coalfield at Mangotsfield. The coalfield, however, lies in what is part of the Malvernian disturbance, for it occupies a syncline running north and south along the west side of the main axis of upheaval. Though the interruption is local and the strata recover their north and south strike to the south of it, yet the east and west axis obviously holds its course right through the Malvernian structure.

Still further south in the direction in which the east and west movements gradually increase in energy a series of sharp folds is well displayed in the coast of South Wales and in an island in the Bristol Channel, ranging for that part of the east and west disturbance which is known as the Mendip axis. This name has been applied to a series of short anticlines which are arranged *en échelon* along a line ranging east-south-east, but each of which runs east and west. Among them we may distinguish the Blackdown anticline, the Priddy anticline, the Penhill anticline, north of Wells, and the Downhead anticline, north of Shepton Mallet. With one exception they all die out eastwards after a course of two to ten miles, but the Downhead anticline holds its course into the Malvernian disturbance, the two engaging in a prodigious *mêlée* south of Radstock. From that much shattered region the Downhead anticline emerges, but the Malvernian axis is seen no more, and, so far as can be judged under the blanket of Secondary rocks, comes to an end.

Mention has been made of the fact that many of the subsidiary east and west folds die away on approaching the Malvernian axis. In a general way we may attribute their disappearance to the influence of the north and south movement, for it is commonly to be observed in these great belts of disturbance that they are composed of a number of parallel anticlines or elongated domes of upheaval, constantly replacing one another; it is a common feature also that these subsidiary folds replace one another not exactly in the direction in which they point, but that they lie *en échelon* along a line slightly oblique to it. The behaviour of the South Wales and Mendip folds is in accordance with these observations, and may be taken to indicate that the effects of the east and west disturbance reached further north in South Wales than they did in Somerset, or, in other words, that they failed to penetrate as far into the region where north and south movements were in progress as in the region where there were no movements of that direction.

The fact that the east and west folds keep their course across the north and south wherever the two actually meet comes out prominently, and supports the inference that they dominate the structure of the Palæozoic rocks which lie hidden beneath the Secondary rocks of the south and south-east of England. Somewhere under this blanket of later formations the east and west axis presumably intersects the other disturbances which traverse the Midlands. To ascertain where and how the intersections take place will be going far towards locating any concealed coalfields which may exist; but the knowledge can be obtained only by boring, and the number of such explorations as yet made is wholly insufficient. The majority have been made in search of water, and have been stopped as soon as a supply was secured. Near Northampton the older rocks were reached at a small depth on what is believed to be the underground continuation of the Charnian axis, and a boring at Bletchley traversed what is thought to have been a great boulder of Charnian rock, suggesting that the axis is not far off; but with these exceptions the counties of Oxford, Buckingham, Bedford, Huntingdon, Cambridge, and Norfolk are unknown ground. Yet under these counties the axes must run if they keep their course. Where exposed at the surface each post-Carboniferous syncline between two axes contains a coalfield. It remains to future exploration to ascertain whether similar conditions hold good under the Oolitic and Cretaceous areas of Central England.

In speaking of the north and south disturbances I have in more than one case stated that the post-Carboniferous movement was but a renewal of activity along an old line of disturbance. The fact is proved by the unconformities visible among the pre-Carboniferous rocks, and it is important for the reason that the geography of this part of the globe at the commencement of the Carboniferous period had been determined by these movements. It has long been known, for example, that the parts of the counties of Stafford, Warwick, and Leicester traversed by the axes of upheaval were not submerged till late in the Carboniferous period. On the other hand, some of the area lying immediately west of the Malvernian axis was submerged at an earlier date, as is shown by the existence of Carboniferous Limestone at Cleobury Mortimer and, in greater development, in the Forest of Dean. The borings near Northampton also proved the presence of Carboniferous Limestone, a fact which is in favour of the occurrence of concealed coalfields, in so far as it indicates that the whole Carboniferous series may have once existed there. It is remarkable that none of the borings in the south and east of England have touched Carboniferous Limestone, all having passed into older or newer rocks. The existence of that formation is neither proved nor disproved.

The determination of the age of these disturbances and a discussion of the pre-Carboniferous geography may seem at first sight to be only of scientific interest, but that problems of great economic importance are involved has been shown recently. It has long been known that the principal coal-seam of South Staffordshire deteriorates westwards as it approaches the pre-Carboniferous ridge evidenced in the neighbourhood of Wyre Forest. There seemed, however, to be no theoretical reasons why it should not keep its characters on either side of the fault which forms the western boundary of the South Staffordshire Coalfield, inasmuch as that fault came into existence after the deposition of the Coal Measures. A shaft recently sunk has proved the correctness of the inference. The seam has been found to be well developed to the west of the fault, and a considerable addition has been made to our productive coalfields.

So much has been written about the range of the Devonshire disturbance under the south of England that I shall add no more than a brief comment on some of the evidence on which reliance has been placed. We have seen that there has been some post-Triassic movement along old lines of disturbance in North Wales and the Midlands and along the Malvern axis. It is suggestive therefore to find that in the region which we believe to be underlain by the east and west disturbance, east and west folding forms the dominant structure of the Secondary and Tertiary rocks.

The anticlines of the Vales of Pewsey and Wardour, the London syncline, the Wealden anticline, the Hampshire syncline, and the anticline of the Isles of Wight and Purbeck, not only lie in the range of the axis, but show an increasing intensity southwards, towards what we may suppose to have been the most active part of that axis. A similar structure prevails in the Oolitic rocks also. They too had been thrown into east and west folds before the Cretaceous period, and this earlier set of movements also grew in intensity towards the south. It would seem then at first sight that the structure of the later rocks gives an easy clue to the structure of the older rocks buried beneath them. This is by no means the case. That the movements manifested in the Oolitic and Cretaceous rocks followed the same general line as the older movement admits of little doubt, but that the later structures correspond in detail with the earlier is improbable.

A brief examination of the region where the Carboniferous rocks disappear under the Secondary formations will give the grounds for this statement. There we find that the Trias passes over the complicated flexures of the Mendip axis in undulations so gentle as to prove that those flexures

had been completed before it was deposited. Nor again do the members of the Oolitic group of the rocks cropping out in succession further east show any such folds as those visible in the Carboniferous, and it is not until we have passed over a considerable tract of Secondary rocks in which there are no signs of east and west folding that we reach the anticlines of the Vales of Pewsey and Wardour. Nor can we then fit these folds in the Cretaceous formation on to any visible axes in the Carboniferous rocks. In these circumstances it would be unjust to suppose that such synclines and anticlines as those of the London and Hampshire basins, or of the Weald, coincide with previously formed synclines and anticlines in the older rocks. They give a clue to the position of the old axis, but not necessarily to the details of its structure. Yet it is upon the determination of the position of the older anticlines and synclines, and of their intersection with the north and south disturbances, that we must depend for locating concealed coalfields. So far but little has been done in the forty-eight years since the question was first mooted by Godwin-Austen. The existence of a coalfield in Kent has been proved, and what appears to be a prolongation of a disturbance from the Pas de Calais along the south-western side of it. The other borings which have reached the Palæozoic floor round London and at Harwich have thrown but little light on the details of its structure. By far the greater part of the ground remains yet to be explored.

In this brief review of the earth-movements of one period, as manifested in one small part of the globe, we have found reason to conclude that they were the result of compression and upheaval; that the crust yielded to the compression by overthrusting and buckling along certain belts; that these belts in the north of England and the Midlands ran for the most part north and south, diverging, however, to the south-west and to the south-east, while in the south of England they took an east and west direction and concentrated themselves along a belt of country which presents the phenomena of crushing on a stupendous scale. We have touched in two cases the flanks of a mountain-range, the Caledonian, which was built and ruined before the Carboniferous period; the Armorican, which was built after that period, and which, though it has stirred so recently as the late Tertiary period, and so energetically as to initiate the physical features and river-system of the south of England, yet expended the greater part of its energy before the Permian period. Lastly, we have found evidence, in the majority of cases, that the disturbances were but renewals of movement along lines of weakness long before established, and that in several cases there has been further renewal along the same lines during successive periods later than the one we have considered. With such a history before us, and with the knowledge that mountain-ranges have been built in other parts of the world by the upheaval of strata of almost recent date, we have more cause to wonder that the internal forces have left this quarter of the globe alone for so long, than reason to believe that they have ceased to exist. Changes of level, however, have taken place in comparatively recent times, and are now in progress. Though almost imperceptibly slow, they serve to remind us that a giant lies sleeping under our feet who has stretched his limbs in the past, and will stretch them again in the future. Nor in view of the fact that the structures I have described have only been revealed by the denudation of vast masses of strata does it seem unreasonable to suppose that they are deep-seated phenomena. The slow changes of level may be the outward manifestation of more complicated movements being in progress at a depth.

It is interesting to speculate on what appearance the globe would have presented had it not been enveloped in an atmosphere and covered for the most part with water. Owing to those circumstances it possesses the power of healing old wounds and burying old scars. In their absence we may suppose that the belts of crushing and buckling would have given rise to ridges growing in size at every renewal of movement, for they would have been neither levelled by denudation nor smoothed over by sedimentation. This globe, we may suppose, would have appeared to the inhabitants of another planet as being encompassed in a network, and we are prompted to ask whether our astronomers can distinguish in any other planet markings that may be attributable to this cause. I must remind you, however, how much more remains to be done than I have been able to touch upon to-day. The map [appended to the address] represents one episode only in a long series of events, and a series of such maps would be required to illustrate the first appearance of lines of weakness in the earth's crust, the subsequent renewals of movement along those lines, and the formation of new lines in successive geological periods. With the case thus set out we shall be justified in appealing to the physicists for an explanation of the restlessness of this globe.

NOTES.

THE Antarctic relief ship *Terra Nova* arrived at Plymouth on Sunday night last, and afterwards left for Sheerness. It will be remembered that the *Terra Nova*, in company with the *Morning*, was engaged in the expedition for the relief of the *Discovery*, which was ice-bound in the Antarctic Sea. The two relief ships left Hobart together, and first encountered pack ice on January 4. They saw the mastheads of the *Discovery* on January 8, and the crews of the three ships were engaged from that time until February 14 in blasting a passage through the 12 miles of ice which lay between the *Discovery* and open water. When they got within two miles of the *Discovery* the ice began to break up freely, and the task was quickly completed. The *Discovery*, having been supplied with coal by the *Terra Nova*, began her homeward journey, the two vessels during the early stages travelling in company. Subsequently the vessels parted owing to bad weather, but met again at the Auckland Isles. Thence they proceeded to Lyttelton and home.

THE first instalment of specimens collected by the National Antarctic Expedition in the *Discovery* has, according to the *Times*, arrived at the British Museum (Natural History). It consists of the collection of sealskins obtained by the expedition in the pack ice and in McMurdo Strait in the Polar summers of 1901–2, 1903–4. It is proposed to await the arrival of the *Discovery* before dealing with this instalment, which has been sent on ahead in order to ensure the proper preservation of the specimens; but the report which has been received with the collection indicates that the four species of true seals known to occur in the Antarctic are all represented. It is probable that the collection also contains one or more specimens of the elephant-seal from McMurdo Strait, a region where it was not hitherto known to exist. The remainder of the specimens collected by the expedition are coming home in the *Discovery*. On the arrival of the *Discovery*, the natural history specimens will be sent to the Cromwell Road Museum to be worked out, the trustees of the British Museum having, says the *Times*, undertaken the classification, description, and publication of the biological and geological results of the expedition.

WE much regret to have to announce the death, in his seventy-fourth year, of Dr. J. D. Everett, F.R.S., for thirty years professor of natural philosophy at Queen's College, Belfast.

WE note with great regret the death of the Rev. Dr. H. P. Gurney, principal of the Durham College of Science, Newcastle-upon-Tyne, which occurred on Saturday last through a fall while climbing in the Alps. Dr. Gurney, who did much to further the interests of science and education, became principal of the Durham College of Science in 1894, and was also professor of mathematics and lecturer in mineralogy in the same institution. In Newcastle he was a recognised leader in educational matters, and was a co-opted member of both the Newcastle and the Northumberland education committees, being particularly useful on the higher and other sub-committees.

It was arranged some time ago to promote a public memorial to Sir Thomas Browne, the author of "Religio Medici," and the executive committee to which was entrusted the work of carrying out the scheme has commissioned Mr. Henry Pegram, A.R.A., to make a statue for erection in the Haymarket, Norwich.

It is the intention of the Senate of the University of Heidelberg to establish a gold medal in honour of Prof. Kuno Fischer, and to award the same every five years for work on the history of philosophy in Germany.

According to the *Journal* of the American Medical Association, the sum of 500*l.* has been placed with the authorities of the University of Heidelberg to award a prize every three years for the best therapeutic achievement during the previous three years published first in German literature. The donor is Prof. Czerny, and the gift is in honour of the clinician Adolf Kussmaul, on whose birthday the prize is to be awarded.

A movement is on foot in Bombay, according to the *Pioneer Mail*, to provide a memorial to Mr. J. N. Tata, the munificent donor of the research institute in India, and a preliminary meeting to further the object was recently held, at which a provisional memorial committee was formed. It was resolved to call a public meeting to decide as to the best way of perpetuating the memory of Mr. Tata.

The title of *grand officier de la Légion d'honneur* has been conferred upon M. Tillaux, president of the Paris Academy of Medicine. Prof. Blondlot, well known for his researches with *n*-rays, has been promoted to be *officier*, and M. J. Liégeois becomes *chevalier*.

According to a Reuter telegram of Sunday last from Athens, violent and repeated earthquake shocks have been felt in the island of Patmos, causing severe damage. Several houses were destroyed in the villages.

The Alexandria correspondent of the *Daily Chronicle* reports that a severe earthquake, moving in a north-westerly direction, was felt at Suez early on Monday morning last.

The sixth International Zoological Congress opened at Berne on Monday last under the presidency of Prof. Studer, of Berne. The next congress will be held at Boston, Mass., in 1907.

The annual meeting of the Association of German Men of Science and Medical Practitioners is to be held this year at Breslau from September 18 to 24.

The department of medicine (under the chairmanship of Prof. Osler) of the forthcoming International Congress of Arts and Science which is to take place in connection with the St. Louis Exposition from September 19 to 25, is to be divided into the following twelve sections:—Public health, preventive medicine, pathology, therapeutics and pharmacology, internal medicine, neurology, psychiatry, surgery, gynæcology, ophthalmology, otology and laryngology, and pædiatrics. According to the *British Medical Journal* the following English medical men will take part in the proceedings, viz.:—Major Ronald Ross, C.B., F.R.S., in the section of preventive medicine; Sir Lauder Brunton, F.R.S., in that of therapeutics and pharmacology; Prof. Clifford Allbutt, F.R.S., in that of internal medicine; and Sir Felix Semon, C.V.O., in that of otology and laryngology.

The New York Board of Health has voted the sum of 2000*l.* to defray the expenses of a commission of experts whose duty it shall be to inquire into the prevalence of pneumonia, and to suggest means of checking the evil.

According to the *Westminster Gazette*, the formation of a National League for Physical Education and Improvement has been suggested, the object of which is to render assistance to all the bodies at present working for the health of the people to extend the benefits of training throughout the country. The movement is the outcome of the recently issued report of the committee on physical deterioration, upon which we commented last week, and it has, we understand, the support of many influential medical men and others.

An exhibition of mineral products and hydraulic machinery is to be held in Barcelona next month, and the time for receiving applications for space from intending exhibitors has been extended up to August 31. Exhibits themselves coming from abroad will be received even after the exhibition has been opened.

It is reported in *Engineering* that the Government has decided to establish a wireless telegraph station on the Marsden, about three miles from South Shields. The station, which is to be primarily used for securing communication with passing warships, will be erected on the edge of the cliffs, which command a view north and south for miles along the coast.

It is stated in the *Engineer* that experiments with electric motive power are to be carried out on the State railways of Sweden, and that to cover the cost of the same the sum of 23,500*l.* has been granted. The experiments are to be begun at the beginning of next year.

Dr. Max Uhle, who for some months past has been carrying on archæological explorations on the coast of Peru for the department of anthropology of the University of California, has, says *Science*, made new excavations at Ancon, in several parts of the so-called necropolis, with the view of determining the relative ages of the cultures represented by the different kinds of mummies and objects. After abundant material for this purpose had been obtained, excavations were made a short distance south of Ancon. Here, in a hitherto unsuspected deposit free from mummies, remains of an early culture distinct in character from any other in Peru were found. After completing his investigations at this spot, Dr. Uhle proceeded northward along the coast towards Supe or beyond.

M. Doumergue, the French Colonial Minister, has just sent, as a circular letter addressed to the governors of the different French colonies, a note drawn up by the Minister of Public Instruction pointing out the special interest attached to the study of the properties of radio-active substances. The governors are invited to undertake inquiries with a view to the discovery in the French colonies of mineral deposits containing radium. It is hoped that the governors will be able to secure the interested assistance of travellers and engineers, and in this way succeed in finding such mineral veins.

The Port Erin Biological Station has been more fully occupied by students during 1904 than in any previous season. Thirty-two workers have occupied tables since Easter, and at times the accommodation and resources of the institution have been severely taxed. The aquarium attached to the institution is becoming increasingly popular with the public. On one day last week (the record so far) 486 visitors were admitted.

Wireless telegraphy is now being turned to practical use for weather forecasting, and if advance is to be made in our knowledge of the law of storms, it is probably in this

direction that we must look. The *Daily Telegraph* has made the first venture in the direction, and its enterprise promises success in the future in affording information of the approach of bad weather. Disturbances are always traversing the Atlantic, and they follow a course from W. to E., or perhaps more often from S.W. to N.E. These storm areas exert a considerable influence on our weather, and if in the summer months they do not actually occasion gales of any strength they are the cause of the rains and unsettled weather which we experience. In the winter, when our coasts are often swept by severe gales, wireless telegraphy will probably be of considerable value in giving early intimation of the approach of storms, and as Marconi's system is improved, and the messages can be sent at greater distances from our shores, the advantage will be much enhanced. The Meteorological Council was some time since in correspondence with Lloyd's with respect to taking advantage of wireless telegraphy, but up to the present it has not been found possible to conclude any arrangements.

According to the *Lancet*, a paper was recently read before the Paris Academy of Medicine by MM. Raymond and Zimmer on the results of the application of a tube of radium containing five cubic centimetres to various patients suffering from nervous affections. In hysterical cases the results were *nil*, and the same was the case in musculo-spiral paralysis and acute facial neuralgia. Very remarkable results, however, were obtained as regards the painful phenomena of tabes. Peripheral pains were rapidly and completely relieved, and in several grave instances of gastric crisis great relief was obtained. These results induced the observers to try the effects of X-rays, and they consider that they met with great encouragement. These results are to be communicated at some future meeting of the academy.

We have received from Messrs. Brewster, Smith and Co. the following pieces of apparatus, which will be found exceedingly useful by workers in chemical laboratories:—A self-lighting Bunsen burner for lecture table use, in which a two-way cock first directs a stream of gas on some black platinum, which, becoming heated, raises the temperature of some fine platinum wires sufficiently for these to ignite the gas from the burner itself. A burette holder with a new form of screw-clamping arrangement which is easily and quickly adjusted, and is a decided improvement on the older forms. A small turbine motor, which may be worked from the usual high-pressure water supply at from 2000 to 4000 revolutions per minute, will be found very efficient in stirring and agitating operations. A circular wire which may be adjusted by a screw to the desired size acts very effectively in fastening a connecting tube on to a high-pressure water tap. An improved cheap form of Ramsay burner, with two forks for supporting the combustion tube at various heights above the burner, gives a very uniform flame along its entire length.

According to some experiments on the formation of ozone at high temperatures by Mr. J. K. Clement, published in the *Annalen der Physik*, vol. xiv. p. 334, no trace of ozone is formed when pure oxygen is passed over the conducting substance of a Nernst lamp electrically heated to a temperature of 2000°–3000° C. When a trace of nitrogen is present, however, the issuing oxygen liberates iodine from potassium iodide solution, and the author believes that most of the recorded observations of ozone formation at high temperatures are in reality due to the formation of small quantities of oxides of nitrogen.

"The Geology of the Country around Kingsbridge and Salcombe" is the title of a memoir issued by the Geological Survey in explanation of the new series geological maps 355 and 356. In it the author, Mr. W. A. E. Ussher, has fully described the rocks of this difficult area. In the northern part there is no doubt about the Devonian age of the slates and grits, which are grouped with the Dartmouth slates and the Meadfoot and Looe beds. In the southern part of the area there is a tract of highly altered sedimentary and basic rocks, of mica schists and quartz schists, together with green or hornblende-epidote schists. Much controversy has arisen concerning the age of these metamorphic rocks, and although the author appears inclined to regard them as altered Devonian, he has refrained from expressing any definite opinion with regard to them. His careful and detailed record of facts will greatly aid further research. There are brief descriptions of the New Red rocks of Thurlestone and Slapton, and of the Pleistocene and recent deposits.

Dr. J. A. Udden contributes an essay on the geology of the Shafter Silver Mine district, in Presidio County, Texas (*Bull.* Univ. Texas, No. 24). The district is composed of Carboniferous with possibly Permian rocks and Lower Cretaceous strata, the whole being invaded by intrusive bosses, dykes, and sheets of various igneous rocks including granite, diorite, andesite, and rhyolite, while extensive lava flows have covered about one-third of the land. The mineral deposits, comprising argentiferous galena, &c., occur in the Cibolo limestone, which is probably of Permo-Carboniferous age, and the Shafter Mine, the only successful silver mine in the State, has been profitably worked for nearly twenty years. In the present report attention is mainly directed to the Carboniferous and Cretaceous strata and their fossils, of which detailed records are given.

In reference to the paragraph in our issue of July 28 with regard to recent captures in England of examples of the striped hawk-moth (*Deilephila livornica*), Mr. F. H. Perry Coste writes to us from Polperro, Cornwall, stating that one of these insects was captured near that village on August 1. Its wings were so rigid that good setting was impossible, and this leads the writer to believe that, like all British members of the species, it was a migrant from the Continent. Our correspondent would be glad to hear whether any of the other recently taken specimens were in the same condition, and whether they were captured near the shore.

A remarkable instance of protective resemblance is described by Mr. L. J. Cole in a paper on pycnogonid arachnida published in vol. xxxi. (pp. 315–328) of the *Proceedings* of the Boston Natural History Society. The pycnogonids in general are long-bodied, long-limbed, spider-like creatures, somewhat recalling the stick insects in their fantastic contour. The form in question (*Anoplodactylus insignis bermudensis*) has this irregular bodily contour specially developed, and is further remarkable for its coloration of mingled pink and yellow. It thus corresponds very closely, both in form and colour, with a hydroid zoophyte (*Obelia marginata*) of common occurrence in the Bermuda sea, among the branches of which it lives. A coloured plate illustrates the striking resemblance between the two organisms.

The *Irish Naturalist* for August contains two botanical papers of considerable interest, the one, by the Rev. H. W. Lett, recording a new species of liverwort (*Adelanthus dugortiensis*) from Dugort, in the Island of Achill, and the

other, by Mr. C. Reid, announcing the discovery in the "elk-marl" of Lough Gur of remains of the submerged flowering plant *Naias marina*. The new liverwort, curiously enough, appears to be very similar to a species from Tierra del Fuego. The Naias, we may remind our readers, is now found living only in one spot in Great Britain, namely, Hickling Broad, but has been found fossil in several localities, although it was hitherto totally unknown in Ireland.

SEVERAL pamphlets dealing with forestry problems have been received from the United States Department of Agriculture. Discussing the future supply of railroad ties, Mr. H. von Schrenck, in a *Bulletin*, shows that timber of inferior quality is rendered as durable as that of a better quality by treatment with suitable preservative substances. A recent process, which is still in the experimental stage, makes use of a strong sugar solution in which the timber is boiled. With the adoption of softer timber, the method of fastening the rails requires consideration, and the respective forms of spikes, plates, and dowels are contrasted. In a *Bulletin* on the planting of white pine, Mr. H. B. Kempton compares the results obtained on four different woodlots, from which it is concluded that the expense of laying out a pure white pine plantation is considerable, but this may be reduced by planting less expensive seedlings, such as sugar maple, between, and these are cut down when thinning is required.

"A CRITICAL Revision of the Genus Eucalyptus" is the title of a memoir by Mr. J. H. Maiden, director of the Sydney Botanic Gardens, which has reached the fourth part. Two species, *Eucalyptus incrassata* and *Eucalyptus foecunda*, with varieties, are described and figured in a number of plates.

THE extension section of the Manchester Microscopical Society has just issued an attractive list of popular science lectures (fifty-four in all) which have been arranged for delivery by its members during the coming winter. The object of the scheme is to bring scientific knowledge, in a popular form, before societies which are unable to pay large fees to professional lecturers, the work of lecturing and demonstrating being gratuitous on the part of the members.

THE Department of the Interior of Canada has recently issued a "Dictionary of Altitudes in the Dominion of Canada," by James White, the work being a supplement to that author's "Altitudes in Canada." The arrangement is alphabetical, by provinces and territories, and the volume should be of service to engineers, surveyors, and others who wish to know the altitude of any place in the dominion.

VOL. i. of the second series of the *Proceedings* of the London Mathematical Society, which has just been published by Mr. F. Hodgson, of Farringdon Street, contains obituary notices of Profs. L. Cremona, G. Salmon, J. Willard Gibbs, and Mr. G. H. Stuart, in addition to the papers read before the society from January, 1903, to February, 1904.

THE volume for 1903 of the *Journal and Proceedings* of the Royal Society of New South Wales has just reached us. It is issued in this country by George Robertson and Co., of 17 Warwick Square, E.C.

WE have received a copy of a catalogue (published by R. . Brothers, Melbourne) of the fine collection of eggs and nests of Australian birds in the possession of Mr. D. le Souëf, director of the Melbourne Zoological Gardens.

OUR ASTRONOMICAL COLUMN.

THE RETURN OF TEMPEL'S SECOND (1873) COMET.—The comet Tempel$_2$ (1873), which has a period of about 5·28 years, made its last perihelion passage on July 28, 1899, and should, therefore, reappear during the later months of the present year. Although this object will be but of feeble intensity throughout the apparition, it should certainly be observable, therefore M. J. Coniel, of the Paris Bureau des Longitudes, has calculated a daily ephemeris for it from the following elements, which were computed by Mr. Schulof. This ephemeris, an extract from which is given below, covers the period July 29—October 25, and is published in No. 3962 of the *Astronomische Nachrichten*.

Epoch 1904 October 30·0 M.T Paris.

$$
\begin{aligned}
M &= 357^\circ\ 51'\ 49'' \\
\omega &= 185\ 44\ 39 \\
\Omega &= 120\ 59\ 52 \\
i &= 12\ 38\ 55 \\
\varphi &= 32\ 50\ 3\cdot7 \\
\mu &= 672''\cdot175 \\
\log a &= 0\cdot41868
\end{aligned}
\quad \left.\begin{matrix} \\ \\ \\ \end{matrix}\right\} 1904\cdot0
$$

In computing these elements the perturbations of Jupiter and Saturn have been taken into account.

Ephemeris 12h. (M.T. Paris).

1904	α (app.) h. m. s.	δ (app.) ° ′ ″	log Δ
Aug. 17	14 23 45	−4 9 10	0·2242
,, 21	14 31 13	−5 17 34	0·2268
,, 25	14 39 4	−6 26 33	0·2292

Sept. 2	14 55 53	−8 45 31	0·2336
,, 6	15 4 51	−9 55 4	0·2356

SPECTRA OF NEPTUNE AND URANUS.—The results of a photographic study of the spectra of Neptune and Uranus are given in No. 13 of the Lowell Observatory *Bulletins* by Mr. V. M. Slipher, reproductions of the photographs being given on an accompanying plate.

The spectrogram of Neptune extends from λ 4300 to D, and is compared with that of the solar type star β Geminorum. There is an apparent brightening, in the planetary spectrum, on the more refrangible side of *b* which seems to indicate intrinsic emission, but may be due to the contrast afforded by two strong absorption bands. Hβ is stronger in the Neptunian spectrum, and one photograph shows Hγ stronger, thereby indicating the presence of free hydrogen in the planet's atmosphere.

The spectrum of Uranus from F to λ 350 exhibits no departure from the normal solar spectrum, but on one photograph there is apparently a line in the position of D_3, indicating, if real, the presence of helium.

A comparison of the two spectra shows that although free hydrogen is present, in the atmosphere of Uranus it is not so abundant as in that of the outer planet. Three bands situated at λ 510, λ 543, and λ 577, respectively, are also stronger in the spectrum of the latter, thereby indicating that the atmosphere of Neptune is much more extensive than that of Uranus. The origins of these bands are at present unknown, unless the second and third are due to water-vapour, and Mr. Slipher suggests that they may be due to gases lighter than, but similar to, hydrogen and helium, which have not been recorded in stellar spectra because the temperature conditions in stars are, probably, unfavourably high.

THE VARIABLE RADIAL VELOCITY OF δ ORIONIS.—In a recent paper, Prof. Hartmann pointed out that the value which he obtained for the period of the "oscillations" of δ Orionis did not agree with those previously published by M. Deslandres.

The latter observer now shows, in No. 3963 of the *Astronomische Nachrichten*, that although the results are divergent the observations are confirmatory, for his result was based on very few observations, and is exactly one-third of the value obtained by Prof. Hartmann, the numbers being 1·92 and 5·73 (days) respectively. Prof. Pickering pointed out some time ago that periods of variable radial velocity which are derived from few observations are

likely to produce acceptable values, which may, however, be multiples or submultiples of the true values.

The intensity of the Meudon spectrograms about the region λ 393 is not sufficient to confirm, or refute, the observation of Prof. Hartmann that the "K" (calcium) line does not appear to share in the periodic displacements of the other lines in the spectrum.

The Solar Surface during 1903.—The annual report of the observations of solar phenomena made at the Lyons Observatory during 1903 appears in the August number of the *Bulletin de la Société astronomique de France*, wherein M. J. Guillaume gives comparative tables showing the numbers, areas, and distribution of spots and faculæ for the years 1900–1903 inclusive.

Of the 260 observing days in 1903 there were only thirty-eight on which "no spots" was recorded. Both the numbers and areas of spots show a marked increase on the previous year, the figures being 1902, 33 and 1785 millionths, and 1903, 115 and 8440 millionths. The mean latitude, for both hemispheres, during 1903 was 19°·3, in place of 15°·9 and 21°·2 for 1901 and 1902 respectively.

The groups of faculæ were fewer in number during 1903 than in 1902 (324 and 363 respectively), but their total area was a little more than twice as great (204·1 and 97·6 thousandths respectively), whilst their mean latitude was 27°·8, as compared with 38°·8 in 1902, and 35°·8 in 1901.

The preponderance of spots in the northern hemisphere remarked in 1901 and 1902 changed over to the southern hemisphere in 1903, the total areas during last year being S. 5071 millionths, N. 3369 millionths.

From the tables showing their distribution in latitude and longitude, one sees that the greatest augmentations of both spots and faculæ, in each hemisphere, took place in the same zones.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—Dr. Wm. Osler, F.R.S., has, with the King's approval, been appointed regius professor of medicine in succession to Sir John Burdon Sanderson, Bart., F.R.S. Prof. Osler has, since 1889, filled the chair of the principles and practice of medicine at Johns Hopkins University, Baltimore.

Cambridge.—In connection with the visit of the British Association, the degree of Doctor of Science, *honoris causa*, will on August 22 be conferred on the following:—J. O. Backlund, director of the Pulkova Observatory; Prof. H. Becquerel, Paris; Prof. J. W. Brühl, Heidelberg; Prof. A. Engler, Berlin; Prof. P. H. von Groth, Munich; P. Kabbadias, Athens; Prof. A. Kossel, Heidelberg; Prof. H. F. Osborn, New York; N. G. Pierson, Amsterdam; Prof. V. Volterra, Rome; Sir David Gill, K.C.B., F.R.S.; A. W. Howitt, the Australian anthropologist; Sir Norman Lockyer, K.C.B., F.R.S.; Major P. A. MacMahon, F.R.S.; Sir W. Ramsay, K.C.B., F.R.S.; Prof. A. Schuster, F.R.S.; Sir W. T. Thiselton-Dyer, K.C.M.G., F.R.S.

The first list of successful candidates for the university diploma in tropical medicine and hygiene has just been issued by the examiners (Sir P. Manson, Major Ross, and Dr. Nuttall). It includes the following:—A. R. Cleveland, A. R. J. Douglas, G. Elliott, P. N. Gerrard, C. M. Heanley, J. C. B. Statham, C. A. Suvoong, and J. C. Thompson.

Mr. S. A. McDowall, Trinity, has been appointed assistant to the superintendent of the Museum of Zoology (Dr. S. F. Harmer).

Dr. Albert S. Grünbaum, lecturer in experimental medicine at the University of Liverpool, and director of cancer research at Liverpool, has been appointed professor of pathology and bacteriology in the University of Leeds in the place of Prof. Trevelyan, who is retiring. Dr. George Wilson has been appointed to the newly created lectureship in civil engineering in the same university.

The syllabus for 1904–5 of the Redruth School of Mines shows that a successful local effort is being made to provide practical scientific training in mining to those engaged in this important Cornish industry. The main object of the School of Mines is to provide theoretical and practical instruction in mining and the allied subjects essential to the training of competent mining engineers. The training in practical mining is given at the Basset Mines and at other mines in the locality, under the general supervision of an instructor. The practical underground work includes the timbering of shafts and levels. Students are taught, in addition, the methods of prospecting for minerals in all positions, and are trained to detect favourable indications on the surface. They are shown by examples in the neighbourhood how to *costean* for lodes, and how to detect the effect of cross-courses and slides on the lodes. The differences between fissure veins, gash veins, and contact lodes are pointed out by examples; the manner in which the lodes are affected by passing through the different strata, and the effect the bearing of the lode has on its productiveness in certain districts. Studies are made of the maps of the neighbourhood, and opportunities afforded for examination of other mines now working, and for investigating, as far as possible, those that have been abandoned.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, July 25.—M. Mascart in the chair.—On a functional equation: Émile **Picard**.—Chemical and geological study of some springs in the north of Madagascar: Georges **Lemoine** and Paul **Lemoine**.—On some facts relating to the observation of variations in the lustre of phosphorescent sulphides under the action of *n*-rays or analogous phenomena: E. **Bichat**.—The academy was invited to send delegates to the second International Botanical Congress at Vienna, to be held from June 12 to 18, 1905.—On a relation between the minima and maxima of sun-spots: Alfred **Angot**.—On the singularities of the equation

$$y^1 = A_0 + A_1 y + A_2 y^2 + A_3 y^3:$$

Pierre **Boutroux**.—On the absorption of gases by wood charcoal at low temperatures: Sir James **Dewar**. The liquid air calorimeter is used to determine the heat liberated by the absorption of certain gases in charcoal, the volume absorbed being measured. With all gases except helium, the volume absorbed is greatly increased by low temperature. Absorption of gases with charcoal at low temperatures forms a good method of producing a vacuum.—On the nature of n and n_1 radiations, and on the radio-activity of the bodies which emit these radiations: J. **Becquerel**.—On the refraction of n- and n_1-rays: J. **Becquerel**.—On the contemplation in a dark room of surfaces feebly illuminated by certain special lights. The case of objects of linear form: F. P. **Le Roux**.—The phenomena of magnetic viscosity in soft industrial steels, and their influence on the methods of measurement: Raymond **Jouaust**.—Magnetic exploration of the Gulf of Padirac: E. **Mathias**.—On the earthquake of July 13, 1904, in the central Pyrenees: E. **Marchand**.—On the discharge of electricity in the air at the summit of the Eiffel Tower during the storm of July 24: A. B. **Chauveau**.—On the form taken by thallous iodide on being deposited from solution: D. **Gernez**.—On radio-active lead, radio-tellurium, and polonium: A. **Debierne**.—Action of zinc on the tungstates of sodium: L. A. **Hallopeau**.—On the acid pyrophosphate of silver: J. **Cavalier**.—On the composition of the homologues of Schweinfurt green: Georges **Viard**.—The heat of formation of the trisulphides of antimony: MM. **Guinchant** and **Chrétien**.—On polishing and connected scientific phenomena: F. **Osmond** and G. **Cartaud**.—On vinyldimethylacetic acid: E. E. **Blaise** and A. **Courtot**.—β-Oxyalkyl and β-oxyphenyl ethylene ketones. The action of hydroxylamine and phenylhydrazine: Ch. **Moureu** and M. **Brachin**.—The action of oxalacetic ether on aromatic aldehydes in the presence of β-naphthylamine: L. J. **Simon** and A. **Conduché**.—The action of acid chlorides on tertiary bases with an aromatic nucleus: V. **Auger**.—On the general arrangement of the nervous system in *Rissoa elata*, var. *oblonga* (Desmaret): G. **Quintaret**.—On the intracellular contents of the parenchyma of certain fruits: Wladimir **Tichomirow**.—On the anatomy of the tubers of *Euphorbia Intisy*: Marcel **Dubard** and René **Viguier**.—Contribution to the study of blight in tobacco leaves: MM. **Bouygues** and **Perreau**.—Researches on the

mechanism of respiratory combustion. The production of citric acid by *citromyces*: P. **Mazé** and A. **Perrier.**—On the law of Bravais and the reticular hypothesis: G. **Friedel.**—On the lode of heavy spar called "la Chandelette," near Villefort: Marcel **Guédras.**—On the evolution of the zone of sub-Carpathian depressions in Roumania: E. **de Martonne.**—The relation between seismic phenomena and the geological age of a chain or region: M. de Montessus **de Ballore.**—On the property possessed by certain portions of the human body of continually giving out a ponderable emanation: Julien **Meyer.**—New facts on the *rôle* of the nervous system in the function of the heart: Jean **Dogiel** and K. **Arkanguelsky.**—Toxic substances extracted from the eggs of the tortoise and of the hen: Gustave **Loisel.**—Researches on the poison of bees: C. **Phisalix.**—On the bactericidal properties of the secretions of parasitic worms: L. **Jammes** and H. **Mandoul.**—On the infectious nature of the anæmia of the horse: MM. **Vallée** and **Carré.**

August 8.—M. Mascart in the chair.—On the changes of curvature exhibited by the air bubble in spirit levels, under the influence of temperature variations: G. **Bigourdan.** A particular level, used on a telescope mounting, showed considerable variations in its constant with temperature. This was traced to the effect of the expansion of the metallic tube in which it was mounted, and the conclusion is drawn that for work of precision it is necessary to reject this form of mounting, and to use instead a nickel steel possessing an expansion equal to that of the glass.—The general equations of motion of sheets of water infiltrated through the soil: J. **Boussinesq.** A continuation of a previous paper on the same subject. Certain restrictions laid down in the first note are removed, and the results worked out to a higher degree of approximation.—On some results recently obtained by metrophotography: A. **Laussedat.** Some additional results obtained with the apparatus of Pulfrich by the method of parallaxes. In the Tyrol, two photographs, with a base of 254 metres, have proved sufficient to construct the greater part of a map of the district on the scale of 1/25,000, including mountains of a height of more than 3000 metres, and 8 kilometres distance from the base. The apparatus has also been successfully applied in Canada.—On the use of a movable reference tetrahedron in the geometry of Cayley: A. **Demoulin.**—On groups of the order p^m, of which all the subgroups p^{m-2} are Abelian: M. **Potron.**—On a theorem of M. Borel in the theory of integral functions: M. **Rémoundos.**—On the loss of electricity in the air observed at the summit of the Eiffel Tower during the storm of August 4: A. B. **Chauveau.**—The theory of dilute solutions, based on the law of van 't Hoff: É. **Ariès.**—On the permanence of crystalline forms in crystals: F. **Osmond** and G. **Cartaud.**—New researches on vanadium steels: Léon **Guillet.** Normal vanadium steels are not more fragile than ordinary steels containing the same percentage of carbon. They are very sensitive to thermal and mechanical treatment.—On some derivatives of pentabasic phosphoric acid: P. **Lemoult.**—On dimethylpyroarsenic acid: E. **Baud.**—On the existence of alkaline rocks in Central Africa: Louis **Gentil.**

NEW SOUTH WALES.

Linnean Society, June 29.—Dr. T. Storie Dixson, president, in the chair.—Descriptions of Australian Microlepidoptera, xviii., Gelechiadæ: E. **Meyrick,** F.R.S. This family forms a smaller proportion of the Tineina in the Australian region than it does in Europe, amounting, perhaps, to about 12 per cent. of the whole. As, however, the species are often retired in habit, small, inconspicuous, and rather difficult to study, they have been much neglected, and may perhaps prove eventually to be more relatively numerous than they seem at present. Fortunately only seven species were known to Walker, others assigned by him to this family being wrongly attributed. Mr. O. Lower has in late years described some number; he has very kindly transmitted specimens of all these (frequently the actual types) for examination, so that the author has been able to ascertain positively their identity in all cases; this assistance has been most valuable. Much material in specimens and notes of localities has also been received from him, as well as from Mr. G. Lyell, the late Mr. G. Barnard, and other collectors whose records are duly acknowledged in their place. Altogether 274 species are here recorded, of which 207 are now described as new. Of this total, 85 species, or not much less than a third, are included in the endemic genus Protolechia, but no other strictly endemic genus attains any large size, though 40 out of the 55 genera are endemic, so far as is known.—A variable galactan bacterium: Dr. R. Greig **Smith.** A bacterium isolated from the tissues of a species of Strychnos grew on gelatin as brittle moruloid colonies which contained an insoluble gum. Cultivation at 30° C. caused the organism rapidly to lose the faculty of forming this insoluble gum. A soluble gum was produced instead, and the colonies in consequence became gummy and otherwise uncharacteristic. The gums from both forms of bacteria were galactans, and differed only in solubility.—The red string of the sugar-cane: Dr. R. Greig **Smith.** Instances of the vascular strings of the sugar-cane being coloured a deep red from the presence of a red gum in the large vessels have been recorded in connection with certain diseases, such as sereh, the sugar-cane disease of Massee, the pine-apple disease of the cane, and red smut (red rot), in all of which it has been denied that bacteria produce the gum. The cases of red string investigated by the author occurred in apparently healthy plants, and also in canes affected with gummosis. The gum was produced by *Bacillus pseudarabinus*, n.sp., and the crimson colour was imparted to it by a mould. The co-existence of the two is essential for the production of the colour in the vessels of the sugar-cane. Both organisms are described in detail. The gum gave the reactions for arabin, but as it hydrolysed to galactose only it was a galactan.

NATURAL HISTORY.

Catalogue of the Library of the British Museum (Natural History). Vol. ii. E—K. Pp. 501–1038. (London: Published by Order of the Trustees, 1904.) Price 20s.

Catalogus Mammalium, tam viventium quam fossilium, Quinquennale Supplementum. By E. L. Trouessart. Fasciculus i. Pp. iv+288. (Berlin: Friedländer and Son, 1904.) Price 12s.

Our Country's Animals and How to Know Them; a Guide to the Mammals, Reptiles, and Amphibians of Great Britain. By W. J. Gordon. Pp. viii+152. (London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd., 1904.) Price 6s.

THOSE responsible for the preparation of the invaluable "Catalogue of the Library of the Natural History Museum" are to be congratulated on the comparatively short interval which has elapsed between the issue of the preceding volume and the appearance of the one before us. About half the works included in the library at the commencement of the undertaking are catalogued in the two volumes now before the public, so that two more volumes, with the addition of a supplement, ought to complete the work. Needless to say, the present volume is compiled on the lines of its predecessor. A feature to which we may direct attention is the printing of the entries in such a manner that they may, if required, be cut out so as to form a card catalogue, the names of authors being given in full with each entry. We venture to think, however, that it would have been better had a few copies been issued with the letterpress on one side only of the paper, so as to have been available for this purpose without the sacrifice of an extra copy. Another noticeable feature is the care with which the dates of publication of works issued in parts have been worked out—in many instances for the first time—whereby several amendments have been made in the commonly accepted dates of certain technical names. An instance of this is afforded in the case of the large series of French voyages entered on pages 606–608 under the heading of France, which contain in many cases original descriptions of species collected during the cruises in question. The bibliographical staff of the Natural History Museum deserves great credit for the accuracy and fulness of detail with which this work is compiled.

With Mr. Palmer's "Index Generum" (recently noticed in our columns) and Dr. Trouessart's work, when complete, the student ought to have little of which to complain in regard to facilities for reference to the literature of his subject. Not that such facilities were by any means uncalled for. During the last ten years or so the number of new generic, specific, and subspecific names proposed for mammals has been so great, and such sweeping changes (whether for better or worse we need not now pause to consider) in current nomenclature have been advocated, that, to use a colloquial expression, naturalists of a conservative type scarcely know where they are. It was, therefore, imperative that something should be done in the way of codifying, and that speedily. Dr. Trouessart, with characteristic energy, has stepped into the breach and supplied the want.

The second, and revised, edition of the author's well known "Catalogue" was published from 1897 to 1899, the last part containing an appendix. To include the additions and changes made since the latter date in an appendix would, however, have been almost a practical impossibility, and as an entirely new edition was considered out of the question, Dr. Trouessart has followed a kind of middle course by the compilation of the present "Supplement," of which the part before us contains the orders Primates, Chiroptera, Insectivora, and Carnivora. While every genus, species, and subspecies is entered, references to the original descriptions are given only in cases where the terms are new, or where they replace those previously in use; in other cases reference is merely made to the last edition of the "Catalogue." By this plan a vast amount of space is saved, without any inconvenience to the student—provided he has access to the original issue.

Dr. Trouessart professes to have brought his labours only down to January, 1903, but many names proposed later on in that year are entered. Nearly all recent proposed changes in nomenclature are adopted—even the transference from the squirrel-monkeys of the name Callithrix to the marmosets so long known as Hapale; but apparently the author will not accept pre-Linnean generic names, as he retains Trichechus for the walrus. Difference in spelling is considered insufficient to justify the use of the same term for two distinct species or groups.

Some idea of the magnitude of the task involved in the compilation of this supplement may be gleaned from the fact that, in the case of the Primates alone, the number of specific (exclusive of subspecific) names has been increased by thirty-five since the appearance of the last edition of the "Catalogue," while most of the genera have been the subjects of more or less important changes and revisions. As usual, Dr. Trouessart's work appears to be exceedingly accurate; as to its value to students, no words of ours are necessary. It is indispensable and unique.

We fear Mr. Gordon's little volume will give rise to a new "Irish grievance," for although Great Britain is alone mentioned on the title-page, the Irish stoat and the fossil vertebrates peculiar to the coal-fields of the sister island come within its scope. Neither is the title in another respect very happy, although we are fain to confess it would be difficult to find a single term to replace the word "animals" in the sense in which it is here employed. Like most other compilers of popular works of this nature, the author appears to be totally ignorant of the existence of that invaluable publication the "Zoological Record"; at all events, we are otherwise unable to account for his omission of any mention of the numerous subspecies of mammals now recognised by

 S

naturalists as peculiar to the British Islands, with the sole exception of *Mus sylvaticus wintoni*. One of the worst omissions of this nature is the absence of any reference to the marked distinctness of the British squirrel and its remarkable seasonal colour-changes. As regards nomenclature in general, we observe that while the author avoids such objectionable alliterations as *Vulpes vulpes* and *Lutra lutra*, he is in many respects—notably in the case of the bats—out of date.

In addition to existing types, the author also records extinct forms, but since the amount of descriptive matter allotted to these is very brief, the lists of genera and species are dismal and uninteresting. Nor are they free from error, Hyracotherium, for instance, being described as tapir-like, while Microchœrus is classed as an insectivore instead of as a lemur. Equally glaring are the errors in the list of fossil reptiles, where we find Ornithostoma among the crocodiles, the sauropod Bothriospondylus among the theropods, the theropod Palæosaurus in the sauropods, and many other errors of a similar type, in addition to numerous misprints.

The coloured illustrations, although not perhaps very artistic, are sufficient in most cases to enable the reader to identify the various species without difficulty, while the excellent glossary of technical terms should prove useful to the beginner. While welcoming this little volume as an honest attempt to popularise a knowledge of the British mammals and reptiles, we cannot but regret that the author did not seek specialist advice and assistance before going to press.

R. L.

PHILOSOPHY OF LIFE AND DEATH.

The Nature of Man: Studies in Optimistic Philosophy. By E. Metchnikoff. English Translation edited by P. Chalmers Mitchell, M.A., D.Sc. Pp. xviii+309. (London: W. Heinemann; New York: G. P. Putnam's Sons, 1903.) Price 12*s*. 6*d*.

PROF. METCHNIKOFF'S work is already known to many; it has been widely read in previous editions, and, now that it is offered in an English version, will become still more widely known. The great merits of the work have already been appreciated. The author is an acknowledged master of his subject, and no more fruitful source of valuable ideas could be imagined than a mind which combined with philosophical breadth and acumen an accurate and far-reaching knowledge of every grade of organism. One sees from the apt choice and effective use of examples how thoroughly the author has his materials at command.

If we might characterise with a word the central problem of the book, ethical would seem the term most appropriate. The key-words are harmony and disharmony; we ask sometimes, Why should we be moral? Prof. Metchnikoff's question is rather, Why do we need morality? The answer lies in the existence of disharmonies. The first part of the work deals with these disharmonies as a matter of scientific discovery; they are shown to exist in the structure of organisms throughout the vast scale of nature; not least do we find in man disharmonies of digestion, of reproduction, and of self-preservation; the whole discussion forms a chapter of extreme interest and importance. The second part reviews the attempts of religion and philosophy to account for or alleviate these disharmonies. The polemic is severe; religion especially is arraigned for failing in its own efforts and hindering those of science; belief in immortality is an illusion with which we soothe a mind conscious that it has been cheated of its due. Old age and death form the topic of greatest interest to the author. The principle underlying the third and closing section of the work is that no natural process should be productive of pain; death as the natural end of life should therefore be normally accompanied by a desire for the end; desire depends on physical conditions, and this harmony can only be produced if life is so far prolonged that the desire to live wanes with the physical strength. This, our author thinks, is a harmony which science can in time secure for us; the details must be left for the reader to discover; at any rate, he will find a topic of great interest excellently treated.

Prof. Metchnikoff's reputation in the scientific world is unique; he comes before us here as something more than a man of science, rather as a prophet, one might almost say, as a high priest. Faith, disillusioned, is to leave its old temples and take sanctuary in laboratories. If progress dictates this course, no prejudice should hinder it. Meanwhile the opposition of the second and third parts of this book affords an interesting view of the prospects. Take, for example, the contrast of the philosophic question and the scientific answer. The question propounded is, Can I hope for immortality? Science replies that the proper term of life is, say, 150 years. The spirit cries out to be saved from the prospect of annihilation; science replies that if you live properly you will some day want to die! Clearly one question is asked, but the answer is the answer of another and a different problem. The materialistic bias of a scientific position, accepted uncritically, seems to have left the refuted philosophy and the triumphant science in a kind of asymptotic relation. At the best it would seem that the theory cannot remove the mental disharmony which the realisation of finitude coexisting with the purpose to live must always produce. It is only in the more limited sphere that science succeeds in being optimistic, and the optimism of this book is conditioned upon our ability to regard the spiritual as a subordinate aspect of the material, a point that the disciple may delight to accept but the unbeliever desires to have demonstrated.

The translation of this book seems to have been carefully done, with only an occasional divergence from accuracy. Why have we three distinct spellings of Buddha (p. 120)? *cp.* Bhuddhism (p. 120), and Bouddha (p. 148). Meringitis (p. 132) requires correction, while the sentence "so there were only Tourgéneff . . . and me" (p. 121) might be improved in its grammar.

G. S. B.

OUR BOOKSHELF.

Warrington's Roman Remains. By Thos. May, F.E.I. Pp. 87. (Warrington: Mackie, 1904.) Price 5s. net.

ARCHÆOLOGISTS have long known that a Roman site existed near Wilderspool Brewery, close to the Mersey on the south side of Warrington. Discoveries have been made during the constructions of various canals, and remains have accumulated in Warrington Museum. Now a local antiquary, Mr. May, has attempted during the last eight or nine years to excavate a small portion of the site—some two or three acres out of an estimated total of thirty or thirty-five acres. In the volume before us he collects, revises, and illustrates various accounts of his work which he had previously published in scattered papers. The collection is a useful contribution to the local study of Roman remains. It has the merits and demerits of many books of the same kind. In his general attack on the problem of what Roman Warrington was, we think Mr. May has not succeeded. He calls it "a partly fortified industrial town" extending over a quarter of a mile on both sides of a Roman road; but his fortifications are puzzling, and his furnaces, smelting floors, &c., do not constitute an "industrial town" in any proper sense of that phrase. On the other hand, he records interesting minor discoveries in the way of pottery and small objects, and the traces noted by him of glass workers, iron workers, and potters are noteworthy, though it may be rash to call them "the earliest in Britain." The little volume is well illustrated, though printed on rather unpleasant paper.

The Experimental Bacterial Treatment of London Sewage. (London County Council.) By Prof. Frank Clowes, D.Sc., and A. C. Houston, M.B., D.Sc. Pp. xii+242. (London: P. S. King and Co.) Price 10s.

THIS report contains an account of the experiments carried out by the London County Council during the years 1902 and 1903. The main conclusions arrived at by Prof. Clowes in the first part (chemical and general) of the report are that coke is a suitable material for bacterial beds and does not disintegrate during use, that the bacterial effluent of settled sewage from such beds does not undergo offensive putrefaction and supports fish life, and that the use of chemicals is unnecessary when this mode of treatment is adopted. In the second part Dr. Houston deals with the bacteriological portion of the experimental work. His results seem to show that though the number of bacteria in the effluent from coke beds is less than in the corresponding crude sewage the reduction is not well marked, and while the bacterial effluent is chemically satisfactory, the bacteriological results are usually quite the reverse, because the microbes pass through the coke-beds. There seems to be small ground for belief that the typhoid bacillus would be destroyed in the beds; an important conclusion.

The report is copiously illustrated with diagrams and photomicrographs. R. T. HEWLETT.

Round the Coast. A Reading Book for Schools. By George F. Bosworth. Pp. viii+248. (London: George Routledge and Sons, Ltd., 1904.) Price 1s. 6d.

THESE short, miscellaneous reading lessons will serve to teach boys and girls many interesting facts about the geography and history of England. Numerous poetical pieces are included, and the maps and pictures much increase the book's attractiveness.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Synthesis of Radio-active Substance.

IN connection with the suggestive letter of Sir William Ramsay and Mr. Cooke, the following observation appears to be of some interest. My friend Prof. H. H. Dixon, in conjunction with Dr. Wigham, in the course of some experiments on the β and γ radiations of radium on bacteria used a platinum rod to cast a shadow on the culture, in order the better to estimate by contrast whether the rays had effected the culture or not. The platinum rod so used to intercept the rays was of cylindrical form and about 3 mm. in diameter. Prof. Dixon's and Dr. Wigham's observations are published in the *Proc.* R.D.S., and also in NATURE.

Happening at the time to be repeating some of Dr. Russell's well known experiments on the influence of metals on photographic plates, I used this rod, among other specimens of metallic elements, to observe their photographic activity. This was about thirty days after Dr. Dixon had made his experiments. I was surprised to find that the rod, after resting twenty-four hours upon an instantaneous plate, had not only affected the plate, but had also produced all the appearance of intense solarisation, darkening the plate in its neighbourhood, but clearing it completely along the line of contact. The negative is still in my possession.

In this experiment the only action upon the plate was from the γ and β rays, the radium (5 mgrs.) being enclosed in a sealed glass tube.

In a subsequent experiment, a copper coin kept enclosed along with some radium contained in an aluminium button, when tested photographically, gave no specially marked result.

It would be desirable in experiments of the kind described by Sir William Ramsay and Mr. Cooke that α rays should in some cases be permitted to exert their influence. If Dr. Harold Wilson's suggestion as to the nature of these radiations is correct, it may well be that these positive ions may take part in synthetic effects.

I have already ventured to suggest the possibility of the synthetic origin of radium, partly in answer to a difficulty I have not seen discussed, *i.e.* what becomes of radiated ions when these are absorbed by atoms. J. JOLY.

Valencia, Co. Kerry, August 14.

Action of Metals on Photographic Plates.

IN the course of the experiments referred to above, as to the nature of the Russell effect, I found that metals (pure mercury and polished speculum metal) placed in contact with a rapid plate submerged under absolute alcohol, and the whole enclosed in an air-tight desiccator over calcium chloride, afforded the photographic marks on subsequent development just as vigorously as if obtained in ordinary moist air. Is not this experiment sufficient to show that Dr. Russell's explanation, which refers these marks to the formation of hydrogen peroxide, cannot be correct? Ought we not rather to seek the explanation in the ionising properties of metals indicated by other observations?

August 14. J. JOLY.

"The Primrose and Darwinism."

YOUR readers may remember a book published under the above title some few years ago, and my apology for bringing up the subject again is the delight with which many reviewers hailed it as totally destructive of Darwin's theory of the fertilisation of the primrose. Whilst viewing with distrust the entirely unscientific method displayed in the book, I considered a useful purpose might be served by repeating some of Darwin's primrose experiments under different conditions.

Plants of primroses were therefore potted up and forced in a hothouse in February, 1904, and crossed and self-

fertilised, and experiments of a similar nature carried out on wild plants *in situ* in June, 1903, and also June, 1904.

In no case could I get a flower to fertilise itself, though crossed flowers produced abundant seed under both conditions. A correspondent in Edinburgh, experimenting upon primroses for quite another purpose, confirms my experience in this matter.

The author of the above-mentioned work has in my opinion fallen into the common error of deducing a function from a structure without recourse to the experimental method, a mode of procedure which has, I believe, led him into grave error. E. A. Bunyard.

The Bungalow, Allington, Maidstone, August 8.

An Optical Phenomenon.

Mr. Hillig's letter in Nature of August 18 (p. 366) reminds me of a somewhat similar phenomenon which I observed last May when using a rotating cubical mirror and sensitive flame.

When the mirror was rotated by hand at moderate speed the upper and lower edges of the band of light seen in the mirror presented exactly the appearance of a faint spectrum, red being outside and pale green and blue inside. The central portion of the band was colourless.

The appearance was most distinct when the flame was influenced by a sound.

I repeated the experiment to-day with the same result.

George W. Walker.

Physical Laboratory, The University, Glasgow, August 19.

Traction of Carriages.

In further answer to your correspondent, p. 270, in passing along a road the wheels of a carriage encounter many small obstacles and inequalities over which they have to rise. In doing so the centre of gravity of the load (which is always higher than the axles) is raised to a greater vertical height when the axles are far apart than when they are close together. The work done in the former case is, therefore, greater than in the latter, by an amount the magnitude of which is proportional to the difference between the versed sines of the angles through which the carriage is tilted in each case respectively. The same argument applies in regard to lateral oscillations of the centre of gravity with the corollary that the narrower the gauge the more easily is the carriage propelled or drawn.

There may also be some question as to the influence of the different rates of retardation and acceleration of the centre of gravity in each case.

Cardiff, August 1. W. Galloway.

Indian Rhynchota.

In the issue of Nature of August 11 (p. 341) there appeared a notice of my second volume on "Indian Rhynchota" (Blanford series), in which I read, "the two last families of the Gymnocerata (Hebridæ and Hydrometridæ) are left over to be included with the Cryptocerata" in the third volume.

This is an error. They have already appeared in their proper location, vol. ii. pp. 167 and 168–192.

W. L. Distant.

Steine House, Selhurst Road, South Norwood, S.E.

[The reviewer regrets the oversight which Mr. Distant has pointed out.—Ed.]

The Earliest Mention of Hydrodictyon.

Twan Ching-Shih (*ob.* 863), in his "Yû-yang-tsah-tsu," Japanese edition, 1697, tom. xix., fol. 12, *a*, writes:—

"The *Shwui-mung-tsiau* (literally, Water-net-alga) grew in Kun-ming-chi [an artificial lake formed by the order] of the Emperor Wu-ti of the Han dynasty [reigned 140–87 B.C.]. Its branches, spreading sidewise, now come out of water slantly. It was eight to nine feet long and so closely resembling the meshes of a net that the ducks could not come out of it when got therein. Hence the name."

This is likely to be an exaggerated Chinese account of the now well known water-net (***Hydrodictyon utriculatum***, Roth.). In this part, when a paddy-field has its water drained off, we meet frequently this alga, "spreading sidewise, now coming out of the remaining water slantly," although such a gigantic dimension as "eight to nine feet" is totally out of the question. Perhaps this is the earliest record of the alga. Kumagusu Minakata.

Mount Nachi, Kii, Japan.

MARCONI WEATHER TELEGRAMS.

Meteorologists have for a long time felt that they have practically come to the limit of their resources in the matter of weather forecasting, so far as the weather changes in the British Isles are concerned, except, perhaps, if finance allowed that telegrams might be received at a later hour than 6 p.m. This later information might avoid the possibility of a storm system advancing towards our western coasts slipping in unobserved between the present hours of observation, 6 p.m. and 8 a.m., without proper intimation of its approach by the fall of the barometer and the backing of the wind being duly notified. Occasionally some of our worst storms spread over us in this way, and the forecaster, who has been unable to foresee the incoming disturbance by aid of the 6 p.m. weather telegrams, finds to his dismay when viewing the next morning's weather information that the full violence of the storm is upon us, for which no storm warnings have been issued. In this way, from time to time, the central area of an important storm is well over the United Kingdom before our Weather Office is aware of its existence.

Wireless telegraphy promises to supply the missing link in the connection of our shore weather system with that over the ocean to the westward of us, and the present praiseworthy effort on the part of the *Daily Telegraph* seems likely to prove, even now with the restricted powers of the Marconi system, that useful information can be obtained. The messages at present are transmitted only about 100 miles from land, but the scheme which has been most ably inaugurated has provided that, in addition to the latest weather report when approaching our shores, there should also be a report of the weather experienced some time previous, so that it is not merely an isolated observation with which we have to deal, but a fair knowledge of the weather from about mid-Atlantic is secured. This information is at times supplied by two or three vessels, so that synchronous observations are obtainable, and it will easily be understood that with further development of the system an approximate synoptic and synchronous map of the Atlantic may be produced. The storm areas very frequently follow a course almost due east when approaching our islands, but often when in fair proximity to our coasts they trend to the north-east, and any help in enabling a true estimate to be formed of the storm's path will be of the greatest possible advantage to the forecaster. Information with settled conditions will be of great value, since it is expected that forecasts should show with some certainty the advent or continuance of settled weather. When an area of high barometer readings is situated to the westward of our shores, and is willing to give way, it affords an indication of the early approach of storm systems, with disturbed weather, from the open ocean, while if the anticyclone maintains its ground the approaching disturbance will be fended off and made to follow a course more to the north-east, and may be taken altogether beyond the limits of the United Kingdom.

For some time past the Meteorological Office has had in hand the charting of the weather over the North

Atlantic, for which purpose it obtains observations of wind, weather, barometer, and temperature of air and sea from observers in the Mercantile Marine who are willing to assist in the advancement of our knowledge of the weather in this way, and a daily chart is prepared giving a picture of the weather over the Atlantic and for the adjacent continents of Europe and America for 8 o'clock each morning. A study of these is helpful to the furtherance of our better understanding of meteorology and its complicated problems, but necessarily these charts picture only what is past, although they afford an explanation of success or failure in forecasting, and often show why an unexpected and altogether unlooked for change of weather has occurred. These charts are prepared as closely as possible to date of occurrence. When the Meteorological Office has the advantage of receiving messages by the wireless telegraphy, both from outgoing and incoming Atlantic liners, they will unmistakably possess a power which has long been known to be wanting. The *Daily Telegraph* has taken the initiative, and it is to be hoped that the arrangements which the Meteorological Office has already been endeavouring to make with Lloyd's for fuller information will shortly meet with that success which it deserves, for the advancement of science and for the public benefit.

With the further development of Marconi's system there seems every reason to hope that we in England may be placed much on the same footing as Denmark, for example, is now, in full possession of the knowledge of what is going on for several hundred miles to the westward of the base of operations, to the immense gain of the forecaster for the country concerned. Knowing what is going on over the Atlantic to the westward of us would not only secure greater accuracy of forecast, but the time limit could probably be extended from twenty-four hours, as at present, to, say, forty-eight hours at least.

PROF. J. D. EVERETT, F.R.S.

THE death of Prof. Everett has removed a familiar figure from the ranks of English physicists. The news of his death came as a shock to his many friends and others acquainted with his great vitality and his intellectual activity, which seemed to remain quite unimpaired by advancing years. Some seven years ago he retired from teaching work in Queen's College, Belfast, where, for upwards of thirty years, he had occupied the chair of natural philosophy. Since that time he resided in London, where he took an active part in the proceedings of scientific societies, specially of the Physical Society, of which he was a vice-president.

Dr. Everett's name has been familiar to many generations of students of physics through his admirable translation of Deschanel's treatise, which has long served as a standard text-book. Many editions of this were called for; and as each fresh edition was carefully brought up to date by additions and alterations, the book became ultimately almost entirely a new work. Another very important service to physical science was rendered by the publication of Prof. Everett's book on the C.G.S. system of units. This very useful compendium made its first appearance at the time when the question of fixing the practical electrical units was being discussed, and proved of material service in that connection. It gives not only clear and precise definitions of fundamental quantities, but also numerical data carefully selected and compiled.

Dr. Everett's earliest original work consisted of an experimental determination of the elastic constants of certain solids. Subsequently he confined himself to work on his text-books and to theoretical investigations. His published papers, which appeared for the most part in the *Philosophical Magazine* or in the pages of this Journal, show by their subjects the wide range of his interests. Thus recent papers treat of the theory of combination tones, Hering's colour-theory, dynamical illustrations of optics, the theory of rent, the properties of certain linkages, and the mathematics of bees' cells. His last paper, elucidating a point in connection with Osborne Reynolds's theory of the universe, appeared only a month or so ago. He served for many years as recorder of the British Association Committee for Investigation of Underground Temperatures, and did much valuable work in drawing up the annual reports.

Dr. Everett's energy and ingenuity found outlets also in directions not purely scientific. He was the inventor of a system of shorthand which has found many adherents. He devised an extended form of slide-rule, ingeniously arranged on sheets of cardboard. An early and enthusiastic votary of cycling, he was much interested in cycle construction, and was an active member of the Cyclists' Touring Club. A man of great kindliness and geniality, he will be missed in many circles. His pupils will remember him always with gratitude and affection.

THE BRITISH ASSOCIATION AT CAMBRIDGE.

THE meeting of the British Association at Cambridge concluded yesterday. The meeting has been in every way a success. In all the sectional sessions large attendances were secured, and the general and social meetings were all successfully carried through and greatly appreciated. In regard to numbers of members, the Cambridge meeting was the largest since the Liverpool meeting of 1896. At this meeting there were 3181 members and associates, at the meeting just concluded at Cambridge the number of members and associates was 2783. It is interesting to compare the numbers of other large meetings with the one just held. The largest number of members and associates that have attended a meeting was at Manchester in 1887, when the number was 3838. At Newcastle in 1863 there were 3335, at Liverpool in 1870 there were 2878, and at Bath in 1864 the number was 2802. These meetings are the only ones which have had a larger attendance than that at Cambridge, and it is interesting to observe that in all these cases the meeting has been in a large city where the number of resident members and associates naturally would be very much larger than in a comparatively small town such as Cambridge. Compared with recent years the numbers show a large increase. Last year in Southport 1754 attended the Association, in Belfast the year before there were 1620, and in Glasgow in 1901 there were 1912. Comparing the meeting just concluded with the three former meetings held in Cambridge we find a great increase in numbers. In 1833 there were 900 members and associates, in 1845 there were 1079, and in 1862, 1161.

The cause of the great popularity of the Cambridge meeting this year is undoubtedly to be found in the great growth and expansion in scientific work at the University during the last twenty-five years. The work done at Cambridge in the last quarter of the nineteenth century in all branches of science has made Cambridge a great centre of attraction for scientific men the world over. At this year's meeting there were present 121 foreign members. Amongst these there was a large number of physicists attracted by

the Cavendish Laboratory, and the interest attaching to it owing to the great succession of Profs. Maxwell, Rayleigh, and J. J. Thomson. The school of research built up by J. J. Thomson has done so much in investigating, especially the new field opened in physics in the last few years, that "the Cavendish" has attracted physicists from all parts of the world. In other branches of science also, in chemistry, in physiology, in zoology, in engineering, in anthropology, in fact, in almost all departments, the new spirit of research, which has permeated Cambridge, and the men who have done so much to put Cambridge in the forefront of progress in scientific discovery, has made this University a great attraction to all those who have the advance of science at heart.

The large number of serious students attending all the sectional meetings this year has been an encouraging sign, showing that the increase in numbers has not been due merely to the camp followers of science, but to those who are really interested, and who wish to make of the British Association more than an annual week of excursions and garden parties. There have been, of course, a large number of members and associates who have not joined the Association for any other purpose than a week of pleasant social meeting, and in some ways it seems a pity that there should be such a number who do not really add to the usefulness of the meeting.

This is not the place for any detailed account of sectional meetings, full accounts of these will appear in other columns of NATURE. Here all that is necessary is to give a short account of the general meetings and lectures. With regard to the entertainment of the Association there has been expressed by visitors to Cambridge nothing but satisfaction. The reception of the members of the Association by the President in Trinity College was a most successful meeting. Over 2000 members attended and were received by Mr. Balfour in the hall. The grounds and courts were illuminated. The President's address was delivered in the Corn Exchange, which was decorated for the occasion, and above 2000 members were present. At Peterhouse about 600 of the members were entertained by invitation of the Master and Fellows. The grounds of the college were illuminated, and a very pleasant evening was spent.

On Friday evening a reception was held at the invitation of the Cambridge Philosophical Society in the combination room and hall of St. John's College. Dr. Baker, the President of the Society, presided. This reception, which was limited in number, and for gentlemen, especially the foreign members of the Association, was perhaps the most successful meeting held. Smoking was freely indulged in, and more was done in the way of promoting acquaintance and friendship between members of the Association than at any other time. Garden parties were held at Emmanuel College, by invitation of the High Sheriff, at Newnham and Girton Colleges, and at the Botanic Gardens, by the invitation of the Lord Lieutenant of Cambridgeshire and the Mayor of Cambridge. The lectures by Mr. J. W. Clark, Prof. Darwin, and Prof. Osborn were crowded, and Mr. Clark and Prof. Darwin repeated theirs to afford the many members who could not obtain tickets the opportunity of hearing them. On Monday honorary degrees were conferred in the Senate House upon representative leaders in science, and the speeches delivered on that occasion are printed elsewhere in this issue (p. 418).

Acting upon the suggestion of the council of the Association, several of the sections arranged discussions upon subjects of wide scientific importance, and devoted afternoon meetings to lectures of a semi-popular character. The discussions have in each case elicited the expression of inspiring and authoritative opinion, and when the subjects of the afternoon lectures have been of a character which appealed to members of the Association in general, and not only to members of a section, the lectures have been attended by large and appreciative audiences. This year's experience shows unmistakably that when sufficient care is taken in the selection of suitable lecturers and subjects, the afternoon addresses are most successful. For the benefit of members of the Association who are not actively engaged in scientific work, but are interested in the progress of natural knowledge, it is to be hoped that these lectures will be given a place in the programme of each section in future meetings.

In the physics sub-section of Section A, great interest was shown in the discussion opened by Prof. J. J. Thomson on radio-activity. Amongst other papers perhaps the most interesting was that of Prof. Rubens, on the optical properties of metals, in which he showed that the theory of Maxwell led to results for reflection from metallic surfaces, which agreed within the limits of experimental error with the actually observed results for infra red rays of wave length about thirty times that of visible light. This result was particularly interesting in the university of Maxwell, as for many years the non-agreement of the theoretical and observed results was regarded as limiting the applicability of Maxwell's theory to the range of steady currents and slow oscillations. The discussion on *n*-rays left those who heard it with the conviction that the phenomena said to be observed correspond to no objective physical reality. In the section devoted to economics the morning given to discussion of fiscal problems was of general interest. The opinion of scientific economists, as far as it was represented in the discussion, is distinctly in favour of free trade. The articles dealing with the separate sections will describe the results of the sectional meetings; the two mentioned have been introduced because of their general interest; the new theory of the constitution of matter being one which has appealed to all men of science as well as physicists, and the economic question being also one of interest wider than Section F. With regard to the new views of the constitution of matter, it seems unnecessary to take quite so serious a view as was expressed by the President of the Association. The new view is in no way contrary to older theories of the atomic and molecular theories of matter, but is an extension and explanation of these, and in the hands of Prof. J. J. Thomson, has made, at any rate to physicists, a simplification and rational view of these without introducing the question of physical reality.

One of the most interesting features of the meeting has been the museums and laboratories, which have been open for inspection during the Association week. Special mention should be made of the zoological exhibits, and the exhibit of teaching apparatus and experiments by Mr. Searle, in the Cavendish Laboratory. Among the demonstrations we may mention, as of special interest, that of Prof. R. W. Wood, of Baltimore, of the anomalous dispersion of sodium vapour; that of Messrs. Heycock and Neville, on methods of investigating metallic alloys, and of Prof. Schäfer, on methods of artificial respiration.

The report of the council which was presented to the general committee on August 17 referred to the organisation of the deputation which waited upon the Prime Minister on July 15, to urge the importance

of increased national provision being made for university education. The result of the action thus taken by the president at the request of the council has already been described in NATURE (July 21, p. 271). Several matters relating to the business of the officers of sections were mentioned in the report, and it was recommended that the following resolution sent to the council by the general committee for consideration, should be acted upon:—

That the sectional committees be continued in existence until the new sectional committees are appointed, and be authorised to bring to the notice of the council in the interval between the annual meetings of the Association any matter on which the action of the council may be desired in the interests of the several sections, and that a committee may be summoned at any time by the president of the section, or by the council.

Hitherto, the organisation of the work of the sections, and the arrangement of the programme, have been in the hands of the officers, but by this resolution the sectional committees are given a voice in the matter during the year between one meeting and the next, instead of ceasing to exist at the close of the meeting at which the members are appointed. The sectional committees, as at present constituted, are, however, so large as to be almost unmanageable as working committees, and probably the simplest practical way to secure continuity would be to select, say half a dozen members, from each committee to work with the officers during the year. The only other plan would be to limit the number of members to be appointed upon the committee of each section.

The members of sectional committees are not, in virtue of their membership, expected to take any essential part in the work of a section, though they may, and occasionally do, attend the meetings of the committees upon which they are appointed. In some cases vice-presidents understand their functions to be of the same negative significance, and neither attend the meeting for which they are appointed, nor send a timely notice of their inability to do so. To avoid this inconvenience the council has resolved that gentlemen nominated as vice-presidents of sections be informed that their attendance at the meeting for which they are nominated is expected.

Arrangements for the South African meeting in 1905 have received much attention during the year from a committee of council appointed for the purpose. The first half of the meeting will be held at Cape Town and the second half at Johannesburg, and official visits of the Association will be made to Natal and the Orange River Colony, in each of which colonies one or more discourses will be delivered by prominent members of the Association. The meeting will open at Cape Town on August 15, so that members starting for South Africa at the end of July will be able to spend at least three weeks in the colonies, and be back in England by the end of September. Prof. George Darwin will be the president of this meeting.

At the meeting of the general committee on August 19 the invitation to meet at York in 1906 was accepted unanimously.

Upon the proposal of Sir J. Dewar, seconded by Sir A. Rücker, Prof. J. Perry was elected to fill the office of general treasurer, in succession to Dr. G. Carey Foster, who has resigned that post.

A vote of thanks to Sir Norman Lockyer for the way in which he has discharged his presidential duties was proposed by Sir Henry Roscoe and seconded by Prof. Perry, and carried unanimously, as was also a similar vote of thanks to Dr. Carey Foster, moved by Sir A. Geikie and seconded by Major Macmahon.

SECTION A.

SUBSECTION, COSMICAL PHYSICS.

OPENING ADDRESS BY SIR JOHN ELIOT, K.C.I.E., M.A., F.R.S., CHAIRMAN OF THE SUBSECTION.

WHEN the suggestion was made to me that I should preside over this important Subsection my first thoughts prompted me to decline the honour. The position had been filled during the past two years by two distinguished physicists, both of whom had dealt chiefly with the problems and the position of meteorological science, and hence I thought that it should be offered to some representative of cosmical physics. I also doubted whether an official meteorologist whose time has been chiefly given up to duties of administration could have anything of interest to communicate to you. However, on fuller consideration it occurred to me that I might be able to place before you some features of Indian meteorology leading up to and assigning, as I hope, adequate reasons for the study of a portion of the field of tropical meteorology as a whole.

My address consists of three parts, viz.:

(1) A brief sketch of the broad features of the meteorology of India in their relations to the general meteorology of the Indo-oceanic region.

(2) Statement of abnormal features of the meteorology of that area for the unique period 1892–1902 illustrating the remarks in the preceding sketch.

(3) Suggestion of the co-ordination of the meteorological observations of the British Empire and the creation of a central office for the investigation of problems of general meteorology.

India is the most typical example of monsoon conditions, that is, of opposite air movements of six-monthly period which, in its case, depend on the annual temperature changes in the sea and land areas of the Indian Ocean and continent of Asia. The monsoon conditions in India are intensified by its unique position and topography. It projects southwards into the Indian seas over 15° of latitude, and is protected northwards by the vast barrier of the Himalaya Mountain range and Tibetan plateau. The axis of the Himalayan range is at least 2000 miles in length and has an average elevation of more than 20,000 feet. The extent of country more than 10,000 feet in elevation to the north of India is from 300 to 500 miles in width. These figures will give some idea of the magnitude of India's northern barrier.

During one period of the year there is an outflow in the lower atmosphere from land to sea. The direction of the lower air drift in India is determined in part by the lie of the mountains and river valleys, and is from north-east over the greater part of the Indian seas. January is the month most typical of this air movement and of the accompanying weather conditions.

During another portion of the year the lower horizontal air movement is from sea to land. This movement is much steadier and more powerful and influential in every respect than the former. July and August are the months most representative of the totality of the weather conditions of this period.

Conditions similar to those of January prevail in their entirety from about the middle of December to the end of February or middle of March—the period known in India as the cold weather or cool season. The lower horizontal air movement in India during the period has its origin in Upper India, where it is very feeble, and whence it increases seawards and is of moderate force in the Bay of Bengal (mean force 2 to 3, Beaufort scale) and the Arabian Sea (mean, 2 to 4). It is fed to a certain extent by drift down the river valleys, and passes in the North-West India frontier hill ranges. There is, on the other hand, no general drift down the Himalayan river valleys or across the main ranges from Central Asia. The normal air movement in the Western Himalayas (and perhaps the whole range) is an alternating up and down, or day-and-night movement, depending upon the diurnal heating and cooling of the plains of Northern India. Hence India (in its lower air movement) is at this time completely shut off from Central Asia.

The lower air movement is continued over the Indian seas southwards to a region of vertical movement over a narrow belt a little to the south of the equator. This belt

is also the goal of the lower air movement of the south-east trades circulation at this time. The equatorial belt of calms is hence the termination of the lower air movement of the south-east trades and north-east monsoon. It is chiefly an area of uptake, and of outflow northwards and southwards, to replace the lower air inflow from the distant south and north. The influx to the Indian land area occurs chiefly or entirely in the upper and (perhaps) middle atmosphere. There is also, as indicated by the wind directions in the lower Assam and Burma hills, an influx from the adjacent seas in the upper portion of the lower atmosphere.[1] The diurnal land and sea breezes alternate with great regularity on the west coast south of Gujarat during this period, but probably do not contribute to the general upper influx compensating in part or whole the lower outflow.

The circulation over the Indo-oceanic region hence consists at this time of two semi-independent circulations, with a common sink or goal for the lower air movement, which shifts with the season and with the relative strengths of the two movements. It is hence probable that they react on each other to some extent, and possible that general abnormal actions may affect the two similarly.

The normal weather during the period is similar to that which obtains in anticyclonic periods during the summer in Central Europe—viz., the prevalence of light winds, with clear or lightly clouded skies, low humidity, moderate temperature, and large diurnal range of temperature, with a bracing, exhilarating atmosphere.

It is interesting to note that the air movement in India itself is from opposite directions in Northern India and the peninsula, with a belt of unsteady movement over the area of the Vindhya and Satpura hill ranges. The variations of weather conditions from the normal are as a rule inverse in these two regions—viz., Extra-tropical and Tropical India.

The season of the opposite air movement is present in its most complete form in July and August, and lasts from the beginning or middle of June to the middle or end of September. It commences as a lower air movement in an anticyclonic region over the South Indian Ocean, and is thence continued northwards to Abyssinia, South Arabia, India, and Burma. Persia, Afghanistan, and Baluchistan (where dry hot north-west winds chiefly prevail) are outside the field of this movement. The direction of the movement is from south, with more or less easting to the south of the equator, and with more or less westing to the north of the equator, dependent in part upon the earth's rotation and in part upon local conditions and the influence of neighbouring land areas, and hence more effective in the Bay of Bengal than in the Arabian Sea. This lower air current advances over an extensive tropical oceanic region before it reaches Southern Asia, and hence arrives charged with vast stores of aqueous vapour, which it discharges chiefly over the peninsulas of Southern Asia and the mountain region of Abyssinia.

The regions of rainfall indicate the areas of upward movement terminating the lower advance of the current. The circulation is undoubtedly maintained in large part by the release or addition of energy due to the condensation of its enormous stores of aqueous vapour. The lower air movement is of very considerable elevation, estimated at 15,000 to 20,000 feet in India. Above it is the outward upper return movement, in part only compensatory, and in part probably slowly filling up the Central and Southern Asian low-pressure region. The movement exhibits some interesting features in India, due to the fact that of the three areas to which it is mainly determined India alone is subject to a double influx from two sea areas in opposite directions. The current from the Arabian Sea passes eastwards across the Malabar, Konkan, and North Bombay coasts, the peninsula and Central India. The Bengal current is deflected in the north of the Bay and Bengal, and advances in a westerly direction up the Gangetic plain. Between the areas or fields of the two currents (roughly proportional to their relative strength and importance—viz., about 2 to 1) is a debatable area of variable winds and low pressure. This trough of low pressure varies in position with the relative strengths of the two currents. The cyclonic storms of the period, which are of comparatively frequent occurrence, advance along the trough. It is hence a factor of considerable importance in determining the distribution of the rainfall of the period. The trough is purely a resultant of the peculiar conditions of the air movement, and is not the cause of that movement; in other words, it is determined by it, and does not determine it.

[1] In India the lower atmosphere may be defined as from 0 to 5000 feet, the middle atmosphere from 5000 to 15,000 or 20,000 feet, and the upper atmosphere above 20,000 feet.

The transformation of the double circulation of the north-east monsoon period into the single circulation of the south-west monsoon over the Indo-oceanic region next requires consideration. It is evident that the chief stages in this change are (1) the discontinuance of the vertical movement over the equatorial belt; (2) the extension of the trade winds of the south-east trades across the equatorial belt, with an accompanying increase of pressure and of horizontal air movement; (3) the continuance of that northerly movement over the Indian seas into the peninsulas of Southern Asia.

The marine data of the Indian seas collected during the past fifteen years establish fully that this transformation is primarily due to actions in the Indian Ocean, producing a movement resembling in many respects that of a bore or storm wave. The actual transition may hence be described as catastrophic, due to impulsive action.

It is preceded in India by a period of preparation (as it may be termed), when pressure and other conditions are slowly established in Southern Asia, which directly contribute to the advance of the monsoon winds over the Indian seas, but which in no way assist the preliminary burst across the equator, the first stage towards the establishment of the south-west monsoon circulation.

This preliminary period is the hot-weather season, lasting from about the middle of March to the middle of June (on the average in Northern India). During this period temperature increases rapidly until the last week in May or first week of June, when maximum day temperatures ranging between 120° and 125° are usually recorded in the driest and hottest interior districts of Northern and Central India. Pressure decreases *pari passu* in the heated land areas of Southern Asia, which become areas of low pressure and indraught relative to the neighbouring seas. The indraught only extends to a comparatively short distance landwards and seawards from the coasts, more especially in the larger sea area, the Arabian Sea, over the centre of which light variable or northerly winds obtain even immediately before the advance of the monsoon currents. In the interior of Northern and in Central India exceedingly dry and hot westerly winds prevail with great steadiness.

The weather in India during this period depends almost entirely upon local thermal actions and contrasts of temperature and humidity conditions. Skies are generally free from cloud, but the air is more or less charged with dust and is excessively dry (humidities of 1 to 5 being of occasional occurrence in North-Western India).

The characteristic features of the dry season are hence most strikingly exhibited immediately before the advent of the wet monsoon. There is no gradual change over the greater part of India from one to the other such as would occur if the furnace, or Central Asia hot area, theory were correct. Over small isolated portions of India, including Tenasserim, Arakan, Lower Burma, Assam, Bengal, and Malabar, thunderstorms giving more or less heavy downpours occur in increasing frequency during the period. The rainfall is considerable to large in amount in these areas, and is of much agricultural value in some districts—*e.g.*, in Assam for the tea crop. In those areas the transition to the rainy season is much less abrupt and spasmodic, the chief differences being that the rainfall in the wet season is more general and frequent, larger in amount, *and rarely accompanies thunderstorms*.

The transformation from the hot weather to the rains is usually effected between June 1 and 15. It commences in the equatorial belt with a considerable increase of pressure and air movement accompanying a strong rush of southerly winds, the continuation of south-east trade winds, across the equator. If the burst be sufficiently strong the rush is continued northwards over the Indian seas as a wave of disturbance, squally weather, heavy rain, and much violent electric discharge or action, invading areas characterised previously by light and variable winds and fine weather. The disturbance usually increases with its

northward advance, and frequently, when it reaches lat. 12° to 16° N., it concentrates into a cyclonic storm. Such a storm almost invariably marks the commencement of the monsoon in the Bay of Bengal, and in about two out of five years in the Arabian Sea. The advancing humid currents in the rear of these initial cyclonic storms or waves of disturbance march over the sea areas in a few days, and thence cross the coasts towards which they are determined by the low-pressure regions in the land areas of Southern Asia, where they produce an almost complete reversal or transformation of the weather conditions, the result of which is that moderately high temperature and small diurnal range of temperature, great humidity frequently approaching saturation, much cloud, and frequent rain obtain for the next three months over the greater part of India, until, in fact, the middle or end of September.

The reverse change—viz., the withdrawal of the humid south-west currents—then commences, and is a slow process, requiring usually from two to three months for its completion.

This is due to a gradual decrease of strength, and hence to a fairly continuous contraction of the field of the current, and also of its elevation or thickness. The current first withdraws from North-Western India, being replaced by light, variable, or north-westerly land winds. These land winds increase in extension and volume with the continued contraction of the south-west monsoon current. The more important phases of the contraction and withdrawal of that circulation from India are of especial interest. The first phase, the retreat of the current from North-Western India, accompanies a rise of pressure over the Persian area and North-Western India, with a shift of the trough of low pressure from W.N.W. to N. or N.E. and corresponding change of direction of the average tracks of the storms of the period. This is followed after a short period of rain in North-Eastern India and Burma by a rise of pressure in Assam, Upper Burma, and Bengal, and the withdrawal of the monsoon current from those areas. The current then recurves over the centre of the Bay, in the same manner as during the monsoon proper over the north of the Bay and Bengal, and is directed or determined to the west or Madras coast of the Bay, which hence receives frequent rain during a short period of about two months—the rainy season of the eastern and southern parts of the peninsula south of Orissa and Ganjam.

These rains were formerly described as accompanying the setting in of the north-east monsoon on the Madras coast. That, however, is a misnomer, as the true north-east monsoon winds are dry land winds, and the rain-giving winds of this period in Madras are those of the south-west monsoon in its retreat or contraction down the Bay. The period during which this rainfall occurs is hence now usually termed the retreating south-west monsoon.

The year in India may hence be divided into two monsoons of nearly equal length, viz. :

(a) The north-east or dry monsoon.

(b) The south-west or wet monsoon.

The first terms are based on the general direction of the air movement in the Indian seas during the periods, and the second on the most prominent feature of the weather in India itself. Of an average annual total rainfall of 41 inches (according to the most trustworthy calculation), at least 85 per cent. falls during the wet season, and only 15 per cent. during the dry season.

The dry monsoon in India is subdivided into—

(1) The cold-weather period.

(2) The hot-weather period or transitional period of preparation for the south-west monsoon.

The wet monsoon is divided into—

(1) The south-west monsoon proper, or the period of general rains.

(2) The period of the retreating south-west monsoon and gradual slow establishment of the dry monsoon.

Each of these periods practically covers three months.

One of the most noteworthy features of the meteorology of India not referred to in the previous statement is that the storms of each period—viz., the cold-weather period, the hot-weather period, and the wet monsoon—are characteristic and special to the period. They are all in the broadest sense of the word cyclonic in character; but they originate under different conditions and exhibit very different features in each of those periods.

The disturbances of the cold weather are large shallow depressions which originate in the upper humid return current of the north-east monsoon circulation, chiefly in the Persian plateau region, and which drift eastward with a slight southing across Extra-tropical India. Storms do not occur south of the Deccan or peninsula-dividing ranges during this period. These storms are chiefly remarkable for the frequent development of stationary secondary depressions in the Punjab, usually of much greater intensity than the primaries; a feature of which, I believe, there is no parallel elsewhere. They are of great importance, as they give the main snow supply to the Western Himalayas and the light but general occasional rain required for the wheat and other cold-weather crops of Northern India.

The storms of the hot weather are local disturbances of very limited extent, usually in large areas of slight depression, and are occasionally of remarkable intensity and great violence. In the areas to which the local sea winds of the period extend (more especially Bengal and Assam) they occur chiefly as local thunderstorms with violent winds and brief heavy downpours of rain, but sometimes as tornadoes rivalling those of certain districts of the United States in intensity and destructiveness. In the dry interior they occur as dust-storms, usually without rain, and are most violent in the driest districts, including Sind, the Punjab, and Rajputana. Occasionally, when the convective movement is especially vigorous, they develop into hailstorms of great intensity. The rainfall accompanying these hot-weather storms is of little general agricultural value except in the tea districts of Assam and Bengal.

Finally, the wet monsoon is characterised by the frequent occurrence of cyclonic storms of every degree of intensity and of very varying extent. The great majority of them originate in sea areas of nearly uniform temperature as disturbances in a massive current highly charged with aqueous vapour and subject to large variations of intensity and extension. The more prominent features of these storms, more especially of the most violent, including the hurricane winds, excessive rainfall, and the phenomena of the central calm and the accompanying storm wave, are too well known to require description. The chief importance of these storms, of which an average of about ten (of different degrees of intensity) occur every year during this period, arises from the manner in which they modify the distribution of the rainfall, discharging it abundantly over the districts traversed by the storms at the expense of the districts outside of their field.

The most important and variable feature of the weather in India from the practical standpoint is rainfall. Its value depends upon its amount and occurrence in relation to the needs of the staple crops. The measurement of rainfall is carried out, on a uniform system, at upwards of 2500 rain-gauge stations. The average distribution of rainfall, month by month and for each season, has been determined from the data of about 2000 stations. It should, however, be recognised that the probability that the rainfall will conform exactly to this distribution in any year is nil. Average rainfall charts represent a distribution about which the actual varies from district to district more or less considerably, the local variation for prolonged periods being practically compensatory. Such mean or normal data and charts are undoubtedly of value, more especially for the determination of rainfall anomalies and their relations to pressure, temperature, and other anomalies. There is apparently a tendency to assign a greater value to these charts of mean rainfall distribution than they deserve. Charts showing the amount and time distribution of the rainfall best suited for the requirements of the staple crops would—for India at least—be more interesting and valuable. This is a work that I regret has, for various reasons, not yet been carried out by the Indian Meteorological Department.

In most regions in India a moderate variation (positive or negative) in the amount of the rainfall is of comparatively small importance, more especially if the precipitation occurs in amount and at intervals suited to the requirements of the crops. During the thirty-year period 1874–1903 there were six years in which the distribution of rainfall affected

to a serious extent the crop returns over large areas, and the rainfall was not compensatory. In four of these years the drought was so severe and widely spread as to occasion famine, with its attendant calamities, over large areas. Severe droughts and famines occur at very irregular intervals. A noteworthy feature is that they frequently follow in pairs separated by intervals of two to four years.

The previous statement of the meteorology of India has indicated the chief conditions which affect the crop returns seriously or disastrously over large areas in India. They may be summed up briefly as follows:—

(*a*) The dry monsoon. Absence or unusual feebleness of cold-weather storms.

(*b*) The wet monsoon. General feebleness of the monsoon current, due either to corresponding feebleness of the south-east trades, or to unusual diversion to East Africa; or local feebleness in a part of India, due to local conditions, or to abnormal diversion to other rainfall areas in South Asia. These conditions give rise in the areas affected to one or more of the following features:—

(1) Prolonged delay in the commencement of the rains.

(2) Scanty rainfall during the season, with prolonged periods of fine, clear, hot weather.

(3) Early termination of the rains.

These features are as a rule more marked in the drier districts of the interior than in the coast districts. The effect on crop production is greatest and most disastrous in the following areas:—

(1) Central Burma.

(2) The Deccan, including the Bombay and Madras Deccan districts, and Hyderabad.

(3) North-Western and Central India, more especially the South Punjab, East Rajputana, and the United Provinces.

The following important inferences are based upon the preceding presentation of facts and the experience of the past thirty years:—

(1) The lower air movement of the south-west monsoon is the northward extension of the lower movement of the south-east trades. The latter is a permanent feature of the Indo-oceanic region, and the former a periodic invasion of the Southern Asian seas and peninsulas initiated over equatorial regions and propagated northwards to the southern mountain barrier of the Central Asian plateau.

(2) The primary factors determining this impulse across the equator (the first stage of the establishment of the south-west monsoon) are to be sought in the permanent field of the south-east trades, and are not due to actions in the heated areas of Southern or Central Asia.

(3) The pressure conditions in the heated areas of Southern Asia and North-East Africa determine the direction, volume, and intensity of the advance over the Indian seas to what may be termed three competing areas for rainfall (viz., Abyssinia, India, and Burma). These conditions are hence important factors in the third stage of the advance of the south-west monsoon current.

(4) The movement when fully established by these actions over the Southern Asian seas and peninsulas is continued—first, by the momentum of the lower circulation; secondly, by the release of energy accompanying aqueous vapour condensation; and thirdly, by thermal actions in Southern Asia, due to direct solar activity. The termination of the lower horizontal current by vertical movement occurs irregularly over the areas of frequent heavy rain in Southern Asia and Abyssinia, and not over a heated area in Central Asia.

(5) The total volume of aqueous vapour brought up by this circulation not only varies in amount from month to month during the season, but also from year to year. The largest variations (seasonal and annual) depend chiefly, if not entirely, upon actions in the source of supply—viz., the Indian Ocean. If those actions determine an increased or diminished supply across the equator into the Indian seas, there is a corresponding variation in the total precipitation of the three competing areas. Amongst such causes and actions may be prolonged and untimely diversion of the south-east trades into East Africa, as in 1896, or general weakness of the air movement over the Indian Ocean, probably accompanying a displacement and decreased intensity of the southern anticyclone, as in 1899.

(6) The relative distribution of the total rainfall in the three areas of discharge of the aqueous vapour of the monsoon currents probably depends upon the relative intensities of the pressure conditions established during the hot weather, which are continued for a part or the whole of the monsoon by actions depending on the rainfall resulting from the initial pressure conditions—an example of the persistence of meteorological conditions and actions which is a prominent feature of Indian meteorology. The total rainfall of each of the three areas may differ considerably from the normal, but there may be partial or complete compensation on the whole. Thus it is the general (but not the invariable) rule that the rainfall variations in Burma and Assam are usually inverse to those of North-Western India and also of India as a whole.

(7) The distribution of the rainfall in any one of the three competing areas (but more especially in India as the largest) may vary widely from the normal—considerable deficiency in some areas accompanying considerable excess in others. This in India is undoubtedly due to local conditions—*e.g.*, local excess or deficiency of pressure at the commencement of the period and established during the previous hot weather. These pressure variations usually accompany abnormally prolonged and heavy snowfall or very scanty snowfall in the Western Himalayas.

(8) Local or general drought in India during the south-west monsoon may hence be due to—

(*a*) General weakness of the south-east trades circulation.

(*b*) Diversion of an unusually large proportion of the south-east trades to South-East or East Africa during the monsoon period.

(*c*) Larger diversion than usual of the monsoon currents to Burma or Abyssinia.

(*d*) Very unequal distribution in India itself, due to local conditions established during the antecedent hot weather.

These factors are given in the probable order of their importance.

(9) Scanty rainfall or drought during the dry season or north-east monsoon in Northern India results from absence or unusual feebleness of the cold weather storms which are the sources of rainfall at that time.

(10) The most prolonged and severe droughts in North-Western and Central India are due to the partial or complete failure of the rainfall of at least two seasons in succession.

(11) As the two circulations in the Indian oceanic region have a common goal in the dry season (more especially from December to March), it is probable that variations in the strength of one circulation (more especially the larger) will modify the field and strength of the other circulation. It appears that this relation would be shown most strongly between the southern circulation and the upper movement of the northern circulation. And, as cold-weather storms are disturbances in that upper movement, it is possible—if not probable—that the larger variations in the number and intensity of the cold-weather storms and the amount of the cold-weather precipitation may be related to conditions in the south-east trades regions.

(12) There appears to be little or no relation between the position and intensity of the Central Asian anticyclone and the number of the cold-weather storms and rainfall of Northern India in any season.

The meteorology of the period 1892–1902 is of especial interest for its confirmation of the above inferences, more especially the phenomena of the variations of rainfall in India and the causes or actions to which they are due. The year 1891 was noteworthy for a severe local famine in Rajputana and the adjacent districts to the north and east consequent on prolonged and excessive snowfall in the Western Himalayas during the winter of 1890–91. The following gives a brief summary of the more prominent features of the meteorology of this unique period:—

(1) The eleven-year period 1892–1902 corresponds in length to the sun-spot period, and it may be divided into two periods of unequal length—a short period of excessive rain and a long period of deficient precipitation. The maximum of the first period was in 1893. The second period had three strongly marked minima in 1896, 1899, and 1901, that of 1899 being the absolute minimum. The following table gives, for convenience of reference, data of the mean annual and seasonal variations of rainfall of the Indian land area for each year of the period:—

Variation of Mean Actual Rainfall of Period from Normal.

	Cold Weather: January and February	Hot Weather: March to May	South-west Monsoon. Complete Period: June to December	Whole year
1891	+0·34	+0·37	− 4·25	− 3·54
1892	0·39	−0·21	+ 5·69	+ 5·09
1893	+1·63	+2·72	+ 4·72	+ 9·07
1894	+0·48	−0·76	+ 6·75	+ 6·47
1895	−0·01	−0·23	− 1·95	− 2·19
1896	0·42	−0·82	− 3·59	− 4·83
1897	−0·01	−0·12	− 0·02	− 0·15
1898	−0·50	−1·00	+ 0·93	+ 0·43
1899	0·38	+0·58	−11·34	−11·14
1900	−0·02	−0·25	− 0·26	0·57
1901	+1·47	−0·48	− 5·12	− 4·13
1902	−0·57	+0·16	− 1·64	− 2·05
Normal roughly..	1 inch	5 inches	35 inches	41 inches

(2) The following gives the chief features of the rainfall of the first period, 1892–4:—

(*a*) The excess was almost as marked in the dry as in the wet season. This is strongly shown in the year 1893 of maximum excess.

(*b*) The excess was on the whole more strongly exhibited in the field of the Bombay than of the Bengal current.

(*c*) The rainfall of the dry season was as markedly in excess in Persia, Baluchistan, Afghanistan, and the Himalayan area as in Northern India.

(*d*) The maximum height of the Nile floods (in September) was above the average. They were abnormally high in 1892 and 1894.

(*e*) The rains were favourable over Australia and South Africa during this period, according to the reports received in India.

(*f*) Hence, as a general inference, the rainfall was in general excess in each year of the period over the Indo-oceanic region, and not only in the south-west but also in the north-east monsoon in Southern Asia.

(3) The chief features of the rainfall of the second period, 1895–1902, in the Indo-oceanic region were as follows:—

(*a*) The rainfall was as deficient relatively to the normal in the cold weather as in the rains or wet season.

(*b*) The cold-weather or winter precipitation was almost continuously in marked defect in Asiatic Turkey, Persia, Afghanistan, Baluchistan, the Himalayan area, and South Tibet. The opposite variation obtained in Central Asia, as is shown by available data for Tashkend, Samarcand, Irkutsk, and other stations.

(*c*) The storms of the cold weather were fewer in number and feebler in character in each year of the period than on the average of the preceding sixteen years 1876–91.

(*d*) The south-west monsoon rainfall was most largely in defect in the interior districts served by the Bombay current.

(*e*) There was a marked tendency in each year for late commencement and early withdrawal of the monsoon currents, and for deficient rainfall throughout the whole season over the greater part of India. These features were very pronounced in the years 1896, 1899, and 1901.

(*f*) The most remarkable feature of the period was that the region to the south of the equator, including South and East Africa, Mauritius, and Australia, was similarly affected.

In India the years 1896 and 1899 were years of severe drought, followed by famine over very large areas. The area in which the crops failed more or less completely was about 250,000 square miles in extent in 1896 and 500,000 square miles in 1899. In the 1899–1900 famine upwards of 6,500,000 people were on famine relief for several months. The loss of cattle due to failure of water and fodder was very great, numbering many millions. In some districts from 90 to 95 per cent. of the cattle died off from slow starvation and want of water. In New South Wales and Queensland almost continuous drought prevailed from 1896 to 1902. It is estimated that more than fifty millions of sheep, value 12,500,000*l*., were lost in New South Wales during these seven years of drought.

Mr. Hutchins, Conservator of Forests, Cape Town, states that drought prevailed more or less persistently over the Karoo region in South Africa from 1896 to 1903, and that cattle and sheep perished by millions. He also states that the drought extended to British Central Africa from 1898 to 1903.

The previous statements evidence the continuity, extension, and intensity of the drought.

The Nile floods followed very closely the variations of the rainfall in Western India. The floods of the years 1899 and 1901 were both amongst the lowest on record. This shows that the rainfall in the Abyssinian region was more or less generally in defect during the period and most largely in the years 1899 and 1901, when the rainfall of the Bombay current was very deficient.

Hence, as a general inference, the period 1895–1902 was characterised by more or less persistent deficiency of rainfall over practically the whole Indo-oceanic area (including Abyssinia). The economic results in the dry interior districts of India, South Africa, and Australia were the same—large loss of cattle and great loss of capital. The drought in Southern Asia was as marked in the north-east as in the south-west monsoon, and hence the variation was not seasonal but general.

The variations of temperature, humidity, and cloud in India during the whole period were large and in direct accordance with the rainfall. In other words, during the period 1892–94 the air was damper with lower temperature than usual, and cloud above the normal. On the other hand, from 1895 to 1902 temperature was steadily in excess, cloud less than usual, and humidity below the normal.

The most remarkable variation was that of the solar radiation as indicated by observations of the solar radiation thermometer (black bulb *in vacuo*).

The most interesting feature of the meteorology of the period 1892–1902 is that the variations of the solar insolation are the inverse of those which might have been expected from the cloud and humidity data. In other words, solar radiation was in excess in the period of increased humidity and cloud, and in defect during the greater part of the period of drought, decreased humidity, and cloud. The series of eight curves exhibited, out of a larger number prepared from the data of a number of stations in India at which these observations are carefully recorded, show the most important facts, and indicate that there was a continuous decrease of insolation on the average of all stations from 1891 to 1902. The curves for Aden, Calcutta, and Leh, it will be seen, agree in their most important features. The observations are quite concordant and probably represent a most important feature of the period. They indicate either a continuous and considerable decrease of emission of solar energy during the period, or unusually large absorption in the upper atmosphere. In order to decide this question comparison is necessary with similar data for other large areas as, for example, Europe and North America. It is, however, clear that in India the insolation data of this unique period are of exceptional interest and value.

The preceding statements have shown that variations of rainfall for prolonged periods similar in character have occurred, and may hence occur again, over the very large area including the Southern Asian peninsulas, East and South Africa, Australia, and, perhaps, the Indian Ocean. The abnormal actions or conditions giving rise to these large and prolonged variations must hence be persistent for long periods, and be effective over the whole of that extensive area, and hence cannot be inferred with certainty from the examination of the data of one small portion of the area affected—*e.g.*, India. The variations undoubtedly accompany variations in the complete atmospheric circulation over the Indo-oceanic area, and the effective forces or actions must be such as to influence the whole movement in a similar manner in the two monsoons or seasons of inverse conditions in Southern Asia. This inference furnishes a very strong reason for the conclusion that the meteorology of the whole area similarly affected from 1892 to 1902 should be studied as a whole, and not in fragmentary

detail by various weather bureaus, and as at present without any co-ordination of the results of these bureaus.

The discussion has also indicated that the south-west monsoon current is a periodic or intermittent extension of the permanent circulation of the south-east trades to the peninsulas of Southern Asia, and also that variations in the strength, volume, and direction of movement of the latter affect the extension, volume, aqueous vapour contents, and precipitation of the south-west monsoon currents in Burma, India, and Abyssinia. This fact further emphasises the necessity for the co-ordination and systematisation of the work of observation in the Indo-oceanic meteorological province and the continuous and systematic examination and discussion of observations for the whole of that area.

It is, of course, possible that it may be necessary to extend this work to a larger area than the Indo-oceanic region. For Sir Norman Lockyer and Dr. Lockyer have shown that similar pressure variations to those of Bombay occur over a large portion of the Eastern Hemisphere, and variations of opposite sign (similar to those of Cordova) over a considerable part of the Western Hemisphere.

The Indian Meteorological Department, with the sanction of the Government of India, is now arranging to collect and tabulate data for the whole area between the Central Asian winter anticyclone and the permanent South Indian Ocean anticyclone, and to utilise the information for the investigation of the causes of the large and general variations of rainfall in Burma and India from year to year. This extension of its labour is recognised as necessary for the improvement of the seasonal forecasts, an important feature of the work of the Department the value and importance of which are fully recognised by the Government of India.

Possibly the practice of the Indian Meteorological Department in the preparation and issue of long-period or seasonal forecasts is considered to be not only unscientific, but not justified by comparison with facts. Prof. Cleveland Abbe, in his paper on "The Physical Basis of Long-range Weather Forecasts," expresses his opinion that "we are warranted in saying that during the thirteen years (1888–1900) the only real failure has been that of the prediction of the monsoon season of 1899, the year of phenomenally great drought in that country." This opinion is probably more favourable than I should myself give, but it is the opinion of an independent meteorologist eminently qualified to give a judgment in the matter.

My own opinion with respect to weather forecasts is that there appears to be too strong a desire for absolute accuracy, possibly due to public and newspaper criticism. Certainty is not possible in weather forecasts based on imperfect information, and in which the introduction of a single unknown factor in regions beyond observation—*e.g.*, the upper or middle atmosphere—may completely alter the course of events. Percentages of success are an inadequate measure of the utility of forecasts. To be of real value as estimates of utility they should be calculated rather on the information required, and which might be reasonably expected, than on that actually given.

It appears to me that the striving after perfection in short-period forecasts to the exclusion of other claims is impeding the extension and progress of meteorology in other useful directions. It is absolutely essential that officials preparing or utilising forecasts should recognise that every forecast is based on imperfect information and experience, and hence that all important forecasts should be expressed as probabilities, and, whenever desirable, an estimate of the value of each probability be given.

The Government of India desires to have these seasonal forecasts, and has ordered its Meteorological Department to furnish them. The Government encourages the work, provides the additional means required by the Department for its proper performance, and issues the forecasts only to those who will use them as probabilities for practical guidance.

The importance of the work of seasonal forecasting in India may be judged from the following remarks:—

India is almost exclusively an agricultural country, with a population of nearly 300 millions. The material prosperity of practically the whole people is determined by the amount and distribution of the periodic rains. The variations in the amount and period of the rains are occasionally so great as to produce the most disastrous results in the staple crops over large areas. In 1899, for example, the crops failed more or less completely over an area several times the extent of England.

There is probably no country where the meteorological problems, of which these rainfall variations form one feature, are of greater interest or more practical importance. The daily weather and rainfall reports are studied during the greater part of the year with the closest attention by the officials, from the Viceroy downwards.

The Government is hence keenly interested in meteorological observation and investigation, and is most anxious to improve its meteorological service and utilise it for practical purposes, of which seasonal forecasting is one of the most important. To give two examples. A reassuring forecast at a critical period, followed by its realisation, might be of the greatest value to the agricultural population of a large province, as well as to the local and Imperial Governments. Again, a statement or forecast the probability of which was, say, at least 10 to 1 that the rains would fail more or less completely during a season over a large area might enable the Government to carry out early prudential measures for relief in the most economical and effective manner with the means at its disposal. The preparation and issue of seasonal forecasts will hence, I am confident, be in the future, as in the past, one of the most important duties of the Indian Meteorological Department.

There are several points in connection with weather forecasting in India which it is desirable should be borne in mind. The first is that weather in India is distinguished rather by the massiveness, intensity, and persistence of abnormal features than by the frequency and rapid succession of important weather changes. It is chiefly on this account that daily weather forecasts, even if they could be communicated with the necessary rapidity, are of no value to the Indian agricultural population. Also, the empirical knowledge of the significance of the important variations as factors determining or indicating future weather accumulates much more slowly than in Europe, and it is hence doubly important that in India the empirical knowledge derived from very limited experience should be, so far as possible, regulated and controlled by theory and scientific knowledge. It should also be remembered that there are large differences between the meteorology of tropical and temperate regions, and also between the relation of crops to weather in India and England. The instincts, habits, beliefs, education of the body of the people in England and India also differ very widely. Hence the possibilities of the practical applications of meteorological science in India cannot be judged from the European standard, and may from that standpoint be unique.

The possibilities of usefulness of the work of seasonal or long-period forecasting in India are almost unlimited. To be acceptable and useful to the agricultural population of areas liable to drought they should be fairly accurate with respect to the dates of commencement and termination of the periodic rains, their general character, and the probable occurrence of prolonged breaks likely to be injurious to the chief food crops. If the forecasts were found to be fairly trustworthy in these respects, it is quite certain that the agricultural population would value them and use them. Indications of a growing belief in the utility and value of this feature of the work of the Department by the people in different parts of India are not wanting.

The Government of India has sanctioned large changes in its Meteorological Department in order to enable it to carry out the extensions of work that recent experience has shown to be desirable. The Department is kept in touch with scientific opinion and judgment at home through the Observatories Committee of the Royal Society. The relations to other scientific departments in India are maintained by a special committee termed the Board of Scientific Advice. The scientific staff has been largely increased. The solar physics observatory at Kodaikanal and the magnetic observatory at Bombay have been placed under the Meteorological Department with a view to the complete co-ordination of the departments of scientific investigation for which they are maintained. Observational data for the whole Indo-oceanic area are now being collected and tabulated with a view to the early publication of daily and monthly weather reports and charts of that area.

The objects of this last extension have already been indicated. It will afford the Indian meteorologists the data necessary for the investigation of the extension and intensity of the more important variations in the meteorology of the whole region, to correlate the abnormal features in the atmospheric circulation over the area, and more especially to ascertain the causes of the occasional failure of the monsoon rains in India. Finally, it will, it is hoped, enable the Department to collect the information and acquire the additional experience necessary in order to render the seasonal forecasts more trustworthy and satisfactory than they have been during the past six or seven years.

The area to be dealt with (viz., the Indo-oceanic area) is partially covered by a number of independent meteorological systems, including those of Egypt, East, Central and South Africa, Ceylon, Mauritius, the Straits Settlements, and Australia. Large areas, as, for example, Arabia, Persia, Afghanistan, Tibet, and the greater number of the islands of the Indian Ocean, are now almost completely unrepresented.

The departments controlling these systems work independently of each other, chiefly for local objects, and are in no way officially correlated or affiliated. Their methods of observation and of discussion and publication of meteorological data differ largely. It is hence difficult, if not almost impossible, to make satisfactory comparisons of the data, and trace out for the work of current meteorology the extension or field of similar variations, their relations to each other, and their probable influence on the future weather.

The work which should be carried out in order that the investigation of the meteorology of the Indo-oceanic area might be effective and as complete as possible includes the following:—

(1) The extension of the field of observation by the establishment of observatories in unrepresented areas, and the systematic collection of marine meteorological data for the oceanic area.

(2) The collection and tabulation of the data necessary to give an adequate view of the larger abnormal features of the meteorology of the whole area.

(3) The direction by some authoritative body of the registration, collection, and tabulation of observations by similar methods in order to furnish strictly comparable data for discussion.

(4) The preparation of summaries of data required as preliminary to the work of discussion, and for the information of the officers controlling the work of observation in the contributory areas. The earliest publication of the data should be regarded as essential for the use of officers issuing seasonal forecasts.

(5) The scientific discussion of all the larger abnormal features in any considerable part of the area and their correlation to corresponding or compensatory variations in the remainder of the area by a central office furnished with an adequate staff.

(6) Possibly, sufficient authority on the part of the central office to initiate special observations required for the elucidation of special features for which there are no arrangements in the general work of the various systems.

The Indian Meteorological Department is making preparations to carry out a portion of this work; and will undoubtedly do the best it can single-handed with its limited means. It cannot do the work fully and as it ought to be done. It can do nothing which requires authoritative control over the remaining meteorological systems in the Indo-oceanic field. It is collecting information from those who are willing to supply it, and will utilise it for its special purposes.

It is evident the work can only be carried out fully by the co-operation of the various systems subject to limited control by a central office with acknowledged imperial or general authority behind it. The most important part of the work from the standpoint of the science of meteorology is the comparison and discussion of the whole body of observations. The constitution, position, and authority of the central office is hence of the greatest importance. It is quite certain that none of the meteorological systems directly concerned can provide such a central office. If the work is to be carried out fully and systematically it can only be arranged for in England, and by the English Government assuming the general direction and control. At the present time a section of the English Meteorological Office is devoted to the study of oceanic meteorology for the information of mariners. Another section should be created for the study of imperial meteorology for the benefit of its dependencies and colonies. I have reason to believe that the Government of India would contribute its share towards the cost of this extension of work.

In the preceding remarks are given the chief reasons for an important extension of work now in progress in the Indian Meteorological Department, an extension which can only be carried out imperfectly by that Department, but which could be performed with most valuable scientific results by the co-ordination of the labours of the weather bureaus concerned, with a central institution or investigating office in England under Government control.

Perhaps I may be permitted, from my Indian experience, to add some general remarks bearing on the methods and progress of meteorological inquiry.

In India the collection and publication of accurate current data relating to rainfall and temperature is required for the information of Government in its various Departments. The collection and examination of pressure and wind data by a central office with a view to the issue of storm and flood warnings is equally necessary. This work may, perhaps, be described as pertaining to descriptive or economic meteorology.

Economic meteorology, so long as it deals only with actual facts of observation, is not a science. Forecasts belong to the same department or branch of meteorology. They may be based on scientific theory and be obtained by scientific methods or the utilisation of empirical knowledge. The latter method is probably sufficient for by far the greater part of short-period forecast work, but the final development of that work and the preparation of long-period forecasts require the application of exact scientific methods and knowledge. And it is, perhaps, not too much to say that the extension of the range or period of forecasts is a measure of the progress of meteorology as a science. India, by the simplicity and massiveness of its meteorological changes (and perhaps Australia and Africa), appears to be best suited for the earliest experiments in this work.

India is, however, poor, not only in material wealth and capital as compared with England, but also in the appliances and means of scientific investigation, and hence looks to England for assistance and guidance in scientific matters. Unfortunately, England lags behind, not only the United States and Germany, but even behind India, in the important field of scientific meteorological inquiry. It will suffice to give a single illustration of the anomalous and inferior position which England takes in such matters.

All meteorologists and scientific men generally are agreed that the exploration of the middle and upper atmosphere by any available means—*e.g.*, kites, balloons, &c.—is of the utmost importance at the present stage of meteorological inquiry. The United States, France, and Germany have taken up the work vigorously. The English Meteorological Office is unable, for want of funds, to share or take any part in the work. The force of scientific and public opinion is apparently powerless to move the English Government to grant an extra five hundred pounds annually for this work. The English Government, on the other hand, some time ago suggested that the Indian Meteorological Department should assist. The Government of India, recognising the importance of the work, has provided the funds and sanctioned the arrangements necessary in order that its Meteorological Department may march with the most progressive nations in this investigation.

India has no body of voluntary observers or independent scientific workers and investigators. Whatever is required to be done to extend practical and theoretical meteorology can only be effected by the Government Department to which that work is assigned, with the sanction and at the cost of the Government—which naturally considers chiefly its practical wants in relation to its limited resources. It is, from one point of view, a painful if not quite an unexpected experience to me, on my retirement, to find that the Government of India is, in its attitude towards meteorological inquiry, more advanced, more liberal and far-sighted than the English Government, and that England has not yet taken up seriously the work of scientific meteorological

investigation. There are undoubtedly too many observations and too little serious discussion of observations. The time has arrived when investigation should go hand in hand with accurate observation, and should direct and suggest the work of observation, and also that the sciences directly related to meteorology should be considered concurrently with it. There are undoubtedly definite relations between certain classes of solar phenomena and phenomena of terrestrial magnetism. The probability of definite relations between solar and terrestrial meteorological phenomena is also generally admitted.

Data for the determination of these relations are being rapidly accumulated, and numerous problems connected therewith are waiting and ripe for investigation. They are too large and complex to be undertaken by present English methods, and can only be attacked by a body of trained investigators under arrangements securing the continuity of method and thought requisite for the prolonged systematic inquiry gradually leading up to their complete solution.

It would hence be desirable to enlarge the scope of the central institution I have suggested, so as to include in its field of labour the investigation of the relation between solar and terrestrial meteorology and magnetism, so far as they can be solved by the comparison of the observations of the British Empire.

The central institution would thus have large and definite fields of work and most interesting problems for investigation. It would hence contribute towards the formation of a body of scientific meteorological investigators adequate to the importance and wants of the empire, and be of the highest educational as well as scientific value.

My predecessor in this position, Dr. Shaw, the head of the English Meteorological Office, made some remarks in his Address last year which deserve repetition in connection with this idea. He said: "The British Empire stands to gain more by scientific knowledge, and to lose more by unscientific knowledge, of the matter than any other country. It should from its position be the most important agency for promoting the advance of meteorological science, in the first place because it possesses such admirable varying fields of observation, and in the second place because with due encouragement British intellect may achieve as fruitful results in this as in other fields of investigation."

The establishment of the central institution as suggested above would provide a remedy for the defects pointed out by Dr. Shaw. The reorganisation of the English Meteorological Office is, I believe, under consideration. Is it too much to hope that a strong expression of opinion on the part of the British Association, and the influence of the learned University at which its present meeting is held, would induce the English Government to spend an additional 5000*l.* or 10,000*l.* annually for the promotion of meteorological investigation and the establishment of a central imperial institution in London in connection with its Meteorological Office?

SECTION D.

ZOOLOGY.

OPENING ADDRESS BY WILLIAM BATESON, M.A., F.R.S., PRESIDENT OF THE SECTION.

IN choosing a subject for this address I have availed myself of the kindly usage which permits a sectional president to divert the attention of his hearers into those lines of inquiry which he himself is accustomed to pursue. Nevertheless, in taking the facts of breeding for my theme, I am sensible that this privilege is subjected to a certain strain.

Heredity—and variation too—are matters of which no naturalist likes to admit himself entirely careless. Everyone knows that, somewhere hidden among the phenomena denoted by these terms, there must be principles which, in ways untraced, are ordering the destinies of living things. Experiments in heredity have thus, as I am told, a universal fascination. All are willing to offer an outward deference to these studies. The limits of that homage, however, are soon reached, and, though all profess interest, few are impelled to make even the moderate mental effort needed to apprehend what has been already done. It is understood that heredity is an important mystery, and variation another mystery. The naturalist, the breeder, the horticulturist, the sociologist, man of science and man of practice alike, has daily occasion to make and to act on assumptions as to heredity and variation, but many seem well content that such phenomena should remain for ever mysterious.

The position of these studies is unique. At once fashionable and neglected, nominally the central common ground of botany and zoology, of morphology and physiology, belonging specially to neither, this area is thinly tenanted. Now, since few have leisure for topics with which they cannot suppose themselves concerned, I am aware that, when I ask you in your familiar habitations to listen to tales of a no man's land, I must forego many of those supports by which a speaker may maintain his hold on the intellectual sympathy of an audience.

Those whose pursuits have led them far from their companions cannot be exempt from that differentiation which is the fate of isolated groups. The stock of common knowledge and common ideas grows smaller until the difficulty of inter-communication becomes extreme. Not only has our point of view changed, but our materials are unfamiliar, our methods of inquiry new, and even the results attained accord little with the common expectations of the day. In the progress of sciences we are used to be led from the known to the unknown, from the half-perceived to the proven, the expectation of one year becoming the certainty of the next. It will aid appreciation of the change coming over evolutionary science if it be realised that the new knowledge of heredity and variation rather replaces than extends current ideas on those subjects.

Convention requires that a president should declare all well in his science; but I cannot think it a symptom indicative of much health in our body that the task of assimilating the new knowledge has proved so difficult. An eminent foreign professor lately told me that he believed there were not half a dozen in his country conversant with what may be called Mendelism, though he added hopefully, "I find these things interest my students more than my colleagues." A professed biologist cannot afford to ignore a new life-history, the Okapi, or the other last new version of the old story; but phenomena which put new interpretations on the whole, facts witnessed continually by all who are working in these fields, he may conveniently disregard as matters of opinion. Had a discovery comparable in magnitude with that of Mendel been announced in physics or in chemistry, it would at once have been repeated and extended in every great scientific school throughout the world. We could come to a British Association audience to discuss the details of our subject—the polymorphism of extracted types, the physiological meaning of segregation, its applicability to the case of sex, the nature of non-segregable characters, and like problems with which we are now dealing—sure of finding sound and helpful criticism; nor would it be necessary on each occasion to begin with a popular presentation of the rudiments. This state of things in a progressive science has arisen, as I think, from a loss of touch with the main line of inquiry. The successes of descriptive zoology are so palpable and so attractive, that, not unnaturally, these which are the means of progress have been mistaken for the end. But now that the survey of terrestrial types by existing methods is happily approaching completion, we may hope that our science will return to its proper task, the detection of the fundamental nature of living things. I say *return*, because, in spite of that perfecting of the instruments of research characteristic of our time, and an extension of the area of scrutiny, the last generation was nearer the main quest. No one can study the history of biology without perceiving that in some essential respects the spirit of the naturalists of fifty years ago was truer in aim, and that their methods of inquiry were more direct and more fertile—so far, at least, as the problem of evolution is concerned—than those which have replaced them.

If we study the researches begun by Kölreuter and continued with great vigour until the middle of the sixties, we cannot fail to see that had the experiments he and his successors undertook been continued on the same lines, we should by now have advanced far into the unknown. More than this: if a knowledge of what those men actually accomplished had not passed away from the memory of our generation, we should now be able to appeal to an informed public mind, having some practical acquaintance with the

phenomena, and possessing sufficient experience of these matters to recognise absurdity in statement and deduction, ready to provide that healthy atmosphere of instructed criticism most friendly to the growth of truth.

Elsewhere I have noted the paradox that the appearance of the work of Darwin, which crowns the great period in the study of the phenomena of species, was the signal for a general halt. The "Origin of Species," the treatise which for the first time brought the problem of species fairly within the range of human intelligence, so influenced the course of scientific thought that the study of this particular phenomenon—specific difference—almost entirely ceased. That this was largely due to the simultaneous opening up of lines of research in many other directions may be granted; but in greater measure, I believe, it is to be ascribed to the substitution of a conception of species which, with all the elements of truth it contains, is yet barren and unnatural. It is not wonderful that those who held that specific difference must be a phenomenon of slowest accumulation, proceeding by steps needing generations for their perception, should turn their attention to subjects deemed more amenable to human enterprise.

The indiscriminate confounding of all divergences from type into one heterogeneous heap under the name "Variation" effectually concealed those features of order which the phenomena severally present, creating an enduring obstacle to the progress of evolutionary science. Specific normality and distinctness being regarded as an accidental product of exigency, it was thought safe to treat departures from such normality as comparable differences: all were "variations" alike. Let us illustrate the consequences. Princess of Wales is a large modern violet, single, with stalks a foot long or more. Marie Louise is another, with large double flowers, pale colour, short stalks, peculiar scent, leaf, &c. We call these "varieties," and we speak of the various fixed differences between these two, and between them and wild *odorata*, as due to variation; and, again, the transient differences between the same *odorata* in poor, dry soil, or in a rich hedge-bank, we call variation, using but the one term for differences, quantitative or qualitative, permanent or transitory, in size, number of parts, chemistry, and the rest. We might as well use one term to denote the differences between a bar of silver, a stick of lunar caustic, a shilling, or a teaspoon. No wonder that the ignorant tell us they can find no order in variation.

This prodigious confusion, which has spread obscurity over every part of these inquiries, is traceable to the original misconception of the nature of specific difference, as a thing imposed and not inherent. From this, at least, the earlier experimenters were free; and the undertakings of Gärtner and his contemporaries were informed by the true conception that the properties and behaviour of species were themselves specific. Free from the later fancy that but for selection the forms of animals and plants would be continuous and indeterminate, they recognised the definiteness of species and variety, and boldly set themselves to work out case by case the manifestations and consequences of that definiteness.

Over this work of minute and largely experimental analysis, rapidly growing, the new doctrine that organisms are mere conglomerates of adaptative devices descended like a numbing spell. By an easy confusion of thought, faith in the physiological definiteness of species and variety passed under the common ban which had at last exorcised the demon Immutability. Henceforth no naturalist must hold communion with either, on pain of condemnation as an apostate, a danger to the dynasty of Selection. From this oppression we in England, at least, are scarcely beginning to emerge. Bentham's "Flora," teaching very positively that the primrose, the cowslip, and the oxlip are impermanent varieties of one species, is in the hand of every beginner, while the British Museum Reading Room finds it unnecessary to procure Gärtner's "*Bastarderzeugung.*"

And so this mass of specific learning has passed out of account. The evidence of the collector, the horticulturist, the breeder, the fancier, has been treated with neglect, and sometimes, I fear, with contempt. That wide field whence Darwin drew his wonderful store of facts has been some forty years untouched. Speak to professional zoologists of any breeder's matter, and how many will not intimate to you politely that fanciers are unscientific persons, and their concerns beneath notice? For the concrete in evolution we are offered the abstract. Our philosophers debate with great fluency whether between imaginary races sterility could grow up by an imaginary Selection; whether Selection working upon hypothetical materials could produce sexual differentiation; how under a system of Natural Selection bodily symmetry may have been impressed on formless protoplasm—that monstrous figment of the mind, fit starting-point for such discussions. But by a physiological irony enthusiasm for these topics is sometimes fully correlated with indifference even to the classical illustrations; and for many whose minds are attracted by the abstract problem of inter-racial sterility there are few who can name for certain ten cases in which it has been already observed.

And yet in the natural world, in the collecting-box, the seed-bed, the poultry-yard, the places where variation, heredity, selection may be seen in operation and their properties tested, answers to these questions meet us at every turn—fragmentary answers, it is true, but each direct to the point. For if anyone will stoop to examine Nature in those humble places, will do a few days' weeding, prick out some rows of cabbages, feed up a few score of any variable larva, he will not wait long before he learns the truth about variation. If he go further and breed two or three generations of almost any controllable form, he will obtain immediately facts as to the course of heredity which obviate the need for much laborious imagining. If strictly trained, with faith in the omnipotence of selection, he will not proceed far before he encounters disquieting facts. Upon whatever character the attention be fixed, whether size, number, form of the whole or of the parts, proportion, distribution of differentiation, sexual characters, fertility, precocity or lateness, colour, susceptibility to cold or to disease—in short, all the kinds of characters which we think of as best exemplifying specific difference—we are certain to find illustrations of the occurrence of departures from normality, presenting exactly the same definiteness elsewhere characteristic of normality itself. Again and again the circumstances of their occurrence render it impossible to suppose that these striking differences are the product of continued selection, or, indeed, that they represent the results of a gradual transformation of any kind. Whenever by any collocation of favouring circumstances such definite novelties possess a superior viability, supplanting their "normal" relatives, it is obvious that new types will be created.

The earliest statement of this simple inference is, I believe, that of Marchant,[1] who in 1719, commenting on certain plants of Mercurialis with laciniated and hair-like leaves, which for a time established themselves in his garden, suggested that species may arise in like manner. Though the same conclusion has appeared inevitable to many, including authorities of very diverse experience, such as Huxley, Virchow, F. Galton, it has been strenuously resisted by the bulk of scientific opinion, especially in England. Lately, however, the belief in Mutation, as De Vries has taught us to call it, has made notable progress,[2] owing to the publication of his splendid collection of observations and experiments, which must surely carry conviction of the reality and abundance of Mutation to the minds of all whose judgments can be affected by evidence.

That the dread test of Natural Selection must be passed by every aspirant to existence, however brief, is a truism which needs no special proof. Those who find satisfaction in demonstrations of the obvious may amply indulge themselves by starting various sorts of some annual, say French poppy, in a garden, letting them run to seed, and noticing in a few years how many of the finer sorts are represented; or by sowing an equal number of seeds taken from several varieties of carnation, lettuce, or auricula, and seeing in what proportions the fine kinds survive in competition with the common.

Selection is a true phenomenon; but its function is to *select*, not to create. Many a white-edged poppy may have germinated and perished before Mr. Wilks saved the

[1] Marchant, *Mém. Ac. roy. des Sci.* for 1719; 1721, p 59, Pls. 6–7. I owe this reference to Coutagne, "L'hérédité chez les vers à soie" (*Bull. sci. Fr. Belg.* 1902).

[2] This progress threatens to be rapid indeed. Since these lines were written Prof. Hubrecht, in an admirable exposition (*Pop. Sci. Monthly*, July, 1904) of De Vries' "Mutations-theorie," has even blamed me for having ten years ago attached *any* importance to continuous variation. Nevertheless, when the unit of segregation is small, something mistakably like continuous evolution must surely exist. (Cp. Johannsen, "Ueb. Erblichkeit in Populationen und in reinen Linien," 1903.)

individual which in a few generations gave rise to the Shirleys. Many a black *Amphidasys betularia* may have emerged before, some sixty years ago, in the urban conditions of Manchester the black var. *doubledayaria* found its chance, soon practically superseding the type in its place of origin, extending itself over England, and reappearing even in Belgium and Germany.

Darwin gave us sound teaching when he compared man's selective operations with those of Nature. Yet how many who are ready to expound Nature's methods have been at the pains to see how man really proceeds? To the domesticated form our fashions are what environmental exigency is to the wild. For years the conventional Chinese primrose threw sporadic plants of the loose-growing *stellata* variety, promptly extirpated because repugnant to mid-Victorian primness. But when taste, as we say, revived, the graceful Star Primula was saved by Messrs. Sutton, and a stock raised which is now of the highest fashion. I dare assert that few botanists meeting *P. stellata* in Nature would hesitate to declare it a good species. This and the Shirleys precisely illustrate the procedure of the raiser of novelties. His operations start from a definite beginning. As in the case of *P. stellata*, he may notice a mutational form thrown off perfect from the start, or, as in the Shirleys, what catches his attention may be the first indication of that flaw which if allowed to extend will split the type into a host of new varieties each with its own peculiarities and physiological constitution.

Let anyone who doubts this try what he can do by selection without such a definite beginning. Let him try from a pure strain of black and white rats to raise a white one by breeding from the whitest, or a black one by choosing the blackest. Let him try to raise a dwarf ("Cupid") sweet pea from a tall race by choosing the shortest, or a crested fowl by choosing the birds with most feather on their heads. To formulate such suggestions is to expose their foolishness.

The creature is beheld to be very good after, not before its creation. Our domesticated races are sometimes represented as so many incarnations of the breeder's prophetic fancy. But except in recombinations of pre-existing characters—now a comprehensible process—and in such intensifications and such finishing touches as involve variations which analogy makes probable, the part played by prophecy is small. Variation leads; the breeder follows. The breeder's method is to notice a desirable novelty, and to work up a stock of it, picking up other novelties in his course—for these genetic disturbances often spread—and we may rest assured the method of Nature is not very different.

The popular belief that evolution, whether natural or artificial, is effected by mass-selection of impalpable differences arises from many errors which are all phases of one—imperfect analysis—though the source of the error differs with the circumstances of its exponent. When the scientific advocate professes that he has statistical proofs of the continuity of variation, he is usually availing himself of that comprehensive use of the term Variation to which I have referred. Statistical indications of such continuity are commonly derived from the study, not of nascent varieties, but of the fluctuations to which all normal populations are subject. Truly varying material needs care in its collection, and if found is often sporadic or in some other way unsuitable for statistical treatment. Sometimes it happens that the two phenomena are studied together in inextricable entanglement, and the resulting impression is a blur.

But when a practical man, describing his own experience, declares that the creation of his new breed has been a very long affair, the man of science, feeling that he has found a favourable witness, puts forward this testimony as conclusive. But on cross-examination it appears that the immense period deposed to seldom goes back beyond the time of the witness's grandfather, covering, say, seventy years; more often ten, or eight, or even five years will be found to have accomplished most of the business. Next, in this period—which, if we take it at seventy years, is a mere point of time compared with the epochs of which the selectionist discourses—a momentous transformation has often been effected, not in one character but many. Good characters have been added, it may be, of form, fertility, precocity, colour, and other physiological attributes, undesirable qualities have been eliminated, and all sorts of defects "rogued" out. On analysis these operations can be proved to depend on a dozen discontinuities. Be it, moreover, remembered that within this period, besides *producing* his mutational character and combining it with other characters (or it may be groups of characters), the breeder has been working up a *stock*, reproducing in quantity that quality which first caught his attention, thus converting, if you will, a phenomenon of individuals into a phenomenon of a mass, to the future mystification of the careless.

Operating among such phenomena the gross statistical method is a misleading instrument; and, applied to these intricate discriminations, the imposing Correlation Table into which the biometrical Procrustes fits his arrays of unanalysed data is still no substitute for the common sieve of a trained judgment. For nothing but minute analysis of the facts by an observer thoroughly conversant with the particular plant or animal, its habits and properties, checked by the test of crucial experiment, can disentangle the truth.

To prove the reality of Selection as a factor in evolution is, as I have said, a work of supererogation. With more profit may experiments be employed in defining the *limits* of what Selection can accomplish. For whenever we can advance no further by Selection, we strike that hard outline fixed by the natural properties of organisms. We come upon these limits in various unexpected places, and to the naturalist ignorant of breeding nothing can be more surprising or instructive.

Whatever be the mode of origin of new types, no theoretical evolutionist doubts that Selection will enable him to fix his character when obtained. Let him put his faith into practice. Let him set about breeding canaries to win in the class for Clear Yellow Norwich at the Crystal Palace Show. Being a selectionist, his plan will be to pick up winning yellow cocks and hens at shows and breed them together. The results will be disappointing. Not getting what he wants, he may buy still better clear yellows and work them in, and so on until his funds are exhausted, but he will pretty certainly breed no winner, be he never so skilful. For no selection of winning yellows will make them into a breed. They must be formed afresh by various combinations of colours appropriately crossed and worked up. Though breeders differ as to the system of combinations to be followed, all would agree that selection of birds representing the winning type was a sure way to fail. The same is true for nearly all canary colours except in Lizards, and, I believe, for some pigeon and poultry colours also.

Let this scientific fancier now go to the Palace Poultry Show and buy the winning Brown Leghorn cock and hen, breed from them, and send up the result of such a mating year after year. His chance of a winner is not quite, but almost, *nil*. For in its wisdom the fancy has chosen one type for the cock and another for the hen. They belong to distinct strains. The hen corresponding to the winning cock is too bright, and the cock corresponding to the winning hen is too dull for the judge's taste. The same is the case in nearly every breed where the sex-colours differ markedly. Rarely winners of both sexes have come in one strain—a phenomenon I cannot now discuss—but the contrary is the rule. Does anyone suppose that this system of "double mating" would be followed, with all the cost and trouble it involves, if Selection could compress the two strains into one? Yet current theory makes demands on Selection to which this is nothing.

The tyro has confidence in the power of Selection to fix type, but he never stops to consider what fixation precisely means. Yet a simple experiment will tell him. He may go to a great show and claim the best pair of Andalusian fowls for any number of guineas. When he breeds from them he finds, to his disgust, that only about half their chickens, or slightly more, come blue at all, the rest being blacks or splashed whites. Indignantly, perhaps, he will complain to the vendor that he has been supplied with no selected breed, but worthless mongrels. In reply he may learn that beyond a doubt his birds come from blues only in the direct line for an indefinite number of generations, and that to throw blacks and splashed whites is the inalienable property of blue Andalusians. But now let him breed from his "wasters," and he will find that the extracted blacks are *pure* and give blacks only, that the splashed whites similarly give only whites or splashed whites—but if the two sorts of "wasters" are crossed together *blues only* will result.

Selection will never make the blues breed true; nor can this ever come to pass unless a blue be found the germ-cells of which are bearers of the blue character—which may or may not be possible. If the selectionist reflect on this experience he will be led straight to the centre of our problem. There will fall, as it were, scales from his eyes, and in a flash he will see the true meaning of fixation of type, variability, and mutation, vaporous mysteries no more.

Owing to the unhappy subdivisions of our studies, such phenomena as these—constant companions of the breeder—come seldom within the purview of modern science, which, forced for a moment to contemplate them, expresses astonishment and relapses into indolent scepticism. It is in the hope that a little may be done to draw research back into these forgotten paths that I avail myself of this great opportunity of speaking to my colleagues with somewhat wider range of topic than is possible within the limits of a scientific paper. For I am convinced that the investigation of heredity by experimental methods offers the sole chance of progress with the fundamental problems of evolution.

In saying this I mean no disrespect to that study of the physiology of reproduction by histological means, which, largely through the stimulus of Weismann's speculations, has of late made such extraordinary advances. It needs no penetration to see that, by an exact knowledge of the processes of maturation and fertilisation, a vigorous stock is being reared, upon which some day the experience of the breeder will be firmly grafted, to our mutual profit. We, who are engaged in experimental breeding, are watching with keenest interest the researches of Strasburger, Boveri, Wilson, Farmer, and their many fellow-workers and associates in this difficult field, sure that in the near future we shall be operating in common. We know already that the experience of the breeder is in no way opposed to the facts of the histologist; but the point at which we shall unite will be found when it is possible to trace in the maturing germ an indication of some character afterwards recognisable in the resulting organism. Until then, in order to pursue directly the course of heredity and variation, it is evident that we must fall back on those tangible manifestations which are to be studied only by field observation and experimental breeding.

The breeding-pen is to us what the test-tube is to the chemist—an instrument whereby we examine the nature of our organisms and determine empirically what for brevity I may call their genetic properties. As unorganised substances have their definite properties, so have the several species and varieties which form the materials of our experiments. Every attempt to determine these definite properties contributes immediately to the solution of that problem of problems, the physical constitution of a living organism. In those morphological studies which I suppose most of us have in our time pursued, we sought inspiration from the belief that in the examination of present normalities we were tracing the past, the phylogenetic order of our types, the history—as we conceived—of Evolution. In the work which I am now pressing upon your notice we may claim to be dealing not only with the present and the past, but with the future also.

On such an occasion as this it is impossible to present to you in detail the experiments—some exceedingly complex—already made in response to this newer inspiration. I must speak of results, not of methods. At a later meeting, moreover, there will be opportunities of exhibiting practically to those interested some of the more palpable illustrations. It is also impossible to-day to make use of the symbolic demonstrations by which the lines of analysis must be represented. The time cannot be far distant when ordinary Mendelian formulæ will be mere *as in praesenti* to a biological audience. Nearly five years have passed since this extraordinary re-discovery was made known to the scientific world by the practically simultaneous papers of De Vries, Correns, and Tschermak, not to speak of thirty-five years of neglect endured before. Yet a phenomenon comparable in significance with any that biological science has revealed remains the intellectual possession of specialists. We still speak sometimes of Mendel's hypothesis or theory, but in truth the terms have no strict application. It is no theory that water is made up of hydrogen and oxygen, though we cannot watch the atoms unite, and it is no theory that the blue Andalusian fowl I produce was made by the meeting of germ-cells bearing respectively black and a peculiar white. Both are incontrovertible facts deduced from observation. The two facts have this in common also, that their perception gives us a glimpse into that hidden order out of which the seeming disorder of our world is built. If I refer to Mendelian "theory," therefore, in the words with which Bacon introduced his Great Instauration, "I entreat men to believe that it is not an opinion to be held, but a work to be done; and to be well assured that I am labouring to lay the foundation, not of any sect or doctrine, but of human utility and power."

In the Mendelian method of experiment the one essential is that the posterity of each *individual* should be traced separately. If individuals from necessity are treated collectively, it must be proved that their composition is identical. In direct contradiction to the methods of current statistics, Mendel saw by sure penetration that masses must be avoided. Obvious as this necessity seems when one is told, no previous observer had thought of it, whereby the discovery was missed. As Mendel immediately proved in the case of peas, and as we have now seen in many other plants and animals, it is often impossible to distinguish by inspection individuals whose genetic properties are totally distinct. Breeding gives the only test.

Segregation.

Where the proper precautions have been taken, the following phenomena have been proved to occur in a great range of cases, affecting many characters in some thirty plants and animals. The qualities or characters the transmission of which in heredity is examined are found to be distributed among the germ-cells, or gametes, as they are called, according to a definite system. This system is such that these characters are treated by the cell-divisions (from which the gametes result) as existing in pairs, each member of a pair being alternative or *allelomorphic* to the other in the composition of the germ. Now, as every zygote—that is, any ordinary animal or plant—is formed by the union of two gametes, it may either be made by the union of two gametes bearing similar members of any pair, say two blacks or two whites, in which case we call it *homozygous* in respect of that pair, or the gametes from which it originates may be bearers of the dissimilar characters, say a black and a white, when we call the resulting zygote *heterozygous* in respect of that pair. If the zygote is homozygous, no matter what its parents or their pedigree may have been, it breeds true indefinitely unless some fresh variation occurs.

If, however, the zygote be heterozygous, or gametically cross-bred, its gametes in their formation separate the allelomorphs again, so that each gamete contains only one allelomorphic character of each pair. At least one cell-division in the process of gametogenesis is therefore a differentiating or *segregating* division, out of which each gamete comes sensibly pure in respect of the allelomorph it carries, exactly as if it had not been formed by a heterozygous body at all. That, translated into modern language, is the essential discovery that Mendel made. It has now been repeated and verified for numerous characters of numerous species, and, in face of heroic efforts to shake the evidence or to explain it away, the discovery of gametic segregation is, and will remain, one of the lasting triumphs of the human mind.

In extending our acquaintance of these phenomena of segregation we encounter several principal types of complication.

Segregation Absent or Incomplete.—From our general knowledge of breeding we feel fairly well satisfied that true absence of segregation is the rule in certain cases. It is difficult, for instance, to imagine any other account of the facts respecting the American Mulattos, though even here sporadic occurrence of segregation seems to be authenticated. Very few instances of genuine absence of segregation have been critically studied. The only one I can cite from my own experience is that of *Pararge egeria* and *egeriades*, "climatic" races of a butterfly. When crossed together, they give the common intermediate type of North-Western France, which, though artificially formed, breeds in great measure true. This crossed back with either type has given, as a rule, simple blends between intermediate and type. My evidence is not, however, complete enough to

warrant a positive statement as to the total absence of segregation, for in the few families raised from pairs of artificial intermediates some dubious indications of segregation have been seen.

The rarity of true failure of segregation when pure strains are crossed may be judged by the fact that since the revival of interest in such work hardly any thoroughly satisfactory cases have been witnessed. The largest body of evidence on this subject is that provided by De Vries. These cases, however, present so many complexities that it is impossible to deal with them now. While so little is definitely known regarding non-segregating characters, it appears to me premature to attempt any generalisation as to what does or does not segregate.

Most of the cases of failure of segregation formerly alleged are evidently spurious, depending on the appearance of homozygotes in the second generation (F_2).

One very important group of cases exists, in which the appearance of a *partial* failure of segregation after the second generation (F_2) is really due to another phenomenon. The visible character of a zygote may, for instance, depend on the coexistence in it of two characters belonging to distinct allelomorphic pairs, each capable of being independently segregated from its fellow, and forming independent combinations. For the demonstration of this important fact we are especially indebted to Cuénot.[1] We have indications of the existence of such a phenomenon in a considerable range of instances (mice, rabbits (Hurst), probably stocks and sweet peas).

Nevertheless, there are other cases, not always easy to distinguish from these, where *some* of the gametes of F_1 certainly carry on heterozygous characters unsegregated. As an example, which seems to me indisputable, I may mention the so-called "walnut" comb, normal to Malay fowls. This can be made artificially by crossing rose-comb with pea-comb, and the cross-bred then forms gametes, of which one in four bears the compound unsegregated.[2] We may speak of this as a true *synthesis*.

In another type of cases segregation occurs, but is not sharp. The gametes may then represent a full series ranging from the one pure form to the other. Such cases occur in regard to some colours of *Primula sinensis*, and the leg-feathering of fowls (Hurst). In the second generation a nearly complete series of intermediate zygotes may result, though the two pure extremes (if the case be one of blending characters) may still be found to be pure.

Resolution and Disintegration.—Besides these cases, the features of which we now in great measure comprehend, we encounter frequently a more complex segregation, imperfectly understood, by which gametes of new types, sometimes very numerous, are produced by the crossbred. Each of these new types has its own peculiarities. We shall, I think, be compelled to regard these phenomena as produced either by a *resolution* of compound characters introduced by one or both parents, or by some process of *disintegration*, effected by a breaking-up of the integral characters followed by recombinations. It seems impossible to imagine simple recombinations of pre-existing characters as adequate to produce many of these phenomena. Such a view would involve the supposition that the number of characters pre-existing as units was practically infinite—a difficulty that as yet we are not obliged to face. However that may be, we have the fact that resolutions and disintegrations of this kind—or recombinations, if that conception he preferred—are among the common phenomena following crossing, and are the sources of most of the breeder's novelties. As bearing on the theoretical question to which I have alluded, we may notice that it is among examples of this complex breaking-up that a great proportion of the cases of partial sterility have been seen.

No quite satisfactory proof as to the actual moment of segregation yet exists, nor have we any evidence that all characters are segregated at the same cell-division. Correns has shown that in maize the segregation of the starch character from the sugar character must happen before the division forming the two generative nuclei, for both bear the same character. The reduction-division has naturally been suggested as the critical moment. The most serious difficulty in accepting this view, as it seems to me, is the fact that somatic divisions appear sometimes to segregate allelomorphs, as in the case of Datura fruits, and some colour-cases.

In concluding this brief notice of the complexities of segregation I may direct attention to the fact that we are here engaged in no idle speculation. For it is now possible by experimental means to distinguish almost always with which phenomenon we are dealing, and each kind of complication may be separately dealt with by a determination of the properties of the extracted forms. Illustrations of a practical kind will be placed before you at a subsequent meeting.

The consequence of segregation is that in cases where it occurs we are rid of the interminable difficulties which beset all previous attempts to unravel heredity. On the older view, the individuals of any group were supposed to belong to an indefinite number of classes, according to the various numerical proportions in which various types had entered into their pedigree. We now recognise that when segregation is allelomorphic, as it constantly is, the individuals are of three classes only in respect of each allelomorphic pair—two homozygous and one heterozygous. In all such cases, therefore, fixity of type, instead of increasing gradually generation by generation, comes suddenly, and is a phenomenon of individuals. Only by the separate analysis of individuals can this fact be proved. The supposition that progress towards fixity of type was gradual arose from the study of masses of individuals, and the gradual purification witnessed was due in the main to the gradual elimination of impure individuals, whose individual properties were wrongly regarded as distributed throughout the mass.

We have at last the means of demonstrating the presence of integral characters. In affirming the integrity of segregable characters we do not declare that the size of the integer is fixed eternally, as we suppose the size of a chemical unit to be. The integrity of our characters depends on the fact that they *can* be habitually treated as units by gametogenesis. But even where such unity is manifested in its most definite form, we may, by sufficient searching, generally find a case where the integrity of the character has evidently been impaired in gametogenesis, and where one such individual is found the disintegration can generally he propagated. That the size of the unit may be changed by unknown causes, though a fact of the highest significance in the attempt to determine the physical nature of heredity, does not in the least diminish the value of the recognition of such units, or lessen their part in governing the course of Evolution.

The existence of unit-characters had, indeed, long been scarcely doubtful to those practically familiar with the facts of variation (*cp.* De Vries, "Intracellulare Pangenesis," 1889), but it is to the genius of Mendel that we owe the proof. We knew that characters could behave as units, but we did not know that this unity was a phenomenon of gametogenesis. He has revealed to us the underworld of gametes. Henceforth, whenever we see a preparation of germ-cells we shall remember that, though all may look alike, they may in reality be of many and definite kinds, differentiated from each other according to regular systems.

Numerical Relations of Gametes and their Significance.

In addition to the fact of segregation, Mendel's experiments proved another fact nearly as significant; namely, that when characters are allelomorphic, the gametes bearing each member of a pair generally are formed in equal numbers by the heterozygote, if an average of cases be taken. This fact can only be regarded as a consequence of some numerical symmetry in the cell-divisions of gametogenesis We already know cases where individual families

[1] When *abc* . . . $\times$ *αβγ* . . . gives in F_1 or F_2 a character (not seen in the original parents), which from F_2 or later may breed true: not because *aα*, *bβ*, *cγ* do not severally segregate, but through simultaneous homozygosis of, say, *aa* and *ββ*, giving a zygote *aaββcγ* . . . which will breed true to the character *aβ*.

[2] Owing to this behaviour, and to the simultaneous production of single-comb (? by resolution), there are, even in pure Malays, five types of individuals, all with "walnut" combs—as yet indistinguishable—formed by gametic unions $r \times p$, $rp \times rp$, $rp \times r$, $rp \times p$, $rp \times s$. Of these kinds three can at once be distinguished by crossing with single; but whether $r \times p$ can be distinguished from $rp \times s$ we do not yet know. [*r*, rose; *p*, pea; *s*, single; *rp* walnut.] In this example four allelomorphs are simultaneously segregated, one being compound. Neglecting sexual differentiation, there are therefore *ten* gametically distinct types theoretically possible; but of these only *four* are distinguishable by inspection.

show such departure from normal expectation that either the numbers produced must have been unequal, or subsequent disturbance must have occurred. But so far no case is known *for certain* where the average of families does not point to equality.

The fact that equality is so usual has a direct bearing on conceptions of the physical nature of heredity. I have compared our segregation with chemical separation, but the phenomenon of numerically symmetrical disjunction as a feature of so many and such different characters seems scarcely favourable to any close analogy with chemical processes. If each special character owed its appearance to the handing on of some complex molecule as a part of one chemical system, we should expect, among such a diversity of characters and forms of life, to encounter some phenomenon of valency, manifested as numerical inequality between members of allelomorphic pairs. So far, equivalence is certainly the rule, and where the characters are simply paired and no resolution has taken place, this rule appears to be universal as regards averages. On the other hand, there are features in the distribution of characters after resolution, when the second generation (F_2) is polymorphic in a high degree, which are not readily accounted for on any hypothesis of simple equivalence; but none of these cases are as yet satisfactorily investigated.

It is doubtful whether segregation is rightly represented as the separation of *two* characters, and whether we may not more simply imagine that the distinction between the allelomorphic gametes is one of presence or absence of some distinguishing element. De Vries has devoted much attention to this question in its bearings on his theory of Pangenesis, holding that cases of both kinds occur, and attempting to distinguish them. Indications may certainly be enumerated pointing in either direction, but for the present I incline to defer a definite opinion.

If we may profitably seek in the physical world for some parallel to our gametic segregations, we shall, I think, find it more close in mechanical separations, such as those which may be effected between fluids which do not freely mix, than in any strictly chemical phenomenon. In this way we might roughly imitate both the ordinary segregation, which is sensibly perfect, and the curious impurity occasionally perceptible even in the most pronounced discontinuities, such as those which divide male from female, petal from sepal, albino from coloured, horn from hair, and so on.

Gametic Unions and their Consequences.

Characters being then distributable among gametes according to regular systems, the next question concerns the properties and features presented by the zygotes formed by the union of gametes bearing different characters.

As to this no rule can as yet be formulated. Such a heterozygote may exhibit one of the allelomorphic characters in its full intensity (even exceeding it in special cases, perhaps in connection with increased vigour), or it may be intermediate between the two, or it may present some character not recognisable in either parent. In the latter case it is often, though not always, reversionary. When one character appears in such intensity as to conceal or exclude the other it is called *dominant*, the other being *recessive*. It may be remarked that frequently, but certainly not universally (as has been stated), the phylogenetically older character is dominant. A curious instance to the contrary is that of the peculiar arrangement of colours seen in a breed of game fowls called Brown-breasted, which in combination with the purple face, though certainly a modern variation, dominates (most markedly in females) over the Black-breasted type of *Gallus bankiva*.

In a few cases irregularity of dominance has been observed as an exception. The clearest illustration I can offer is that of the extra toe in fowls. Generally this is a dominant character, but sometimes, as an exceptional phenomenon, it may be recessive, making subsequent analysis very difficult. The nature of this irregularity is unknown. A remarkable instance is that of the blue colour in maize seeds (Correns; R. H. Lock). Here the dominance of blue is frequently imperfect, or absent, and the figures suggest that some regularity in the phenomenon may be discovered.

Mendel is often represented as having enunciated dominance as a general proposition. That this statement should still be repeated, even by those who realise the importance of his discoveries, is an extraordinary illustration of the oblivion that has overwhelmed the work of the experimental breeders. Mendel makes the specific statement in regard to certain characters in peas which do behave thus, but his proposition is not general. To convict him of such a delusion it would be necessary to prove that he was exceptionally ignorant of breeding, though on the face of the evidence he seems sufficiently expert.

A generalisation respecting the consequences of heterozygosis possessing greater value is this. When a pair of gametes unites in fertilisation the characters of the zygote depend directly on the constitution of these gametes, and not on that of the parents from which they came. To this generalisation we know as yet only two clear exceptions. These very curious cases are exactly alike in that, though segregation obviously occurs in a seed-character, the seeds borne by the hybrid (F_1) all exhibit the hybrid character, and the consequences of segregation in the particular seed-character are not evident until the seeds (F_3) of the second (F_2) generation are determinable. Of these the first is the case of indent peas investigated especially by Tschermak. Crossed with wrinkled peas I have found the phenomena normal, but when the cross is made with a round type the exceptional phenomenon occurs. The second case is that discovered by Biffen in the cross between the long-grained wheat called Polish and short-grained Rivett wheat, demonstrations of which will be laid before you. No satisfactory account of these peculiarities has been yet suggested, but it is evident that in some unexplained way the maternal plant-characters control the seed-characters for each generation. It is, of course, likely that other comparable cases will be found.

Appearances have been seen in at least four cases (rats, mice, stocks, sweet peas) suggesting at first sight that a heterozygosis between two gametes, *both* extracted, may give, *e.g.*, dominance; while if one, or both, were pure, they would give a reversionary heterozygote. If this occurrence is authenticated on a sufficient scale, we shall of course recognise that the fact proves the presence in these cases of some pervading and non-segregating quality, distributed among the extracted gametes formed by the parent heterozygote. As yet, however, I do not think the evidence enough to warrant the conclusion that such a pervading quality is really present, and I incline to attribute the appearances to redistribution of characters belonging to independent pairs in the manner elucidated by Cuénot. The point will be easily determined, and meanwhile we must note the two possibilities.

Following, therefore, our first proposition, that the gametes belong to definite classes, comes the second proposition, that the unions of members of the various classes have specific consequences. Nor is this proposition simply the truistical statement that different causes have different effects; for by its aid we are led at once to the place where the different cause is to be sought—Gametogenesis. While formerly we hoped to determine the offspring by examining the *ancestry* of the parents, we now proceed by investigating the *gametic composition* of the parents. Individuals may have identical ancestry (and sometimes, to all appearances, identical characters), but yet be quite different in gametic composition; and, conversely, individuals may be identical in gametic composition and have very different ancestry. Nevertheless, those that are identical in gametic composition are the same, whatever their ancestry. Therefore, where such cases are concerned, in any considerations of the physiology of heredity, ancestry is misleading and passes out of account. To take the crudest illustration, if a hybrid is made between two races, A, B, and another hybrid between two other races, C, D, it might be thought that when the two hybrids AB and CD are bred together, four races, A, B, C, and D, will be united in their offspring. This expectation may be entirely falsified, for the cell-divisions of gametogenesis may have split A from B and C from D, so that the final product may contain characters of only two races after all, being either AC, BC, AD, or BD. In practice, however, we are generally dealing with *groups* of characters, and the union of all the A group, for instance, with all the C group will be a rare coincidence.

It is the object of Mendelian analysis to state each case of heredity in terms of gametic composition, and thence to

determine the laws governing the distribution of characters in the cell-divisions of gametogenesis.

There are, of course, many cases which still baffle our attempts at such analysis, but some of the most paradoxical exceptions have been reduced to order by the accumulation of facts. The consequences of heterozygosis are curiously specific, and each needs separate investigation. A remarkable case occurred in stocks, showing the need for caution in dealing with contradictory results. Hoary leaves and glabrous leaves are a pair of allelomorphic characters. When glabrous races were crossed with crossbreds, sometimes the results agreed with simple expectation, while in other cases the offspring were all hoary when, in accordance with similar expectation, this should be impossible. By further experiment, however, Miss Saunders has found that *certain* glabrous races crossed together give nothing but hoary heterozygotes, which completely elucidates such exceptions. There is every likelihood that wherever segregation occurs similar analysis will be successful.

Speaking generally, in every case the first point to be worked out is the magnitude of the character-units recognised by the critical cell-divisions of gametogenesis, and the second is the specific consequence of all the possible combinations between them. When this has been done for a comprehensive series of types and characters, it will be time to attempt further generalisation, and perhaps to look for light on that fundamental physiological property, the power of cell-division.

Segregation and Sex.—Acquaintance with Mendelian phenomena irresistibly suggests the question whether in *all* cases of families composed of distinct types the distinctness may not be primarily due to gametic segregation. Of all such distinctions none is so universal or so widespread as that of sex: may it not be possible that sex is due to a segregation occurring between gametes, either male, female, or both? It will be known to you that several naturalists have been led by various roads to incline to this view. We still await the proof of crucial experiments; but without taking you over more familiar ground, it may be useful to show how the matter looks from our standpoint. As regards actual experiment, all results thus far are complicated by the occurrence of some sterility in the hybrid generation. Correns, fertilising ♀ *Bryonia dioica* with pollen from ☿ *B. alba*, obtained offspring (F_1) *either* ♂ or ♀, with only one doubtful exception. Gärtner found a similar result in *Lychnis diurna* ♀ × ☿ *L. Flos-cuculi* as ♂, but only raised six plants (4 ♂, 2 ♀). From *L. diurna* ♀ × ☿ *Silene noctiflora* as ♂ he got only two plants, spoken of as females which developed occasional anthers. These results give a distinct suggestion that sex may be determined by differentiation among the male gametes, but satisfactory and direct proofs can only be obtained from some case where sterility does not ensue.

Apart, however, from such decisive evidence—which, indeed, would be more satisfactory if relating to *animals*—several circumstances suggest that sex is a segregation-phenomenon. Prof. Castle in a valuable essay has directed attention to distinct evidence of disturbance in the heredity of certain moths (*Aglia tau* and *lugens*, Standfuss's experiments; *Tephrosia*, experiments of Bacot and others, summarised by Tutt),[1] where the disturbance is pretty certainly connected with sexual differentiation. Mr. Punnett and I are finding suggestions of the same thing in certain poultry cases. Mr. Doncaster has pointed out that the evidence of Mr. Raynor clearly indicates that a certain variety of *Abraxas grossulariata*, usually peculiar to the female, is a Mendelian recessive. It is scarcely doubtful that this will be shown to hold also for some other female varieties, *e.g.*, *Colias edusa*, var. *helice*, &c. We can therefore feel no doubt that there is some entanglement between sex and gametically segregable characters. A curious instance of a comparable nature is that of the Cinnamon canary (Norduijn, &c.), and similar complications are alleged as regards the descent of colour-blindness and hæmophilia.

In one remarkable group of facts we come very near to the phenomenon of sex. Experiments made in conjunction with Mr. R. P. Gregory have shown that the familiar heterostylism of Primula is a phenomenon of Mendelian segregation. Short style, or "thrum," is a dominant—

[1] *Trans. Ent. Soc. Lond.*, 1898.

with a complication;[1] long style, or "pin," is recessive; while equal, or "homostyle," is recessive to both.

Even nearer we come in a certain sweet-pea example, where abortion of anthers behaves as an ordinary Mendelian recessive character.[2] By a slight exaggeration we might even speak of a hermaphrodite with barren anthers as a "female."

Consider also how like the two kinds of differentiation are. The occasional mosaicism in Lepidoptera, called "gynandromorphism," may be exactly paralleled by specimens where the two halves are two colour-varieties, instead of the two sexes. Patches of *Silene inflata* in this neighbourhood commonly consist of hairy and glabrous individuals,[3] a phenomenon proved in Lychnis to be dependent on Mendelian segregation. The same patch consists also of female plants and hermaphrodite plants. Is it not likely that both phenomena are similar in nature? How otherwise would the differentiation be maintained? The sweet-pea case I have spoken of is scarcely distinguishable from this. I therefore look forward with confidence to the elucidation of the real nature of sex—that redoubtable mystery.

We now move among the facts with an altogether different bearing. "Animals and Plants under Domestication," from being largely a narration of inscrutable prodigies, begins to take shape as a body of coherent evidence. Of the old difficulties many disappear finally. Others are inverted. Darwin says he would have expected "from the law of reversion" that nectarines being the newer form would more often produce peaches than peaches nectarines, which is the commoner occurrence. Now, on the contrary, the unique instance of the Carclew nectarine tree bearing peaches is more astonishing than all the other evidence together!

Though the progress which Mendelian facts make possible is so great, it must never be forgotten that as regards new characters involving the addition of some new factor to the pre-existing stock we are almost where we were. When they have been added by mutation, we can now study their transmission; but we know not whence or why they come. Nor have we any definite light on the problem of adaptation; though here there is at least no increase of difficulties.

Besides these outstanding problems, there remain many special points of difficulty which on this occasion I cannot treat—curiosities of segregation, obscure aberrations of fertilisation[4] (occasionally met with), coupling of characters, and the very serious possibility of disturbance through gametic selection. Let us employ the space that remains in returning to the problem of variation, already spoken of above, and considering how it looks in the light of the new facts as to heredity. The problem of heredity is the problem of the manner of distribution of characters among germ-cells. So soon as this problem is truly formulated, the nature of variation at once appears. For the first time in the history of evolutionary thought, Mendel's discovery enables us to form some picture of the process which results in genetic variation. It is simply the segregation of a new kind of gamete, bearing one or more characters distinct from those of the type. We can answer one of the oldest questions in philosophy. In terms of the ancient riddle, we may reply that the Owl's egg existed before the Owl; and if we hesitate about the Owl, we may be sure about the Bantam. The parent zygote, the offspring of which display variation, is giving off new gametes, and in its gametogenesis a segregation of their new character, more or less

[1] It is doubtful if "thrum" ever breeds true, as both the other types can do. Perhaps "thrum" is a *Halbrasse* of De Vries.

[2] Neglecting minor complications, the descent is as follows:—Lady Penzance ♀ × Emily Henderson (long pollen) ♂ gave purple F_1. In one F_2 family, with rare exceptions, *coloured* plants with *dark* axils were fertile, those with *light* axils having ♂ sterile, whites being either fertile or sterile. The ratios indicated are 9 coloured, dk. ax., fertile ♂ : 3 coloured, lt. ax., sterile ♂ : 3 white, fertile ♂ : 1 white, sterile ♂. The fertile whites, therefore, though light-axilled (as whites almost always are), presumably bear the dark-axil character, which generally cannot appear except in association with coloured flowers. This can be proved next year. Some at least of the plants with sterile ♂ are fertile on the ♀ side, and when crossed with a coloured light-axilled type will presumably give only light-axilled plants.

[3] This excellent illustration was shown me by Mr. A. W. Hill and Mr. A. Wallis. A third form, glabrous, with hairy edges to the leaves, also occurs.

[4] In view of Ostenfeld's discovery of parthenogenesis in *Hieracium*, the possibility that this phenomenon plays a part in some non-segregating cases needs careful examination.

pure, is taking place. The significance and origin of the discontinuity of variation is therefore in great measure evident. So far as pre-existing elements are concerned, it is an expression of the power of cell-division to distribute character-units among gametes. The initial purity of so many nascent mutations is thus no longer surprising, and, indeed, that such initial purity has not been more generally observed we may safely ascribe to imperfections of method.

It is evident that the resemblance between the parent originating a variety and a heterozygote is close, and the cases need the utmost care in discrimination. If, for instance, we knew nothing more of the Andalusian fowl than that it throws blacks, blues, and whites, how should we decide whether the case was one of heterozygosis or of nascent mutation? The second (F_2) generation from Brown Leghorn × White Leghorn contains an occasional Silver-Grey or Duckwing female. Is this a *mutation* induced by crossing, or is it simply due to a recombination of pre-existing characters? We cannot yet point to a criterion which will certainly separate the one from the other; but perhaps the statistical irregularity usually accompanying mutation, contrasted with the numerical symmetry of the gametes after normal heterozygosis, may give indications in simple cases—though scarcely trustworthy even there. These difficulties reach their maximum in the case of types which are *continually* giving off a second form with greater or less frequency as a concomitant of their ordinary existence. This extraordinarily interesting phenomenon, pointed out first by De Vries, and described by him under the head of "*Halb-*" and "*Mittel-Rassen*," is too imperfectly understood for me to do more than refer to it, but in the attempt to discover what is actually taking place in variation it must play a considerable part.

Just as that normal truth to type, which we call heredity, is in its simplest elements only an expression of that qualitative symmetry characteristic of all non-differentiating cell-divisions, so is genetic variation the expression of a qualitative asymmetry beginning in gametogenesis. Variation is a novel cell-division.[1] So soon as this fact is grasped we shall hear no more of heredity and variation as opposing "factors" or "forces"—a metaphor which has too long plagued us.

We cease, then, to wonder at the suddenness with which striking variations arise. Those familiar with the older literature relating to domesticated animals and plants will recall abundant instances of the great varieties appearing early in the history of a race, while the finer shades had long to be waited for. In the sweet pea the old purple, the red bicolor, and the white have existed for generations, appearing soon after the cultivation of the species; but the finer splitting which gave us the blues, pinks, &c., is a much rarer event, and for the most part only came when crossing was systematically undertaken. If any of these had been seen before by horticulturists, we can feel no doubt whatever they would have been saved. An observer contemplating a full collection of modern sweet peas, and ignorant of their history, might suppose that the extreme types had resulted from selective and more or less continuous intensification of these intermediates, exactly inverting the truth.

We shall recognise among the character-groups lines of cleavage, along which they easily divide, and other finer subdivisions harder to effect. Rightly considered, the sudden appearance of a total albino or a bicolor should surprise us less than the fact that the finer shades can appear at all.

At this point comes the inevitable question, what *makes* the character-group split? Crossing, we know, may do this; but if there be no crossing, what is the *cause* of variation? With this question we come sharply on the edge of human knowledge. But certain it is that if causes of variation are to be found by penetration, they must be specific causes. A mad dog is not "caused" by July heat, nor a moss rose by progressive culture. We await our Pasteur; founding our hope of progress on the aphorism of Virchow, that every variation from type is due to a pathological accident, the true corollary of "*Omnis cellula e cellula.*"

[1] The parallel between the differentiating divisions by which the parts of the normal body are segregated from each other, and the segregating processes of gametogenesis, must be very close. Occasionally we even see the segregation of Mendelian characters among zygotic cells.

In imperfect fashion I have now sketched the lines by which the investigation of heredity is proceeding, and some of the definite results achieved. We are asked sometimes, Is this new knowledge of any use? That is a question with which we, here, have fortunately no direct concern. Our business in life is to find things out, and we do not look beyond. But as regards heredity, the answer to this question of use is so plain that we may give it without turning from the way.

We may truly say, for example, that even our present knowledge of heredity, limited as it is, will be found of extraordinary use. Though only a beginning has been made, the powers of the breeder of plants and animals are vastly increased. Breeding is the greatest industry to which science has never yet been applied. This strange anomaly is over; and, so far at least as fixation or purification of types is concerned, the breeder of plants and animals may henceforth guide his operations with a great measure of certainty.

There are others who look to the science of heredity with a loftier aspiration; who ask, Can any of this be used to help those who come after to be better than we are—healthier, wiser, or more worthy? The answer depends on the meaning of the question. On the one hand it is certain that a competent breeder, endowed with full powers, by the aid even of our present knowledge, could in a few generations breed out several of the morbid diatheses. As we have got rid of rabies and pleuro-pneumonia so we could exterminate the simpler vices. Voltaire's cry, "*Écraser l'infâme!*" might well replace Archbishop Parker's Table of Forbidden Degrees, which is all the instruction Parliament has so far provided. Similarly, a race may conceivably be bred true to some physical and intellectual characters considered good. The positive side of the problem is less hopeful, but the various species of mankind offer ample material. In this sense science already suggests the way. No one, however, proposes to take it; and so long as, in our actual laws of breeding, superstition remains the guide of nations, rising ever fresh and unhurt from the assaults of knowledge, there is nothing to hope or to fear from these sciences.

But if, as is usual, the philanthropist is seeking for some external application by which to ameliorate the course of descent, knowledge of heredity cannot help him. The answer to his question is *No*, almost without qualification. We have no experience of any means by which transmission may be made to deviate from its course; nor from the moment of fertilisation can teaching, or hygiene, or exhortation pick out the particles of evil in that zygote, or put in one particle of good. From seeds in the same pod may come sweet peas climbing five feet high, while their own brothers lie prone upon the ground. The stick will not make the dwarf peas climb, though without it the tall can never rise. Education, sanitation, and the rest, are but the giving or withholding of opportunity. Though in the matter of heredity every other conclusion has been questioned, I rejoice that in this we are all agreed.

NOTES.

THE sum of 120*l*. has been granted by the Paris Municipal Council to Prof. Grancher in furtherance of his researches as to the means of preventing tuberculosis in schools.

ON Monday and Tuesday, September 12 and 13, a visit is to be paid to London by a large party of Belgian engineers, members of the Association des ingénieurs sortis de l'Ecole de Liège—one of the most important technical societies on the Continent. The party will be the guests of the Iron and Steel Institute.

PROF. APPELL, dean of the faculty of sciences in the University of Paris, has had the civil title of commandeur de la Légion d'honneur conferred upon him by the French Minister of War. Prof. Appell has served for some time on the commission appointed to examine inventions likely to be of service to the French Army and Navy.

THE *Gazette* of August 23 gives notice that by the Wireless Telegraphy Act, 1904, it is provided that a person shall not establish any wireless telegraph station or instal or work any apparatus for wireless telegraphy in any place in the British Isles or on board any British ship in the territorial waters abutting on the coast of the British Isles except under and in accordance with a licence granted in that behalf by the Postmaster-General. Wireless telegraphy is defined by the Act to mean any system of communication by telegraph as defined in the Telegraph Acts, 1863 to 1904, without the aid of any wire connecting the points from and at which the messages or other communications are sent and received.

THE death is announced of Dr. George Pirie, professor of mathematics in the University of Aberdeen.

DR. HANS BATTERMANN, astronomer at the Berlin Observatory, has been appointed director of the observatory and professor of astronomy at Königsberg.

THE *Athenaeum* announces the death of the well known German geographer, Prof. F. Ratzel, at the age of sixty. Since 1886 he had been professor at the University of Leipzig.

THE twenty-third annual summer meeting of the English Arboricultural Society took place last week at Aberdeen, when Prof. Fisher, of the R.I.E. College, Coopers Hill, was elected president for the ensuing year.

AN international exhibition of hygiene, life-saving, first aid, and of industrial arts has been opened at the Grand Palais des Champs Elysées in Paris by the French Minister of Commerce, M. Georges Trouillot. The exhibition will be open until November.

THE first International Congress of Education and Home Protection of Infants will be held in September of next year in Liège in connection with the Universal Exposition at that place. There will be four sections in all, devoted to the following subjects:—(1) Study of childhood; (2) education of children (*a*, general questions; *b*, education by parents at home; *c*, collaboration of the family with the school; *d*, education in the family after the school period); (3) abnormal children; (4) various lines of work relative to childhood.

ACCORDING to the *Scotsman*, Mr. Eagle Clarke, of the Natural History Department of the Edinburgh Museum of Science and Art, will, by permission of the Commissioners of Northern Lights, spend some time during the coming autumn in the lighthouse on the Flannan Islands for the purpose of studying the migratory movements of birds. Since the lighthouse was erected on this outlying group a few years ago it has been ascertained that the islands lie in the course of a considerable stream of migratory birds *en route* between their northern spring and southern winter quarters, a fact which is of special interest owing to the far westerly situation of the isles, and one which renders it very desirable that the phenomena observed there should be investigated by an expert. Mr. Clarke will also investigate the limited terrestrial fauna and flora of the islands, which, owing to their remote situation and the difficulty of landing on them, have not hitherto received attention.

IN a recently published pamphlet entitled "An Introduction to the Study of Forestry in Britain," Sir Harold G. Hewett, Bart., makes an appeal in favour of the so-called new school of forestry, that is, scientific forestry as it is understood and taught on the Continent. In the author's opinion the different works on forestry in the English language recommend methods differing so widely as to bewilder the beginner. The object of this booklet is to criticise, compare, and reconcile where possible the advice given by the several writers. The author strongly advocates the adoption of more scientific methods in the treatment of British woodlands, the existing methods being too haphazard and antiquated.

IN celebrating its twenty-seventh annual excursion, the Royal Scottish Arboricultural Society visited France, where a fortnight was spent inspecting the various types of forests and studying the different methods of forest management as practised there. Three centres were chosen, where the society in turn established its headquarters. The party, numbering seventy members, proceeded first to Nancy, where the forest school and neighbouring forests belonging to the State were inspected. After spending several days in Nancy, the excursionists proceeded to Gerardmer, with the object of inspecting the coniferous forest of the Vosges Mountains. During the few days' sojourn in Gerardmer, the party had an opportunity of making a trip on the electric railway to the summit of the Schlucht, the highest point of the French Vosges, which reaches an altitude almost equal to that of Ben Nevis. During the ascent many interesting observations were made on the character of the trees and other vegetation according to altitude. On nearing the wind-swept summit, the forest trees became reduced to mere bushes and scrub. From Gerardmer the party then proceeded to Paris, where headquarters were established for the last week of the excursion, when the forests of Villiers Cotterêts, Compiègne, and Bellême were visited, which afforded many valuable object lessons in the treatment of beech and oak woods.

WE have received the report of the Meteorological Service of Canada for the year 1902, containing monthly and annual summaries for a large number of stations, including some in Newfoundland and one in Bermuda. Most of the telegraphic reports are forwarded to the weather bureau at Washington, which office in return supplies the Canadian Service with some sixty-eight reports from the United States, affording data for a very comprehensive daily weather chart, and for the issue of weather forecasts for all parts of the Dominion lying to the eastward of the Rocky Mountains. The percentage of success of these forecasts in each district is given for each month and for the year, and the general total reaches the high figure of 86·6. The predictions partly verified are divided by two before being added to the total percentage, which makes the figure quoted even more successful than appears at first sight. The storm warnings attain still higher success; 88 per cent. were fully, and 95 per cent. were fully and partially, verified. We congratulate the director, Mr. R. F. Stupart, on these very satisfactory results.

A NUMBER of papers dealing with experimental progress in the direction of aërial navigation have reached us during the last few months. As long ago as November last an illustrated account of the Barton airship was given in the *Automotor Journal*. Among other peculiarities we notice the use of aëroplanes for raising and lowering the balloon, the introduction of water tanks for maintaining a level keel, and the peculiar form of the propellers, each of which consists of three pairs of blades fixed one behind the other, thus embodying in the propeller the principle of superposed narrow vanes which has been so successfully applied to aëroplanes. In the *Revue scientifique* (5), i., 2, M. Jean Jaubert gives an account of the aëroplane machine constructed by Mr. Ernest Archdeacon at Berck-sur-Mer (France). A paper communicated to the American Associ-

ation last year by Mr. Octave Chanute, contained a general account of recent progress in aërial navigation; this paper appeared in the *Popular Science Monthly* for March. Still more recently Captain Ferber, of the French Artillery, has brought out reprints of a paper from the *Revue d'Artillerie*, published by Berger-Levrault, of Paris, dealing mainly with gliding flight. Captain Ferber's own experiments were first conducted with pure gliding machines of the same type as those of the brothers Wright, but for his later experiments he has procured a mechanically propelled machine carrying a six horse-power motor, and weighing only 230 kilograms. Instead of experimenting in free air, Captain Ferber has adopted the principle of the captive machine, his machine being attached to a revolving arm 30 metres long supported on a pillar 18 metres high. This aërodrome is after the designs of MM. Goupil and Bazin.

IN the *Bulletin* of the Johns Hopkins Hospital (xv., No. 159, June) Dr. Percy Dawson gives an interesting biography of the Rev. Stephen Hales. The name of this great Englishman is familiar to every student of physiology as the first discoverer of the blood pressure, which he demonstrated by connecting a glass tube, now called the "Hales manometer," with an artery, and noting the rise of the blood within it. In addition, Hales contributed many papers on ventilation and natural history to the *Philosophical Transactions* of the Royal Society.

CAPTAIN GEO. LAMB, I.M.S., contributes a second communication on the specificity of anti-venomous sera to the *Scientific Memoirs of the Government of India* (No. 10, 1904; see NATURE, vol. lxviii. p. 395). He details experiments performed with two anti-venomous sera, one prepared with the venom of the *Hoplocephalus curtus* (tiger snake), the other with that of the cobra, these two sera being tested against the poisons of eight other snakes, including the king cobra, two kraits, common Indian sea snake, daboia, green pit viper, and Californian rattlesnake. Against the king cobra venom the cobra anti-serum had a slight neutralising effect, but not marked; as regards other venoms it had practically no neutralising power. The same holds good for the tiger snake anti-serum; while powerfully antitoxic for tiger snake venom, it is practically inactive against other venoms. These results confirm Captain Lamb's, and also Dr. Tidswell's, former observations that anti-venomous sera are strictly specific, and are active only against the venoms used to prepare them.

TWO out of the three articles in the May number of the *American Naturalist* are devoted to botanical subjects, Prof. Penhallow continuing in the one his account of the anatomy of North American conifers, while in the second Dr. B. M. Davis commences a study of the structure of the vegetable cell. In the one zoological article, Dr. A. Hrdlička gives further examples of a division in the malar bone of the skull in man and monkeys.

IN the *Biologisches Centralblatt* for August Mr. G. Klebs continues his studies of the problem of development, as exemplified by the lowest plants, while Mr. C. Schaposchnikow offers a new explanation for the presence of a red coloration in the hind-wings of the butterflies of the genus Catocala. The red-winged Catocalas, as the author remarks, are restricted to the Holarctic region, and this distribution is of itself sufficient to indicate that their peculiar type of coloration is connected with their environment.

FIVE out of the six articles in the July issue of the *Quarterly Journal of Microscopical Science* are devoted to invertebrate morphology and anatomy. In the first of these Mr. E. S. Goodrich describes a remarkable arrangement in the branchial vascular system of the worm Sternapsis, by means of which the blood has an alternative path to the normal one, leading from the main dorsal to the main ventral vessel. In a second Dr. E. J. Allen describes the anatomy of the annelid Pœcilochætus, while in a third Dr. Herbert Fowler communicates notes on *Rhabdopleura normani*, an ally of Balanoglossus. A paper on the anatomy and affinities of the molluscs of the family Trochidæ, by Mr. W. B. Randles, and one on a sporozoan parasite found in the mouse, by Mr. H. M. Woodcock, complete the invertebrate list. Special interest attaches to an article by Mr. G. Smith on the middle ear and columella in birds. As the result of observations carried on at a very early stage of development, the author concludes that, while the stapes of birds and reptiles (Sauropsida) represents the same bone in mammals, the other parts of the auditory region have undergone a different development in the two groups. It may be noticed that Mr. Smith makes no mention of Dr. Broom's recent provisional identification of the inter-articular cartilage of Ornithorhynchus with the quadrate.

DR. J. P. THOMSON, secretary of the Queensland branch of the Royal Geographical Society of Australasia, contributes a paper on Queensland to the *Geographical Journal*. Dr. Thomson gives a very clear picture of the geography of north-eastern Australia, and we commend his paper to the notice of teachers.

WE have received a copy of a valuable paper issued by the Norwegian "Gradmaalings-Kommission" on the tides of the Norwegian coast. Analyses and discussion of extended observations at a number of stations are given, chiefly with the view of separating the two different systems of Atlantic and North Sea origin, and treating the complex interference phenomena observed off the southern extremity of Norway.

IN the *Bibliotheca mathematica*, v. 2, Prof. Gino Loria, of Genoa, gives an account of the life and works of the late Prof. Luigi Cremona, accompanied by a portrait and a chronological list of Prof. Cremona's writings.

THE theory of Maxwell and wireless telegraphy, by Prof. H. Poincaré, form the subject of the twenty-third volume of the physico-chemical series of *Scientia*, published by Messrs. Carré and Naud, of Paris. It appears to be an extension of the first volume of the series by the addition of chapters dealing with the principles and applications of wireless telegraphy.

WE have received a reprint of a lecture delivered by M. Maurice d'Ocagne at the Conservatoire des Arts et Métiers, having the title "Les instruments de précision en France." It contains a description of the more refined instruments in use at the Bureau international des Poids et Mesures, in the principal observatories in France, and in the French military survey.

UNDER the title of "Malerbriefe," Prof. Ostwald has published through the house of Hirzel, Leipzig, a series of seventeen short and suggestive essays on the theory and practice of painting. Though this slight brochure can scarcely add anything to the reputation of the distinguished author, it furnishes another example of the versatility of his genius.

AN instructive series of lantern slides illustrating waves and kindred forms of the atmosphere, hydrosphere, and lithosphere has been collected by Dr. Vaughan Cornish for Messrs. Newton and Co. The collection includes the

most interesting pictures shown by Dr. Cornish at the Royal Geographical Society and elsewhere, and the descriptive notes which have been prepared for the slides direct attention to the chief points of interest.

We have received from New York the first number of the *Mining Magazine*, an international monthly review of progress in mining and metallurgy. Though new in name, the magazine is really a development of the *Pacific Coast Miner*, a weekly journal of repute. It is edited by specialists, and the illustrations and typography reach the high standard that characterises American magazines. The contents are of varied interest. Mr. J. A. Church gives a sketch of mining, past and future. The geographical distribution of ores within the United States is discussed by Mr. F. L. Ransome. Mr. Carl Henrich gives an admirably illustrated account of the Guanajuato mining district of Mexico; and Mr. Henry S. Fleming discusses the commercial divisions of the competitive coal markets. Lastly, a useful index of current literature is provided.

OUR ASTRONOMICAL COLUMN.

VISIBILITY OF THE MARTIAN CANALS.—In *Bulletin* No. 12 of the Lowell Observatory Mr. Lowell extends and sums up the results recently outlined by him in a communication to the American Academy of Sciences under the title "The Cartouches of the Canals of Mars." During the last opposition he made 372 drawings of the planet's visible surface on 143 nights, and by carefully examining these and eliminating all known extrinsic variations he secured sufficient data to enable him to plot a visibility curve for each canal, between January 19 and July 26, which he believes exhibits only the actual, intrinsic variability of the marking in question. This curve he calls the "cartouche" of that canal.

Analysing the 109 curves thus obtained he finds, except in three cases, a well marked seasonal variation. These curves are not exactly similar, but on arranging them in a steadily progressive order it was seen that the order was one of latitude, the increase of visibility taking place in the north polar canals first and in the equatorial canals last. The reason assigned for the earlier quickening of the polar canals is that all these markings are due to vegetable growth, which requires both warm sunshine and water for its increase, and, as the general surface of Mars is devoid of water, this growth has to await the arrival of the liberated fluid from the polar caps before it can assume its vernal appearance. Naturally, the sun having already passed the summer solstice, those portions of the planet's surface nearer to the water supply will be the first to grow the new vegetation.

Further considerations, dealt with *in extenso* in the *Bulletin*, lead Mr. Lowell to the conclusion that both the anomalies and the generalities he has discovered argue for the artificial origin of the Martian canals.

TOTAL SOLAR ECLIPSE OF 1905.—An article in the August number of the *Bulletin de la Société astronomique de France* gives a number of details concerning the eclipse of 1905, and maps showing the entire path and the sections of it which traverse Spain and Tunis. A set of diagrams showing the appearance, at various places, of the greatest phase of the eclipse, indicates that for Paris the eclipse commences at 12h. 3·1m. (Paris Civil M.T.), has its greatest phase (0·818) at 13h. 19·1m., and finishes at 14h. 31·7m.

SOLAR PROMINENCES DURING 1903.—In No. 6, vol. xxxiii., of the *Memorie della Società degli Spettroscopisti Italiani*, Prof. Mascari summarises the results of the observations of prominences made at Catania during 1903.

Very few prominences were seen during the first months of the year, but they were notably augmented later. In January and February the phenomena presented themselves with equal intensity in each hemisphere, but in the second and third trimestres they prevailed in the northern hemisphere, whilst in the fourth they were more numerous in southern latitudes.

The number of days without prominences during 1903 was 38 per cent. of the total number of days of observation, instead of 67 per cent. as in 1902. The mean latitude of the prominences in 1903 was 42°·1, as compared with 48°·4 in the previous year. The undecennial minimum of prominence activity apparently occurred in October, 1902.

THE LOWELL SPECTROGRAPH.—In No. 1, vol. xx., of the *Astrophysical Journal*, Mr. V. M. Slipher gives a detailed description of the complete spectrographic equipment obtained for the Lowell Observatory from Mr. J. A. Brashear in 1901.

The chief instrument differs but little from the Mills spectrograph (Lick), and its linear and angular dispersion at Hγ, as compared with the other large instruments of its class, may be seen from the following table:—

Spectrograph		Focal length of camera mm.	Dispersion: Linear, tenth-metres per mm.	Dispersion: Angular, for one-tenth metre ″
Lowell	Short	386	14·5	36·8
,, ...	Long	471	11·4	36·8
Mills (Lick) ...		406	12·6	40·5
Potsdam III....	1	560	10·2	36·5
,, ...	2	410	13·8	36·5
Bruce (Yerkes)	A	449	10·7	42·8
,,	B	607	7·9	42·8

Mr. Slipher's communication gives all the details of the instrument's construction and mounting, and is illustrated by several photographs and colour-curves.

A NEW BAND SPECTRUM OF NITROGEN.—Whilst photographing the spectrum of the afterglow from metallic spark discharges in an atmosphere of nitrogen, Mr. Percival Lewis, of the University of California, has discovered what is presumably a new band spectrum of nitrogen. He found that the afterglow occurred only in chemically prepared, dried and purified nitrogen, and then only when a strong condenser discharge was employed.

The spectrum is discontinuous, consisting of lines and bands, some of the latter belonging to Deslandre's third group, whilst others were of unknown origin. No afterglow occurred in the metallic vapours unless there was an afterglow in the gas. New bands occur in most of the spectra obtained at λλ 2750, 2890, 3035, and 3200, whilst others, at approximate wave-lengths 3380, 3575, 3805, 4130, and 4540, only occur in some of the photographs. Of the latter bands several may be due to NO, but none of them are found in the spectrum of NO_2 (*Astrophysical Journal*, No. 1, vol. xx.).

THE PERSEID METEORIC SHOWER OF 1904.

THIS shower has not furnished a rich display this year; in fact, the number of meteors visible appears to have been decidedly below the average. Yet there was no moonlight to offer any impediment, and the nights were very clear just at the important time.

On August 9 there were a few Perseids, but the meteors recorded from all sources little exceeded the average number observable on an ordinary night in August, and I wrote down in my notebook that I had never seen so few meteors on August 9 in any previous year.

On August 10 there was an increase in the number visible, but I made no lengthy observations.

On August 11, between 10h. 30m. and 13h. 30m., Perseids were falling at the rate of about 25 per hour for one observer, and the radiant was at 46°+58° from 37 paths. This horary rate is for an observer who registered a few of the tracks, and whose attention, therefore, was not given continuously to the sky. Mr. McHarg at Lisburn, Ireland, says that from 10h. to 11h. local time the Perseids averaged 30 to the hour. Mr. J. Webb, of Bristol, counted 21 between 9h. 50m. and 10h. 50m.; Mr. W. E. Besley, of London, saw 66 meteors in 3 hours between 10h. 30m. and 13h. 30m., and others must have been missed while records were being made. He saw meteors as bright as Jupiter or Venus at 10h. 30m., 11h. 14m., 11h. 20m., and 13h. 7m. Mr. McHarg noted a brilliant green fireball > ♀ at 10h. 20m. G.M.T. falling in Libra a little west of α and directed from ε Boötis, so it was probably a Perseid.

On August 12 the Perseids were again in evidence, but not very abundantly. At Bristol between 10h. and 12h. 30m. there were about 17 or 20 per hour, but the watch was not quite continuous. The radiant was very sharply defined at $47^\circ + 58^\circ$ from about 20 paths.

On August 13 the sky was less favourable; there was a good deal of haze, and the stars were blurred and faint; only a few Perseids were seen in these adverse circumstances.

Though the shower generally was not a plentiful one, it is likely to prove interesting in some of its results, for a number of its meteors appear to have been observed at more than one station, and their real paths can be computed.

Three features in reference to the shower of 1904 appear to the writer to deserve special mention:—

(1) The sharply defined point of radiation on August 11 and 12.

(2) The comparatively meagre character of the display.

(3) The fact that nearly all the Perseids appeared on the right (western side) of the radiant. This was very marked, and the writer has been struck with the same peculiarity in preceding years. There were many Perseids in Andromeda, Pegasus, Cassiopeia, Cepheus, and Cygnus, but few in Camelopardus, Auriga, the Lynx, and Ursa Major.

W. F. Denning.

THE THIRD INTERNATIONAL CONGRESS OF MATHEMATICIANS.

THERE are few towns better suited for a scientific gathering than Heidelberg, and few scientific gatherings have passed off so successfully as the third International Mathematical Congress which met there from August 8 to 13. The number of mathematicians attending the congress was 330, giving with holders of ladies' tickets a total membership of nearly 400. The German Government, the Grand Duke of Baden, the municipal and university authorities of Heidelberg, the Deutsche Mathematiker Vereinigung, and an influential executive committee all joined in giving the congress a hearty welcome, and the local arrangements were perfect.

The formal proceedings opened on Tuesday, August 9, under the presidency of Prof. H. Weber, of Strasburg. The year 1904 being the centenary of the birth of Jacobi, the occasion was selected for the delivery of an address by Prof. Leo Königsberger on Jacobi's life and works. A large volume by Prof. Königsberger dealing with the same subject was published by Messrs. Teubner in connection with the present commemorations.

Another feature of the congress was the presentation, by Prof. Klein, of the first copy of vol. i. of the "Encyklopädie der matematischen Wissenschaften," which volume has just been completed. Considerable progress was also reported in the preparation of the French edition of the "Encyklopädie."

Prof. Gutzmer, of Jena, presented a history of the Deutsche Mathematiker Vereinigung, founded in 1890, as well as the July part of the *Jahresbericht* of the society, containing papers on the teaching of mathematics.

Passing on to a review of the work done in the sectional and general meetings, the most noticeable feature revealed by the general spirit in which many of the papers were written was the growing tendency in the mathematical world to devote greater attention to the practical and experimental aspects of mathematics, especially in connection with mathematical teaching. From such signs as this it appears not unlikely that we are on the eve of a renaissance period in the history of mathematics. A large collection of models, mathematical instruments, apparatus, and books was exhibited in the large hall of the museum. Prof. Runge, of Hanover, exhibited and described Leibnitz's calculating machine. A number of experiments on fluid motion past various boundaries were shown by Prof. Prandtl, of the same town. These differed from Prof. Hele-Shaw's experiments with thin films in that a vessel of some depth (say an inch or two) was used, and water or liquid of small viscosity employed; in this case a series of vortices were seen to be thrown off in succession from a cylindrical or other obstacle, and the various stages of formation of each vortex were clearly demonstrated by photographs as well as experimentally.

Prof. Greenhill's discourse on the theory of the top, considered historically, also contained an attempt to give graphical representations of the motion of the top, and was illustrated by experiments with bicycle wheels and other equally simple apparatus.

Coming to matters of more purely educational interest, Prof. Klein, in his address to the applied mathematics section, gave an amusing account of the methods in vogue in certain German middle schools for obviating the use of the calculus, a state of affairs reminding one of the old Cambridge "three days." Prof. Loria, of Genoa, stated that the attempt to abolish Euclid in Italy had failed owing to the badness of the text-books brought out to meet the new conditions, that a Government prize had been in consequence offered for a good manual on geometry, and that the books of Veronese, Enriques, Amaldi, Paolis and others were the result.

Prof. Gutzmer urged that elasticity and thermodynamics should form part of the training of every professor of applied mathematics. Resolutions were passed by the congress urging the Government to provide models and projection-lanterns for use in teaching mathematics in the German schools and technical colleges. A further resolution related to the teaching of geometrical drawing in schools.

In connection with the historical section, a resolution was passed relating to the publication of Euler's works by the Carnegie Institution. Prof. Schlesinger announced the appearance of the first volume of the works of L. Fuchs, and a bibliography of Wronski's works was presented by Prof. S. Dickstein.

Of papers in applied mathematics, the most remarkable was Prof. Sommerfeld's investigation on the motion of electrons; the remaining papers dealt *inter alia* with the problem of three bodies (Profs. Delaunay and Levi-Civita), equations of wave motion (Profs. Volterra and Hadamard), attractions (Prof. Genese), and geodesy (Prof. Börsch and others).

In pure mathematics the most striking papers were those by Prof. Hilbert on integral equations and on the foundations of arithmetic, and Prof. König's proof that the continuum cannot be equivalent to any well ordered group. Prof. Painlevé, of Paris, gave an admirable discourse on the integration of differential equations; Prof. Segre, of Turin, on the geometry of to-day; and Prof. Wirtinger, of Vienna, on Riemann's lectures on hypergeometric series. We also note papers by Prof. Schlesinger on Riemann's problem, by Prof. Borel on approximations of continuous functions, and many others too numerous to mention. Prof. E. Study showed that the paradoxical result $2=4$ could be obtained from considerations of intersections of quadric surfaces.

The congress was international in every sense, the membership including representatives of Germany, France, Great Britain, Italy, Switzerland, Austria, Sweden, Denmark, Spain, Russia, Japan, the United States, Greece, and other countries. Only seven of the members present were from Great Britain.

For the meeting place of the next congress in 1908, Rome has been selected, and the congress will take place at a somewhat earlier time of the year (probably about Easter). In this connection a prize is offered for the best thesis on the theory of algebraic gauche curves. It has been decided to hold the next following congress in England.

Not the least important feature of the congress was the large amount of local interest shown in the organisation of social entertainments. On Wednesday, August 10, a dinner was given to all the members in the new Town Hall of Heidelberg. On the Thursday we were received and entertained at Schwetzingen by the Hereditary Grand Duke of Baden. The next evening we sailed down the Neckar in illuminated barges, and on reaching Heidelberg the castle was illuminated by red fire, the proceedings ending with fireworks, including a set-piece of the Pythagorean Theorem (Euc. i., 47). The last evening we were entertained at a concert at the castle, followed by another illumination and a Kommers, for which a special song-book had been published that included a number of amusing mathematical songs written for the occasion. To make this insight into German student life more real, two delegates were elected by the students of German universities to officiate in the uniform of their corps, and with their swords.

The town concerts and many places of interest were specially thrown open to members. The arrangement of meeting places in one or more *cafés* was another feature which added considerably to the social success of the meeting. Excursions were organised to the Stift Neuberg, to Speyer, and up the Neckar Valley.

Mathematicians who had known of one another for years as mere names have now become personal friends, and we shall carry away life-long reminiscences of the many pleasant meetings which have done much to cement the bond of union between fellow workers in all branches of mathematics, and of all nationalities. G. H. BRYAN.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—On Monday, August 22, the University of Cambridge conferred seventeen honorary degrees on the occasion of the meeting of the British Association. The following are the speeches delivered by the Public Orator, Dr. Sandys, of St. John's College, in presenting those of the recipients who received the degree of Doctor in Science for distinction in natural sciences, mathematics, or anthropology:—

OSKAR BACKLUND, PROFESSOR OF ASTRONOMY, ST. PETERSBURG.

Ab exteris exorsi, primum omnium salutamus nuntium quendam sidereum, ab arce illa celeberrima prope Petropolin stellis observandis dedicata ad nos devectum, quae trium deinceps Struviorum nominibus iamdudum gloriatur. Ipse talium virorum haeres dignissimus, planetarum potissimum in moles motusque perturbatos diligenter inquisivit, et Enckii praesertim cometen, ter in quoque decennio inter sidera nostra lucentem, indagandum sibi sumpsit. Dum cometae illius reditum in mense proximo spe certa expectamus, sideris illius indagatorem indefessum hodierni diei inter lumina libenter numeramus.

HENRI BECQUEREL, PROFESSOR OF PHYSICS, PARIS.

Francogallorum e republica vicina cursu prospero ad nos pervenit scientiarum Academiae Parisiensis socius illustris, cuius etiam patrem avumque honore eodem ornatos fuisse constat. Ipse in vi magnetica praesertim exploranda diu praeclare versatus, nuper propterea imprimis famam est adeptus, quod metallum, sideris Urani inventoris in honorem, olim Uranium nominatum, primus omnium nuper probavit ipsum radios quosdam mirabiles emittere, quos etiam per metalla transire non dubitare. Laetamur virum tam illustrem scientiae lumen, a patre suo sibi olim traditum, splendore novo a sese exauctum, etiam aliis invicem iamdudum tradere. Etenim, scientiae quoque in lumine vitali per saecula hominum tradendo,

> "sic rerum summa novatur
> semper, et inter se mortales mutua vivunt,...
> et quasi cursores vitai lampada tradunt."

J. W. BRUEHL, PROFESSOR OF CHEMISTRY, HEIDELBERG.

Salutamus deinceps virum urbis Palatinae inter professores illustres iamdudum numeratum, virum in scientia chemica insignem. Ut rem scientiae illius ad historiam pertinentem paulo altius repetamus, inter physicos antiquos olim, uti nostis, finem secandis corporibus esse negavit quidem Anaxagoras, Democritus autem affirmavit; Democriti vero atomos, per duo milia annorum inutiles et infructuosas existimatas, scientiae chemicae saltem inter professores rursus in honore esse constat. Viri huiusce autem inter merita id potissimum commemoratur, quod, experimentis exquisitis iam per quattuor et viginti annos adhibitis, praeclare ostendit, quae potissimum inter res in unum revera compositas atque atomorum, rerum earum in particula quaque consociatarum, distributionem ratio intercedat. Unde fit, ut etiam in rebus perquam multiplici modo compositis, atomorum illarum nexus accuratius explicentur, atque etiam in coloribus quibusdam novis vetera illa Lucretii verba denuo vera reddita sint, quo docente rerum primordia

> "variis sunt praedi a formis,
> e quibus omne genus gignunt variantque colores
> propterea, magni refert quod semina quaeque
> cum quibus et quali positura contineantur."

ADOLF ENGLER, PROFESSOR OF BOTANY, BERLIN.

Universitatis Berolinensis e professoribus praeclaris adest vir, qui arborum et herbarum provinciam eximiam iam per annos quadraginta luculenter illustravit. Hoc iubente, quot arborum genera conifera, quot liliorum varietates, quot dicotyledonum species obscurae, e tenebris in lucem novam surrexerunt! Idem (ne plura commemorem) etiam scientiae suae Acta a se condita iam per annos tres et viginti edidit, genera plantarum omnia in ordinem optimum reduxit, ne palaeontologiam quidem neglexit, neque Africam Orientalem neque Americam Australem inexploratam reliquit. Quod ad alios attinet, Victoris Hehnii librum celeberrimum de transitu plantarum ex Asia in Europam conscriptum accuratiorem reddidit, etiam plantarum per orbem terrarum distributionem Alexandri Humboldtii in memoriam prosecutus. In scientia botanica nemo fortasse hodie Plinii ipsius verba sibi verius potest arrogare:—" non unius terrae sed totius naturae interpretes sumus."

PAUL VON GROTH, PROFESSOR OF MINERALOGY, MUNICH.

Ex urbe pulcherrima, quod Bavariae totius caput est, ad nos pervenit vir studiorum in regione pulcherrima versatus, qui crystallorum scientiam physicam professus, Milleri nostri, viri insignis, crystallorum describendorum rationem et ipse praetulit et aliis omnibus per Europam totam commendavit. Quantum in scientia sua in ordinem redigenda atque etiam aliis tradenda profuerit, testantur Acta illa ab ipso condita et per annos plus quam quinque et viginti edita; testantur tot discipulorum et amicorum etiam inter exteros gratulationes recentissimae; testatur praeceptoris tanti in honorem imago ipsius arte eximia depicta et anni huius paulo ante Kalendas Maias donata; testatur hodiernus denique dies, quo nomen viri " quem rumor alba gemmeus vehit pinna," tituli nostri signo honorifico consignamus. Etiam hodierni diei memor, poterit fortasse Martialis verba mutuari:—

> "Felix utraque lux, diesque nobis
> Signandi melioribus lapillis."

ALBRECHT KOSSEL, PROFESSOR OF PHYSIOLOGY, HEIDELBERG.

Urbem Palatinam denuo in memoriam vocat physiologiae illius chemicae professor insignis, quae quicquid vivit perscrutata, tot corpuscula textu tenuissima explorat et explicat, tot cellulas absconditas in lucem protrahit et enucleat. Abhinc annos sex eiusdem Universitatis, eiusdem scientiae, professorem in hoc ipso loco laudavimus, qui in unoquoque e tribus decenniis hanc scientiam magnopere adiuvit. In professore illo laudando sperabamus intra proximum decennium fore ut talium virorum laboribus physiologiae in provincia chemica laurus plurimae referentur. Quod illo die sperabamus professoris illius successor feliciter ratum effecit.

HENRY F. OSBORN, PROFESSOR OF ZOOLOGY, NEW YORK.

E republica maxima trans aequor Atlanticum diu prospere constituta laetamur ad nos advectum esse virum palaeontologiae praesertim in scientia insignem, qui non modo in Universitate Columbiana, nobis et linguae et studiorum communium societate coniunctissima, zoologiam praeclare profitetur, sed etiam, Eboraci Novi in Museo maximo, animalium ingentium e rupibus ipsis effossorum multitudinem saxeam, sive Dinosauri sive Atlantosauri nominantur, sive alio aliquo nomine splendido gloriantur, summa sollertia conquisivit, summa arte disposuit, summa cura custodit. Gaudemus rempublicam illam, tot rerum novarum varietate excellentem, etiam vitae pristinae vestigia tam antiqua tanta cum alacritate persequi. Iuvat virum hospitii iure cum plurimis coniunctum Ennii ipsius in verbis etiam propterea laudare, quod, in Museo illo " multa tenens antiqua," ipse " egregie cordatus homo " esse perhibetur.

VITO VOLTERRA, PROFESSOR OF APPLIED MATHEMATICS, ROME.

Quem genuit Ancona, quem arx antiqua Etruriae suo nomine ornavit, quem primum Pisarum, Galilei cum memoria consociatarum, deinde Augustae Taurinorum, denique Romae ipsius Universitas inter professores suos numeravit, multis profecto nominibus observantiae vestrae commendatur. Sed, ut relictis nominibus ad res ipsas progrediamur, inter peritos constat virum hunc lucis praesertim

in legibus investigandis esse imprimis illustrem atque scientiae dynamicae (ut aiunt) in ratione universa exploranda plurimum pollere. Viri Italiae tutius inter mathematicos conspicui meritis accuratius explicandis gravamur prorsus imparem esse veterem illam linguam Latinam, quam ipsa Italia Britannis olim donavit. His saltem in studiis Italia hodierna Italiam antiquam superavit.

Sir David Gill, K.C.B., F.R.S., H.M. Astronomer at the Cape.

Ad patriam reversi, quam libenter salutamus virum in stellis observandis insignem, qui inter Aberdonienses suos astronomiae studia olim auspicatus, planetae Veneris transitum in oceano Indico accurate observandum curavit. Idem et Aegypti et Africae Australis coloniae extremae et Terrae Natalis spatia ampla dimensus est; stellarum omnium imaginum lucis ipsius auxilio reddendarum auctor fuit assiduus; Africae denique in promontorio remotissimo arcem caelestem sibi creditam quinque et viginti per annos fortiter et feliciter occupavit. In excubiis illis patria procul tolerandis quam fortem ipsum, in alios quam generosum sese praestitit; aliorum labores quantis stimulis incitavit, ad exitum felicem perductos quanta benevolentia excepit! Viri talis sub auspiciis et unius e professoribus nostris sub praesidio pro scientiarum societate Britannica in annum proximum Bonae Spei in Promontorio bene nominato licet omnia fausta augurari.

A. W. Howitt, F.G.S., Honorary Fellow of the Anthropological Institute, &c.

Australiae praesertim aborigines, in annos singulos ad minorem numerum redactos, nonnullis vero in locis prope funditus extinctos, simplicitatis pristinae mores antiquos diutissime conservasse constat. Hic autem, a collega optimo, Collegii vicini alumno adiutus, indigenarum illorum primum consuetudines nuptiales, deinde adulescentium initiationes, denique religionis rudimenta prima, diligenter investigavit, et prioris aevi memoriam evanescentem litterarum monumentis fideliter mandavit. Talium virorum laboribus historia, si non "magistra vitae," at certe "lux veritatis," "nuntia vetustatis," "vita memoriae" esse gloriatur.

Sir Norman Lockyer, K.C.B., F.R.S., Director of the Solar Physics Observatory, South Kensington.

Inter astronomiae et scientiae physicae fines patet provincia, ubi, instrumentis subtilissimis adhibitis, etiam solis ipsius radii retexuntur, et, linearum varietate quadam minutissima observata, corpora prima, e quibus sol ipse est compositus, inter sese distinguuntur. Adest vir in regione tam pulchra exploranda inter principes numeratus, qui, ne his quidem finibus contentus, non solis tantum defectus identidem observavit, sed etiam astronomiae provinciam amplissimam sibi vindicavit. Idem, per annos prope quinque et triginta Actis quibusdam praeclaris luculenter editis, anni cuiusque septimo quoque die rerum naturae totius varietatem orbi terrarum patefecit.

Major P. A. MacMahon, F.R.S., formerly Professor of Physics at the Ordnance College, Woolwich.

Adest deinceps militis insignis filius, miles mathematicis praesertim in studiis spectandus, qui praeter alios laudis titulos etiam scientiarum societatis Britannicae inter ministros praecipuos numeratur. Studiorum suorum in caelo puro, in regione illa sublimi a Cayleio nostro feliciter peragrata, diu versatus, studiis illis caelestibus sermonis Latini Musam pedestrem, longe infra in terris relictam, nihil aliud quam numerorum theoriam quandam e longinquo contemplari patitur. Cetera omnia scientiae tam sublimis mysteria, peritis patefacta, a nobis certe palam divulgari non concessum. Illud autem unum dixerim. Si, Syracusis captis, Archimedem, intentum formis, quas in pulvere illo erudito descripserat, Marcelli in exercitu miles talis aspexisset, caeli spectatorem illum unicum, tormentorum bellicorum machinatorem illum mirabilem, sine dubio nunquam interfecisset, sed velut socium et fratrem statim esset amplexus.

Sir William Ramsay, K.C.B., F.R.S., Professor of Chemistry at University College, London.

Virum inter Caledones suos atque inter Germanos educatum, titulo nostro Academico fortasse eo digniorem putabitis, quod iam in orbe terrarum toto Academiis fere viginti honoris causa est adscriptus. Per annos septemdecim inter Londinienses scientiam chemicam praeclare professus, aëris praesertim elementa exploravit, et (cum alumno nostro insigni, Rayleio, consociatus) elementum illud *Argon* nuncupatum repperisse confitetur. Etiam propterea laudandus est quod in metallis *Helium* invenit; quod in aëre ipso *Neon*, quod *Krypton*, quod *Xenon*, tot elementa ex ipsa rerum naturae origine latentia detexit, detecta nominibus pulchris, nominibus Graecis, ornavit. Nonnullis certe e nobis non ingratum, etiam in elementis novis nominandis linguae Graecae antiquae utilitatem comprobatam contemplari; iuvat etiam ipsius nomen gentile et olim et nuper propter linguarum peritiam inter Caledones celebratum, in rerum et nominum inventore tanto, etiam rerum naturae scientia illustratum admirari.

Arthur Schuster, F.R.S., Professor of Physics in the Victoria University of Manchester.

Virum libenter rursus agnoscimus, qui primum Moeni sui in ripa, deinde inter Mancunienses, denique in urbe Palatina educatus, inter nosmet ipsos et Maxwellii et Rayleii nostri inter adiutores praecipuos olim numerabatur. Postea solis defectioni in India trans Gangen observandae quondam praepositus, a societate regia ob lucis arcana feliciter explorata numismate aureo est donatus. Laetamur virum, qui fluminis paterni in ripa ad rem argentariam non sine lucro magno sese dedere potuisset, scientiae lucem lucro praetulisse et lucem ipsam explorandam elegisse. Virum talem dum coronat, Academia Virtutem ipsam aemulatur,

"diadema tutum
deferens uni propriamque laurum
quisquis ingentes oculo irretorto
spectat acervos."

Sir William Thiselton-Dyer, K.C.M.G., F.R.S., Director of the Royal Botanical Gardens, Kew.

Laurea nostra iuvat hodie decorare virum Florae in studiis insignem, cuius socerum in eisdem studiis illustrem abhinc annos duodequadraginta Academia libenter ornavit. Isidis propter undas educatus, scientiam suam eximiam et in Anglia et in Hibernia professus, Tamesis in ripa, Florae in hortis pulcherrimis, iam per annos prope triginta vitae suae tabernaculum collocavit. Nomen autem eius non modo regionis Tamesinae sed etiam Africae Australis, Africae denique interioris, cum floribus consociatur. Satis amplus igitur laudandi campus patet, campus floribus consitus, omnique pulchritudinis varietate distinctus; sed Flora vocat, sed horti nostri vos invitant, sed oratorem vestrum, Maronis non immemorem, hortos canere volentem, temporis spatium excludit.

"Extremo ni iam sub fine laborum
vela traham et terris festinem advertere proram,
forsitan et pingues hortos quae cura colendi
ornaret canerem, biferique rosaria Paesti,...
verum haec ipse equidem, spatiis exclusus iniquis,
praetereo, atque aliis post me memoranda relinquo."

Dr. J. Lorrain Smith, Musgrave professor of pathology at Queen's College, Belfast, has been appointed professor of pathology and pathological anatomy in the University of Manchester.

Dr. Jules Tannery, subdirector of the Paris École normale supérieure, has been appointed professor of differential and integral calculus, and Dr. Houssay professor of zoology in the faculty of science. These two appointments are consequent upon the inauguration of the new régime at the normal school, which has now been attached to the Sorbonne.

In September, 1902, the Board of Education referred to the consultative committee the question of drafting regulations for the establishment of supplemental registers for teachers of special subjects. Acting upon the report of a subcommittee appointed to consider the subject, the Board of Education has announced that the establishment of supplemental registers will be postponed until the teaching

of the subjects proposed for the supplemental registers has been further organised in connection with general education.

THE Duke of Devonshire, on August 20, handed over from the trustees of the Keighley Mechanics' Institute to the Corporation of the town the title deeds of premises valued at more than 50,000*l.*, which the municipality is taking over. During the course of his speech on that occasion, the Duke of Devonshire referred to the work with which he has been associated as president of the National Association for the Promotion of Technical and Secondary Education. The association has pointed out that the industrial and commercial supremacy of our country, upon which its power and greatness mainly, if not entirely, depend—a supremacy which once was unquestioned and undisputed—is not unassailable and is not unassailed. Our former supremacy rested mainly, if not entirely, upon the possession of great natural resources, and upon the energy and industry of our people. These are not now the only, if they are the chief, elements in industrial success. The discoveries of science and the application of science to industries have revolutionised the conditions of industry. Other nations, among whom Germany and the United States have been foremost, but all other Continental nations—France, Italy, Switzerland, and others—have appeared to realise this fact sooner than we have done, and to make greater efforts, and more organised efforts, than we have done to give to all classes engaged in these industries the scientific instruction which is in the present day the necessary condition of success. There are signs that these efforts on their part, and on the part of other countries, and this comparative negligence on our part are already having effect, and it is incontrovertible that it must sooner or later have a vast effect prejudicial to our own commercial and industrial supremacy. It is now recognised that scientific instruction for the whole of our people is a necessary element to our industrial success. Cultivated brains are as essential to industrial efficiency as even the strongest arms or the most willing hearts. The duty of imparting this instruction to those who need it is one that can no longer be safely left to the efforts of the benevolent or the philanthropic, but is the duty of the State as much as that of national defence, the defence of our Imperial possessions, or the defence of our own shores.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 16.—"The Lethal Concentration of Acids and Bases in respect of *Paramoecium aurelia*." By J. O. Wakelin **Barratt**.

The author finds that the strong mineral acids, hydrochloric, nitric, and sulphuric, in 0·0001 N concentration kill Paramœcia in ten to fifty minutes. Organic acids, in the same concentration, kill sometimes with greater rapidity (formic, lactic, and oxalic acids), sometimes with less rapidity (citric and acetic acids). Exceedingly weak acids (carbonic, carbolic, boric, hydrocyanic) require a much greater concentration in order to kill Paramœcia in the above period of time.

The hydrates of potassium, sodium, lithium, calcium, strontium, and barium in 0·002 N concentration are fatal in five to sixty minutes. Ammonium hydrate is more lethal, and far more so is the extremely weak base anilin. The lethal character of the alkalis exhibits an order corresponding to their periodic grouping.

The experiments made indicate that the action of acids and alkalis upon the living protoplasm of Paramœcia is of the nature of a chemical reaction, and is not purely hydrolytic in character.

PARIS.

Academy of Sciences, August 16.—M. Mascart in the chair.—The second approximation to the equation for the flow of sheets of underground water under slight pressures: J. **Boussinesq**.—New researches on the liquefaction of helium: Sir James **Dewar**. A side tube containing charcoal is added to a vacuum tube, and the tube filled with helium. When the charcoal is cooled down by means of liquid hydrogen to 15° C. absolute temperature, the vacuum produced is so good that a coil giving a 16-inch spark in air is required to produce a slight phosphorescent discharge in the middle of the tube. It follows that at this low temperature the charcoal is a good absorbent of helium. These experiments are regarded as confirming the conclusion that the boiling point of helium will not be found to be below 5° C. absolute.—On a crystalline combination of the acetate and thiosulphate of lead, $2PbS_2O_3,(CH_3-CO_2)_2Pb$: P. **Lemoult**. This compound is precipitated from a solution of lead acetate to which some sodium thiosulphate has been added, and the precipitate of lead thiosulphate re-dissolved by the addition of acetic acid. The above formula was established by analysis.—The alloys of zinc and magnesium: O. **Boudouard**. A series of alloys was prepared containing from 5 per cent. to 90 per cent. of magnesium, the melting points of which were determined. The melting point curve showed a maximum and two minima. The maximum corresponded to a definite combination, Zn_2Mg, and the microscopic study of a polished section proved the existence of a second definite compound, $ZnMg_4$. Both these alloys were isolated.—The properties and constitution of chrome steels: Léon **Guillet**. Two series of chrome steels were studied, both by micrography and by mechanical tests. One series contained very little carbon, the other 0·85 per cent. The steels studied were found to fall into four classes, and the limitations to their practical use are given.—On the evolution of structure in metals: G. **Cartaud**. AMERICAN AND BRITISH YACHTING.

American Yachting. By W. P. Stephens. Pp. ix + 380. (London: Macmillan and Co., Ltd.) Price 8*s.* 6*d.* net.

THIS excellent book not merely contains a well written history of American yachting, but puts on record the principal points in the development of yacht designing, both in the United States and in this country, during the fifty years since the famous *America* came to this country (in 1851) and astonished English yachtsmen by her remarkable performances. The contests between English and American yacht designers have been continuous and keen, including struggles for the America Cup as well as matches of equal or possibly greater interest between yachts of many classes. Some of these have received little attention, although the results have had considerable influence on later construction. The author is a keen sportsman, fully informed upon all branches of his subject, and capable—as many other yachtsmen are in these days—of discussing the problems of yacht design on a scientific basis. Americans have inherited from this country the love of yachting as a sport, and have given repeated proofs that they are formidable rivals in the design and management of yachts. They have gradually reached an appreciation of what Mr. Stephens describes as "the importance of Yachting to a maritime nation." He says:—

"It is a stimulus to the advancement of Naval Architecture, such as is necessary in maintaining the Naval and Merchant Fleets at the highest standard; it is a training school for seamen both amateur and professional; and its mimic battles are constant reminders of the necessity for perpetual progress in all details of Naval development."

As to its influence on individual yachtsmen, Mr. Stephens considers that yachting

"can fairly claim a place amongst the arts and sciences as a purely intellectual pursuit. The Science of Yacht designing, a branch of Yachting which many amateurs follow as a recreation, offers an unlimited field for study and research. The man who can design his own Yacht, large or small, construct her, or at least plan and supervise the construction, and finally can guide her to the head of the fleet with his hand on the tiller, his active brain anticipating each move of clever opponents, may well lay claim to one of the highest achievements within the reach of any sportsman."

Concurrently with the abandonment of "rule of thumb" methods in yacht design, there has been an important change in regard to the publication of information respecting the forms and equipment of yachts. Formerly, secrecy was the rule. Yacht owners took elaborate precautions to prevent the publication of details. Very often this secrecy was associated with an ignorance of principles, resulting in false estimates of the relative value and importance of causes influencing success. The late Mr. Dixon Kemp did much to break down this practice; his books on yachting remain valuable to this day. Mr. Stephens does not enter into technicalities so fully as Mr. Dixon Kemp did, but he writes with intelligence and a grasp of principles, and his summary of events is accompanied by an analysis of distinctive features in successive designs which can be read with interest even by naval architects. He traces the influence of local conditions, and of rules of measurement for competitive sailing, upon American and British yachts. He indicates clearly how these widely differing types have, in process of time and as the result of continuous competition, gradually approximated, and led to the production of vessels on both sides of the Atlantic closely resembling one another in their main features. He gives illustrations of the general principle that as soon as a rule for time allowance is established, yacht designers begin to exercise their ingenuity so as to produce vessels which shall get the greatest possible advantage in time allowance under the particular rule in force, and he shows how, in some cases, very unsatisfactory types have been brought into existence simply for racing purposes. The story of the contests for the America Cup is told with fairness and good feeling. Like most practical yachtsmen, he does not consider that yachting has benefited on the whole thereby. He is too good a yachtsman to favour the production of mere "racing machines," and his opinion of the latest example of American skill (the *Reliance*) is noteworthy, being summed up in the words that while she "represented a new and extreme step in the development of the racing machine, her whole form is confessedly bad for all purposes but cup-racing." In his judgment the tendency of international racing has been to minimise the importance of model and construction, and to increase the influence of the designer, owner, and skipper. His remarks on the "challengers" in recent years run counter to the popular view. He directs attention to the fact that recent challenges have not come from yachtsmen who sail their own yachts, but from men of ample means with little or no yachting experience, who see, in the publicity attending a cup match, a means of advertising themselves.

Incidentally, Mr. Stephens brings into relief the fact that, in the United States, the design of the most successful yachts in recent years has been the work of men of considerable culture and scientific knowledge, like Burgess and the younger Herreshoff. Further, he makes perfectly clear the thoroughness of the study devoted to every problem affecting ultimate success. Not merely has close attention been given to form, stability, and sail equipment, but no expense is spared in the United States to obtain the best possible materials—thus associating strength with lightness; in modifying structural arrangements for the same purpose, or in arranging every item affecting efficiency and rapid working of sails. He frankly acknowledges that in all these matters (which greatly influence the result of yacht racing) his countrymen have obtained substantial advantages over ourselves, and equally he shows his appreciation of the favourable conditions under which they can proceed in drilling their crews and "tuning up" the vessels (to use an American expression) before the cup races take place. To one fact, however, he hardly attaches adequate importance.

namely, that as British yachts have to cross the Atlantic in order to take part in the cup races, they can never be built with that extreme lightness of hull which is possible in vessels constructed on the American coast. This undoubtedly counts for much.

Mr. Stephens is an advocate of yachting as a sport, not in the sense of the races for the America or Seawanhaka Cups. He believes in the Corinthian style of yachting—owners working their own vessels. It is obvious that if he could have his way mere racing machines would disappear. Some incidents which he describes as to the performances of American yachts, and the special risks run in consequence of the production of racing machines, are very striking. Only one can be mentioned, that of the *Mohawk*, a centre-board schooner 140 feet long and more than 30 feet broad, with a depth of hold of less than $9\frac{1}{2}$ feet. This vessel drew only 6 feet when her centre-board was housed. Her sail area was enormous, and she had great initial stability; but in 1876, when at anchor off Staten Island, with all sails set and sheets made fast, she was capsized and sank, carrying with her half a dozen persons. On this side we have had equally extreme dimensions, but under our sailing rules, fortunately, there has not been the same inducement to accept serious risks; our vessels have not been lacking in stability in the sense that they were liable to be capsized.

The book may be heartily commended to all interested in yachting, either as a sport deserving continuance or as a branch of ship design.

W. H. White.

A COMPREHENSIVE WORK ON PHYSICS.

Lehrbuch der Physik. By O. D. Chwolson. Translated into German by H. Pflaum. Second volume. Pp. xxii + 1056. (Brunswick: Vieweg und Sohn, 1904.) Price 18 marks.

A SERIOUS problem is presenting itself to lecturers and writers of text-books on physics. Never, perhaps, has there been such rapid accumulation of knowledge, both in respect to phenomena the fundamental facts of which were found out in the early ages of physical discovery and in respect to new phenomena which reveal themselves in succession to the physical investigator. The brilliant experimental discoveries of Faraday in electrodynamics, the equally distinguished theoretical and experimental researches of Fresnel in optics, the researches of Mayer, Helmholtz, Lord Kelvin, Clausius, and Joule in thermodynamics, which are unsurpassed in importance owing to their wide reaching application to almost every branch of physics, all these make the first half of the nineteenth century unique as an age of physical discovery. This period was followed by one of comparative quiet, in which physicists began to acquire a comfortable feeling that the universe was now known; details undoubtedly there were to be made out, but no striking discovery was expected. This attitude of content was roughly disturbed by the discovery of Röntgen rays in 1895, and still more startlingly so by the discovery of various other types of rays and emanations by Becquerel and his followers. Each of these discoveries has given birth in a most prolific way to a vast crowd of minor discoveries demanding a history of their own; and meanwhile the accumulation of fact and theory in older subjects has steadily gone on, and the problem which presents itself is, How is this huge and ever increasing amount of knowledge to be successfully presented to a student? It is becoming unmanageable. No single course of lectures can deal adequately with it. College courses are beginning to spread over two years, and even then merely skim the subject. The text-book under review illustrates the state of things. It is the second volume out of four. It extends to more than a thousand pages, and deals only with sound and with radiant energy. It contains no elaborate development of mathematical theory—in fact, the weak point of the book is that there is not enough mathematics in it. Wherever the mathematics required is other than of simple kind it is omitted; the final formula may be given, but it is often quoted unproven. How is a student to master the vast mass of material which is extended to him here? It seems inevitable that before long some process of selection must be adopted in order that a student's work may be made more easy for him. Of course, if a book is intended as a book of reference chiefly, the more encyclopædic it is the better; but the present volume is intended as a text-book, and not as an encyclopædia. We think that the ideal text-book is one which will present such a selection from ascertained knowledge as will give a student an adequate grasp of the facts, principles, and methods of his subject. The selection need not and should not be skimped, but no attempt should be made to include *all* that is known to be true.

Regarded as a book of reference, this volume is most admirable, and we commend the enterprise which now brings it into a wider circle of readers. German is not popular amongst English students, but Russian is barred altogether. The matter is excellent and is excellently presented. It is thorough, and is brought well up to date in this edition; *e.g.* there is a good account of Siedentopf and Szigmondy's recent work on the vision of (so-called) ultramicroscopic particles. The chapter on interference is specially good. The illustrations throughout are unusually clear, especially those explanatory of the various instruments of observation.

The man who gets this book has only himself to blame if he learns no physics. Our only quarrel is with the size of the dose. Experience has shown us that a student fights shy of this heroic treatment, and turns for help to the text-books of the cramming institutions. Less formidable treatment might induce him to put the latter away with advantage.

OUR BOOKSHELF.

Wilhelm Ostwald. By P. Walden. Pp. vii + 120. (Leipzig: Wilhelm Engelmann, 1904.) Price 4*s.* net.

Prof. Ostwald has only just attained his fiftieth year, and in appearance he is full of life and vigour. He has done and is doing a great work in science; he is a man one may delight to honour, both for his intellect and for his heart. It may be merely the prejudice of the reticent Englishman, but I must confess to a feeling that these biographies of eminent men in the prime of

life must be very uncomfortable to their subjects, and a doubtful kindness. If they are to become common, mediocrity will find a new consolation.

It is impossible, however, not to admire and, knowing Ostwald, not to share the warmth of feeling which has prompted the publication of this book. It is written on the occasion of the twenty-fifth anniversary of Ostwald's graduation, and in the 120 pages Prof. Walden gives a very readable account of his subject from the age when the hero was "unser Wilhelm" up to the present time. From it we learn that the life of Ostwald has been free from any very dramatic incidents, and that, like so many eminent men, he was an ordinary boy and a not strikingly exceptional student. When once inspired by the teaching of Lemberg, he really breasted the sea of science and struck out on the course which he has followed with such success. His early career as a teacher was fraught with scanty means and imperfect appliances, but resolution, single-minded devotion and splendid ability overcame all obstacles, and have been rewarded, as we know, with every kind of success to which a true man of science may properly aspire. The book will be read with interest not only by Ostwald's friends and pupils, but by all who are interested in the foundation of the modern school of physical chemists. A. S.

The Lepidoptera of the British Islands. A Descriptive Account of the Families, Genera, and Species Indigenous to Great Britain and Ireland, their Preparatory States, Habits, and Localities. By Charles E. Barrett, F.E.S. Vol. ix., Heterocera, Geometrina—Pyralidina. Pp. 454. (London: Lovell Reeve and Co., Ltd., 1904.) Price 12s. net.

THE ninth volume of Mr. Barrett's great work marks substantial progress, and practically completes the Macrolepidoptera. About 180 species are described. The Geometrina include the families Larentidæ (the conclusion here given chiefly consisting of the great genus Eupithecia, of which forty-eight British species are admitted, one doubtful, but also including Eubolia and its allies, formerly placed in a distinct family), and Œnochromidæ, with only two British genera, Tanagra and Aplasta. The Pyralidina include the families Pyraustidæ, Pyralidæ, Hydrocampidæ, Endotrichidæ, Scopariidæ, Pterophoridæ, Orneodidæ, and Phycitidæ. The last family is not quite completed in vol. ix., so there now remain but the Galleriidæ, Crambidæ, Tortricina, and Tineina to be dealt with. As it is possible that these may not require to be treated in such great detail as the Macrolepidoptera, perhaps four or five more volumes may be sufficient to complete the book, which will remain as a permanent record of the work accomplished by British lepidopterists during the latter half of the last century and the opening years of the present. Among the more interesting features of vol. ix. may be noted the carefully-drawn-up table of the large and difficult genus Eupithecia, which ought much to facilitate the determination of species; and the exact records of the occurrence of the rarer species of Pyralidæ, many of which are met with, at least in Britain, only singly and sporadically at long intervals and in widely separated localities. Many interesting species, some of wide distribution abroad, have thus been added to our British lists of late years.

It will be seen that to a considerable extent Mr. Barrett still follows an arrangement similar to that of Stainton's "Manual"; it is, however, a great improvement to associate the Pterophoridæ with the Pyralidæ, as is now generally done. The Orneodidæ are a more aberrant family, and we are not sure that their real affinities have yet been finally determined.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Flowering of the Bamboo.

I HAVE read Mr. Tingle's letter in NATURE for August 11, as well as Prof. Farmer's comments on it, and hope you will permit me to add my remarks to the discussion of the subject.

Mr. Tingle ought to have specified which of the Chinese bamboos it is that has now flowered. According to the list given by Dr. Rendle in the recently published part of the *Journal* of the Linnean Society, vol. xxxvi., there are about forty-two species of bamboo, large and small, in China, and it would be interesting to know which of them it is. Let us hope that Mr. Tingle is sending good specimens to the Kew and British Museum herbaria. Until the species referred to has been ascertained, discussion is rather difficult, except from a general point of view.

My own experience of bamboos is confined to India, where there are more than 120 species, large and small, but I have never heard that their flowering, even when it takes place gregariously, has caused alarm among the natives. The gregarious flowering of the common species such as *Dendrocalamus strictus* or *Bambusa arundinacea* often takes place in an exceptionally dry season, when there may also be partial failure of the crops, and on such occasions advantage is sometimes taken of the general seeding to collect and use the seeds for food. Signs of approaching flowering may, perhaps, occasionally be received with misgiving as foreshadowing a dry season and bad crops, but I have never heard of their being regarded with anything approaching to superstitious terror.

So far as we know at present, some of the Indian-Burmese species only flower gregariously at long intervals, but even then there is some doubt whether the flowering is local only or widespread. The well known Kyathaungwa (*Bambusa polymorpha*), a large species with culms up to 80 feet in height and 6 inches in diameter, and notable as a common associate of the teak tree, was collected in flower by Dr. M'Clelland in Pegu in 1854, by Sir D. Brandis in the Salween in 1862, and by Mr. S. Kurz in the Sittang Valley in 1871, and flowers have once been reported since from Bassein; but in more recent years it has not flowered, though its gregarious flowering is being anxiously awaited by forest officers, who hope to use the opportunity for the extension of teak reproduction. There are some species of bamboo which flower regularly every year and do not die off: among them are the little *Arundinaria Wightiana*, so common in the forests around Ootacamund in the Nilgiri Hills; *Bambusa lineata*, a small reedy species of the coast forests of the Malay Archipelago, extending westwards only to Rutland Island in the Andamans, though strangely enough it has not, so far as I am aware, been known to produce seed; and *Ochlandra stridula*, a shrubby species of the low country of Ceylon. The great majority of species, however, have their chief flowerings gregarious, at more or less regular intervals, while every now and again a few clumps may be found in flower sporadically in almost any year. This is especially the case with *Dendrocalamus strictus*, the "male bamboo" so widespread in the deciduous more or less dry forests of India and Burma; with the thorny *Bambusa arundinacea* of the Western Peninsula; with *Dendrocalamus Hamiltonii*, the most common species of northern Bengal and Assam; and with *Bambusa Tulda* in Bengal, the east coast hills, and Burma. Gregarious flowerings may really be often quite local, though widespread enough within their locality.

When, in India, bamboos flower gregariously, they usually produce quantities of good seed, and the old clumps then die off; but in sporadic flowerings my experience is that seed is very little produced, or if produced infertile, while the clumps occasionally may recover, though rarely. Damage to a clump may often produce a partial or sporadic flowering. Information on the subject is being gradually collected in India; the dates of flowering of the different species are, when observed by forest officers,

recorded in their journal, the *Indian Forester*, and the behaviour of the clumps is being carefully watched, especially as the dying off of the clumps of a species over large areas may mean a serious dearth for several years of the most useful material for the construction of native houses and of many articles of common domestic use. I would therefore invite the attention of those interested in the subject to the pages of the journal mentioned, and I hope Mr. Tingle and others will collect similar information in China. As regards the flowering of cultivated species in the gardens of this country, some very useful information was given by Mr. Bean, of Kew, in the *Gardeners' Chronicle* for 1903. I am not quite sure that all the flowered clumps of *Arundinaria Falconeri* will die. I have one in my own garden, and I think it is quite likely to live. I recently saw, in a neighbour's garden, a large clump of *A. Simoni* which had flowered and apparently died, but the root-stock is now studded with young green shoots, and they look as if they intended to grow. I think it is because all the culms had been cut away after the flowering.

J. S. GAMBLE.

Highfield, Liss, Hants, August 14.

The Spontaneous Scintillations of Hexagonal Blende.

A SHORT time ago I pointed out in the *Chemical News* (1904, p. 33) that scintillations, similar to those produced by a radium salt, but feebler, can always be observed in hexagonal blende, in the absence of any radium or radium-emanation.

I have recently made experiments in order to determine whether the blende itself is radio-active, and whether such inherent radio-activity is the cause of the spontaneous scintillations.

An electroscope was used with paraffin-wax insulation and a long aluminium leaf. The rate of leak was first determined, and then the effect produced on the rate by placing the blende on the brass plate of the electroscope. Two specimens from a French firm were examined in this way, and showed no effect whatever; they were spread over the plate in the form of powder.

A specimen from an English firm, in the form of a screen 4 cm. square, showed a marked effect, but a piece of writing-paper of the same size produced the same effect; consequently, no radio-activity can be attributed to the blende on the screen. All these specimens showed the scintillations distinctly, and I can only adhere to my original opinion that the scintillations are caused by a spontaneous change in the structure of the crystals.

Sooty Rain.

I SHOULD be glad if any of your readers could explain the following phenomenon:—

It occasionally happens that on still days, usually with light northerly winds, a heavy shower of rain will carry down a black greasy deposit which forms a film or scum on this and other lakes in the district. It is a recognised nuisance to owners of pleasure boats, as, from the adhesive nature of the scum, scrubbing with soap and water is necessary to remove it.

This black deposit has been examined for me by a competent biologist, and contains no products of organic life. It has, in fact, the appearance and oily character of ordinary soot. I have seen a small handful (when dry) scraped up here from the shore. Sooty rain is the exception, and not the rule. In May last there were about eight days of sooty rain, with the wind out of the north-east. During the last three months, though the lake has risen more than a foot, there has been only one sooty rainfall, viz. on August 17, when the wind was again in the north.

Yesterday (Sunday, August 21, 4 p.m.) I had an opportunity of observing the formation of the scum, and was surprised to see how quickly it appeared. The day had been still, with heavy clouds at a considerable height coming up slowly from west-south-west, with an occasional light breeze from the north. At 4 o'clock the wind dropped entirely, and a sudden heavy shower of rain fell which lasted about fifteen minutes.

As soon as the rain began, the surface of the lake appeared broken up into faintly defined dull and bright patches, which in two or three minutes became strongly intensified without losing their original shape. The dull patches consisted of the sooty film, which was easily observable by dipping in a sheet of white paper, to which the soot adhered.

The position of the Lake District in regard to manufacturing centres renders the occurrence of sooty rain under the conditions described rather remarkable. It would be interesting, too, to know why the sooty film should not cover the surface of the water uniformly, instead of in patches. These patches, by the way, are known locally as "tarns," and are supposed to forecast a spell of bad weather.

Coniston, Lancs., August 22. J. B. COHEN.

Adaptive Colours of Eyes.

SOME time ago Prof. Wallace, of the School of Mines, Kimberley, suggested to me the possible explanation of the difference in colour of the light reflected from the iris of the eyes of different people—that it was in accordance with the natural law of protection against external influences. He pointed out that people hailing from regions where blue light is predominant—Swedes, Norwegians, and sailors, for instance—have blue eyes, whilst near the equator, or in sandy climes such as South Africa, where intense yellow light is experienced, the eyes take a rich dark yellow hue, as those of the Kaffirs and Malays, Italians and Spaniards. The Scotch have blue, the English grey, and the French dark eyes, generally speaking.

I wish to know whether this novel explanation will bear criticism under the searching light some of your readers may be able to throw on the matter.

Beaconsfield, Kimberley, South Africa, July 21.

An Optical Phenomenon.

SOME sixteen years ago I observed phenomena which appear to be related to those mentioned by Mr. Hillig on p. 366 of NATURE, and by Mr. Walker on p. 396. A disc, in which was a ring of holes, was rotated between the eye and the sky. I saw coloured patches and rings, changing with the velocity of rotation. The appearances vanished as the rate of rotation increased. The colours were pale green and purple. The purple flowed about as if fluid, and the green appeared as islands mottling its surface. It occurred to me that there might be some connection with the visual purple of the retina.

It would be of interest to repeat the experiments, using the different spectral colours, and varying the rates of rotation.

Intermittent stimulation of the retina may give rise to very curious and interesting results.

In the concluding chapter of Mr. Bidwell's "Curiosities of Light and Sight" will be found an account of some remarkable effects produced by intermittent illumination.

Leeds, August 27. C. T. WHITMELL.

The Constitution of Matter.

HAVING followed the almost brilliant discussions concerning the constitution of matter which took place at the recent Cambridge British Association meetings, I was not a little surprised to come across the following remarks made by Ralph Waldo Emerson in 1867. He said: "The chemists already find the infinite variety of things contained in sixty-six elements; and physicists promise that this number shall be reduced to twenty, ten, five. Faraday declares his belief that all things will, in the end, be reduced to one element with two polarities."

It would be interesting to know exactly the phraseology in which Faraday expressed this belief.

R. W. Emerson merely uses the statement to aid religious views. And yet in several of his writings he has selected almost prophetic utterances concerning science.

THE INFANTS' MILK DEPÔT.

THE annual toll of infant lives in all countries is a heavy one. At the present day in most civilised countries the problems of infantile mortality have come into prominence from many causes, chiefly the declining birth-rate, and although in England the general death-rate has fallen from 22·6 per 1000 in the five-yearly period 1851–5 to 17·6 in 1896–1900, the infant mortality, that is, the death-rate of infants under one year per 1000 births, has remained stationary (156) in those two periods. In the great industrial centres the infant mortality ranges from 168 to 182, and if it could be reduced to 104, which is the average of the semi-rural counties, there would be a saving of 40,000 lives annually. Dietetic diseases are mainly responsible for this terrible loss of life, and from one-third to one-half of the total infant mortality is due to diarrhœa, which is especially active in hot summers.

These conditions are chiefly attributable to improper feeding, and to the use of milk which bacteriologically is grossly polluted. These sources of danger to the infant population would, of course, be inoperative were breast-feeding the rule, but breast-feeding seems to be difficult to secure, partly from the selfishness of mothers, and partly from an ignorance which assumes that hand-feeding can take its place. It is naturally among the poor that improper feeding chiefly obtains. The infant from its earliest days, in lieu of its natural nourishment, has tit-bits from the parents' table and various concoctions of cow's milk, condensed milk, and infants' foods. With regard to the latter, it has been remarked that if a mixture of chicory with coffee is sold as pure coffee the trader is liable to prosecution, but that anyone may make up any sort of mixture and call it a perfect infants' food, and the law leaves him alone!

There is obviously a great field for specialised measures of prevention against the dietetic diseases of infants, and organisations have therefore been established for the supply of sterilised milk for the babies of the poor, and incidentally to teach the mothers how their children should be reared, and to encourage breast-feeding whenever practicable.

Many of these infants' milk depôts are now in active work, both on the Continent, and in England at St. Helens, Liverpool, Battersea, and other districts, and their administration is summarised by Dr. McCleary, the medical officer of health for Battersea, in a useful paper.[1] In Battersea this is as follows:—The milk for use at the depôt is carefully controlled, and special conditions have to be accepted by the contractor. The amount of milk requisite for a single meal, and suited to the age of the infant, is contained in a screw-stoppered bottle; for the youngest infants it is modified by the addition of water, cream, and sugar according to recognised principles. The bottles are then placed in the sterilising chamber (see illustration), steam is injected, and the temperature raised to 212° F., which is maintained for about ten minutes. They are then taken out of the steriliser and rapidly cooled in a cooling tank. The bottles are supplied in wire baskets, each basket holding from six to nine bottles, and containing a twenty-four hours' supply. The next day the basket of empty bottles is returned, and a fresh supply obtained. When a child is entered at the depôt the mother is instructed by the manageress as to the proper method of using the milk, and she receives a printed leaflet of instructions. The cost varies according to age, from 2s. to 2s. 9d. per week.

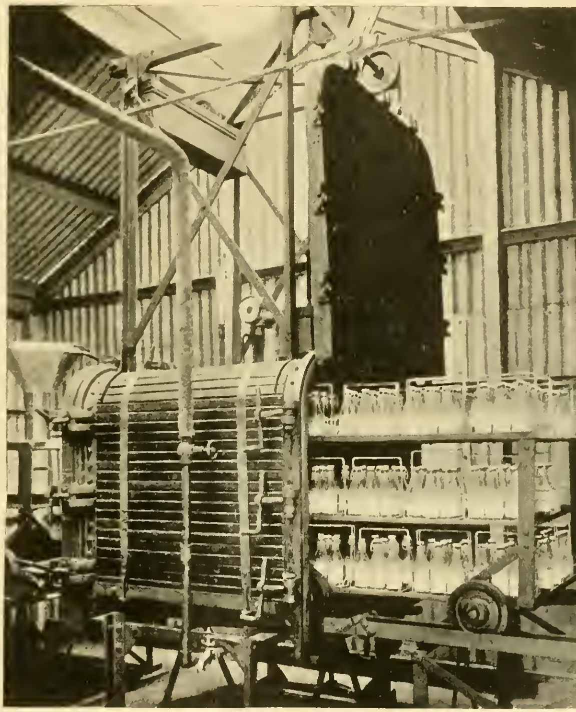

FIG. 1. Infants Milk Depôt, Battersea. Interior o. sterilising room, showing steriliser with loaded trolley. (From the *Journal of Hygiene*.)

The method of infant feeding is a very simple matter so far as the mother is concerned. When feeding time arrives, all she has to do is to place a bottle, unopened, in a basin of warm water until it reaches body temperature, to open the bottle, put on a rubber teat supplied at the depôt, and feed the baby from the sterilised bottle direct. There is no need for a "feeding bottle," which alone is a great advantage.

The homes of the children fed on the milk are visited by the lady sanitary inspectors, who endeavour

[1] "The Infants' Milk Depôt: its History and Function" (*Journal of Hygiene*, iv., No. 3, July, 1904, p. 329).

to secure that the instructions are properly carried out. If the child does not appear to be progressing favourably, the mothers are strongly advised to seek medical advice. Mothers are urged to bring the children once a week to be weighed.

As to the results of the working of these institutions, it is not yet possible to speak, and there are many fallacies that have to be guarded against in considering the statistics. Dr. Drew Harris calculated that for the three years 1899–1901 at St. Helens the death-rate among children attending the depôt averaged 104, while in the whole borough it was 173. At the recent Congress of the Royal Institute of Public Health, Mr. Councillor Shelmerdine stated his conclusions for Liverpool as follows:—"that of the 4453 infants coming very promiscuously to the depôts at varied ages and in conditions of health below the average the mortality was 78 per 1000 as against 159 per 1000 for the whole city. But it must be remembered that in that 159 per 1000 for the whole city and 88 to 118 for the best districts, and 212 to 215 for the worst districts, were included also breast-fed infants; clearly if breast-fed infants were excluded and artificially-fed infants only taken into account the rate of mortality amongst them would be enormously higher, and would show even more forcibly the advantages of the sterilised food which, of course, is an artificial food, over other methods of artificial feeding."

R. T. HEWLETT.

EXHIBITION OF ANCIENT EGYPTIAN SCULPTURE AT THE BRITISH MUSEUM.

VISITORS to the British Museum galleries of antiquities will notice that a considerable alteration has lately been effected in the arrangement of the Egyptian sculptures of the early period, and that many antiquities which have not hitherto appeared in the galleries are now on exhibition for the first time. Most of the newly exhibited monuments date to the most ancient period of the Egyptian monarchy, of which the British Museum has until lately not possessed many specimens; some are monuments of prime importance historically as well as artistically, and nearly all owe their appearance in London to the present Keeper of the Department of Egyptian and Assyrian Antiquities, Dr. E. A. Wallis Budge, who has personally superintended their removal from Egypt and their exhibition in the galleries of his department. The British Museum is now in a fair way of making up its deficiency in larger monuments of the older period—the "ancient" and "middle" Empires—and few museums out of Egypt can show so fine a collection of funeral stelæ of the fourth and fifth dynasties.

These are chiefly exhibited in the vestibule at the end of the Egyptian saloon. This vestibule is now practically given up to monuments of the "ancient Empire." The most important of them takes the central position, and is one of the finest Egyptian monuments in the museum. This is the great stele which faced the doorway in the *mastaba* tomb of Ptahshepses, at Sakkara. Ptahshepses was one of the chief men of the court of Shepseskaf, the last king of the fourth dynasty. He was brought up by Menkaura, Herodotus's Mykerinos, the builder of the third pyramid of Giza, among the royal children, and was given the king's daughter Khamaat to wife. Offices of trust and honour were piled upon him, and to judge by the explanatory label below his monument, upon which all his titles are set forth, he ought to be the patron saint of pluralists. The colour of this monument is well preserved, and used as we may be to the idea of paint laid on under the eighteenth dynasty (B.C. 1500) being still preserved in all its pristine brilliancy of colour, it is another thing to find delicate colouring applied in the days of the pyramid builders—whose days were separated from those of the eighteenth dynasty by nearly as much time as separates the eighteenth dynasty from us—still bright and still delicate. It is to be hoped that London fogs will not sully it.

Other monuments of the same period and type are arranged round this fine centre-piece, and all are interesting. Those who are interested in the work of men's hands in the dawn age of civilisation should not miss this important exhibition of Egyptian antiquities of the Ancient Empire.

THE BRITISH ASSOCIATION AT CAMBRIDGE.

AT the final meeting of the general committee last week, a report from the committee of recommendations was received and accepted with some slight alterations. One of the recommendations was made with the object of securing the continuity of sectional committees from one meeting to the next. Secondly, it was proposed that each sectional committee should have power to appoint during the annual meeting not more than three vice-presidents. Another recommendation had reference to the constitution of the council and the appointment of assistant secretary.

The following is a synopsis of grants of money appropriated to scientific purposes by the general committee:—

Mathematics and Physics.	
*Rayleigh, Lord—Electrical Standards	£40
*Judd, Prof. J. W.—Seismological Observations ...	40
*Shaw, Dr. W. N.—Investigations of the Upper Atmosphere (Kites)	40
*Preece, Sir W. H.—Magnetic Observations	50
Chemistry.	
Kipping, Prof. F. S.—Aromatic Nitramines	25
Armstrong, Prof. H. E.—Dynamic Isomerism ...	20
*Roscoe, Sir A. E.—Wave-length Tables of Spectra ...	5
*Divers, Prof. E.—Study of Hydro-Aromatic Substances	25
Geology.	
*Watts, Prof. W. W.—Movements of Underground Waters	Balance in hand
*Marr, Dr. J. E.—Life Zones in British Carboniferous Rocks	Balance in hand
*Lamplugh, G. H.—Fossiliferous Drift Deposits	Balance in hand
*Marr, Dr. J. E.—Erratic Blocks...	10 and unexpended balance
*Herdman, Prof. W. A.—Fauna and Flora of British Trias	10
Zoology.	
*Woodward, Dr. H.—Index Animalium...	75
*Hickson, Prof. S. J.—Table at Zoological Station at Naples	100
*Weldon, Prof.—Development of Frog	10 and unexpended balance
*Hickson, Prof. S. J.—Higher Crustacea	15 and unexpended balance
Geography.	
Murray, Sir J.—Investigations in the Indian Ocean...	150
Economic Science and Statistics.	
*Cannan, Dr. E.—Trade Statistics	20

* Reappointed.

Anthropology.	
*Read, C. H.—Age of Stone Circles	£40
*Cunningham, Prof. D. J.—Anthropometric Investigations	10
*Evans, A. J.—Excavations on Roman Sites in Britain	10
Evans, Sir J.—Excavations in Crete	75 and unexpended balance
Macalister, Prof. A.—Anthropometry of Native Egyptian Troops...	10
*Munro, Dr. R.—Glastonbury Lake Village ...	Balance in hand
*Tylor, Prof. E. B.—Anthropological Teaching	Balance in hand
Physiology.	
*Gotch, Prof.—Metabolism of Individual Tissues ...	30 and unexpended balance
*Halliburton, Prof. W. D.—State of Solution of Proteids	20
Schäfer, Prof.—The Ductless Glands	40
Botany.	
Scott, Dr. D. H.—Structure of Fossil Plants... ...	50
*Ward, Prof. H. Marshall—Physiology of Heredity ...	35
Miall, Prof.—Botanical Photographs	5
Educational Science.	
Magnus, Sir P.—Studies suitable for Elementary Schools	20
Corresponding Societies.	
*Whitaker, W.—Corresponding Societies Committee...	20
	£1000

The concluding meeting of the Association was held in the Senate House on August 24, the President being in the chair.

Sir J. Evans moved a vote of thanks to the Vice-Chancellor of the university and to the Mayor and Corporation of Cambridge for their reception of the Association, and for the use of the municipal and university buildings; also to the chairman of the County Council of Cambridge and the Isle of Ely for their assistance on behalf of the Association.

The Vice-Chancellor (Dr. Chase) replied for the university, the Mayor of Cambridge on behalf of the corporation, and Mr. E. S. Fordham on behalf of the county council.

Votes of thanks to the local committee and to the gentlemen and public bodies who had extended their hospitality to the Association were also carried.

At the suggestion of Mr. Balfour, Prof. George Darwin, the president of the meeting to be held next year in South Africa, made a few remarks, in the course of which he said that he was deeply sensible of the compliment that had been paid to him in nominating him for the office of president of the British Association, but he felt that he had exceptional difficulties to face. It was not only that for one year he had been nominated to serve as the figure-head of British science, but on this occasion he would have to act as a sort of ambassador for science in the home country to budding science in South Africa. Cambridge was a university of many centuries' standing; and South Africa had aspirations that her universities should in future be as great. But there was a long road to travel before that hope could be fulfilled. One of the objects of the Association's visit to South Africa was to aid her in achieving those aspirations. The visit might do much good in helping local men to foster their institutions for higher education and for the prosecution of science.

Mr. Balfour said that there could not be a more fitting conclusion to Prof. Darwin's speech than to announce, as he now did, that the meeting was adjourned until August 15, 1905, at Cape Town.

* Reappointed.

SECTION E.

GEOGRAPHY.

OPENING ADDRESS BY DOUGLAS W. FRESHFIELD, PRESIDENT OF THE SECTION.

On Mountains and Mankind.

A GEOGRAPHER or traveller who has been called upon to preside over the meetings of our Section of the British Association may be excused for feeling some hesitation as to the character he shall give to the Address which custom compels him to deliver. He cannot but be aware that his audience, while it includes not a few experts, probably far better qualified than himself to take the Chair, is composed mainly of those whose concern in Geography can only be a general and occasional one.

To compose a summary of the geographical events of the year would be a simple and obvious expedient, were I not conscious that in this I have been forestalled by the indefatigable President of the Royal Geographical Society. To consider the progress of geography, during, say, the last quarter of a century, might be instructive to "the general." On the other hand, on his special subject your President may possibly be able to add something to the common stock by way of observation or suggestion.

Bearing in mind the, from the point of view of posterity, almost excessive energy with which the nineteenth century carried on the exploration of the globe, narrowing in every direction the field left to our explorations and our imaginations, 1904 may so far be counted as an "annus mirabilis" in the annals of Geography. We have seen the successful return, if not as yet to our own shores, to safe seas, of the most important expedition ever sent South Polewards. In the success obtained by Captain Scott and his comrades, we have welcomed a full justification of the course taken in putting the supreme command and direction of the undertaking in the hands of an officer of His Majesty's Navy. "England expects every man to do his duty," and I will not indulge in hyperbolical praise, which must be distasteful to men who have shown in trying circumstances the daring, the cheerfulness, and the resourcefulness which we are accustomed to associate with the British Navy. We have every reason to expect that the results obtained by the energetic and capable men of science attached to the expedition will be of wide bearing and interest, but to attempt to estimate them to-day would be obviously premature.

The current year has been distinguished by a, perhaps, even more remarkable geographical event. His Majesty's Government, not satisfied with the laurels it has won in the Antarctic, has embarked on a second geographical adventure on a larger scale and at a far greater cost (which, however, will presumably be borne by India). It has sent forth a Gold Medallist of the Royal Geographical Society, Colonel Younghusband, with a numerous escort to reach the forbidden capital of Tibet. The saffron-vested monks on the "golden terraces" of the Pota La have seen the glimmer of British bayonets on the horizon, and the castle-palaces of Lhasa will, we hope, open to the military explorer their mysterious halls, hitherto known to us best by the descriptions of that entertaining traveller, my friend Chandra Das.

But the fruits of these great expeditions are not yet ripe. I must leave them to be plucked by my successors. I do so with regret, for I should have listened with a peculiar interest to an account of the fascinating land, over whose peaks and pastures I lately gazed from the Pisgah heights of the Jonsong La.

To review the progress of Geography during the last twenty-five years, the time that has passed since I first joined the Council of the Royal Geographical Society, is tempting. The retrospect would on the whole be encouraging. The past quarter of a century, if not an era of the most extensive discoveries, has been an era of profitable occupation—I mean profitable in the scientific and not in the commercial sense, though the two are frequently connected—of the ground seized by the great pioneers in Africa, in the backlands of North America, and elsewhere. And when we come to consider the manner in which the results of modern exploration are recorded, what an advance we find! Compare the geographical publications of Great Britain in 1880 and 1904; take the most conspicuous instance, those of the Royal Geographical Society at the

two periods. Consider the way in which our lectures and literature are now illustrated by the aid of photography, new processes, and the lantern. Petermann's *Mitteilungen* was for long the one first-rate geographical magazine in Europe. We have now, as we ought to have had long before, a *Journal* that rivals it.

Take a wider survey. Look at maps, beginning with the Ordnance Survey. Compare the last issues of the one-inch maps, with all the advantages of colour-printing, over their doubtless (except as to roads) accurate, but far less intelligible predecessors. Consider the maps private firms, Messrs. Bartholomew and Messrs. Stanford, have provided us with; note the new editions of "Murray's Guides."

The correction and completion of maps by new explorations is always desirable. But it is even more important that a sound system for the delineation of natural features should be adopted both for Government surveys and general maps. I begin to look forward to a time when glaciers will no longer be represented, as they were on the early Indian and Caucasian surveys, without their heads or tails—that is, without either their névés or their moraine-cloaked lower portions or with rivers rising above them and flowing through them. In time, perhaps, every closet cartographer will recognise that glaciers do not lie along the tops of lofty ridges, but descend into valleys. In these matters I have had many an arduous struggle. It is cruel that a poor man should be set to delineate snow mountains who has never seen one, and when "a week at lovely Lucerne" can be had for 5*l*. 5*s*. it is inexcusable.

In my schooldays there was an exercise of memory known to us by the contemptuous appellation of "Jog," which boys and masters united to depreciate and despise. This sentiment is now confined to a few elderly generals and headmasters. Geography flourishes as a branch of science under the august shadow of the elder Universities. At Oxford we have produced Mr. Mackinder and Dr. Herbertson, Mr. Grundy, Mr. Hogarth, Mr. Beazley. We have started a school of Geography and a school of Geographers. At Cambridge a Board of Geographical Studies has been established. I may quote what Sir C. Markham said three months ago:—

"The staff of the new geographical school at Cambridge will consist, instead of one reader, of several lecturers and teachers, who will cover the various departments of the science. A diploma in geography will be granted as at Oxford. But Cambridge goes a step further than Oxford, by introducing geography into the examination for the B.A. degree. The importance of according geography such a position in the studies of the Universities must be evident to all, and must be specially gratifying to those who, for more than thirty years, have fought hard, amid much discouragement, to have geography recognised as a University subject. It will be interesting to see how the Board of Geographical Studies at Cambridge will draw up the detailed regulations for the degree and the diploma, what steps will be taken to secure a competent staff to cover the whole field of our science, and especially to train young University men for practical work in the field. We have every reason to expect that the results will prove satisfactory.

"The Geographical Association of Teachers, of which Mr. Mackinder and Dr. Herbertson are active members, is doing much to enlighten teachers with regard to the capabilities of the subject, to raise its standard, and to introduce improved methods of teaching. An interesting and useful conference was held last winter at the Chelsea Polytechnic, under its auspices, and in connection with the conference there was an excellent exhibition of appliances used in teaching geography, the usefulness of which was increased by sending it to various provincial centres."

In primary schools many teachers are furnishing excellent instruction, and are instructing themselves in the handbooks provided by our friends Dr. Mill and Mr. Chisholm and others. In the higher branches of education the problems of scientific geography are studied, and teachers are encouraged to develop the geographical aspects of other subjects, such as archæology, history, commerce, colonisation on the one hand, botany and natural history on the other. We have moved forwards and upwards, but do not let us flatter ourselves that we have as yet reached any considerable eminence. Probably many more of our countrymen can read a map in this generation than could in the last. A small percentage, I am glad to notice, are not hopelessly bewildered even by contour lines.

We are learning our geographical alphabet. In time we may, as a nation, be able to read and to understand what we read. We shall recognise that ability to use a map and judge ground is a considerable safeguard against waste of life and disasters in war, and that an acquaintance with the features of the earth's surface and geographical distribution is an invaluable help to a nation in the commercial rivalries and struggles of peace.

When the question of establishing Geography at Oxford was being discussed, Dr. Jowett (who had himself somewhere in the 'fifties suggested the erection of a geographical chair) asked me if I believed Geography could be taught so "as to make men think." We should, I believe, "think imperially" to more purpose if we also took pains "to think geographically." But I will not detain you and use up my time by going in any detail into the progress of Geography. I might find myself only repeating what others have said better. And as to one important branch, perhaps the most important branch, geographical education, on which I addressed this Section at Birmingham some fifteen years ago, I feel myself debarred by the fact that the Association has now a Section specially devoted to Education.

I have determined on the whole, therefore, to run the risk of wearying some of my listeners by inviting your attention to the place in Geography of the natural objects which have had for me through life the greatest and most enduring attraction. I propose to talk about mountains, their place in Nature, and their influence, both spiritual and material, on mankind.

We have all of us seen hills, or what we call hills, from the monstrous protuberances of the Andes and the Himalaya to such puny pimples as lie about the edges of your fens. Next to a waterfall, the first natural object (according to my own experience) to impress itself on a child's mind is a hill, some spot from which he can enlarge his horizon. Hills, and still more mountains, attract the human imagination and curiosity. The child soon asks, "Tell me, how were mountains made?" a question easier to ask than to answer, which occupied the lifetime of the father of mountain science, De Saussure. But there are mountains and mountains. Of all natural objects the most impressive is a vast snowy peak rising as a white island above the waves of green hills—a fragment of the arctic world left behind to commemorate its past predominance—and bearing on its broad shoulders a garland of the Alpine flora that has been destroyed on the lower ground by the rising tide of heat and drought that succeeded the last Glacial epoch. Midsummer snows, whether seen from the slopes of the Jura or the plains of Lombardy, above the waves of the Euxine or through the glades of the tropical forests of Sikkim, stir men's imaginations and rouse their curiosity. Before, however, we turn to consider some of the physical aspects of mountains, I shall venture, speaking as I am here to a literary audience, and in a University town, to dwell for a few minutes on their place in literature—in the mirror that reflects in turn the mind of the passing ages. For Geography is concerned with the interaction between man and Nature in its widest sense. There has been recently a good deal of writing on this subject—I cannot say of discussion, for of late years writers have generally taken the same view. That view is that the love of mountains is an invention of the nineteenth century, and that in previous ages they had been generally looked on either with indifference or positive dislike, rising in some instances to abhorrence. Extreme examples have been repeatedly quoted. We have all heard of the bishop who thought the devil was allowed to put in mountains after the fall of man; of the English scribe in the tenth century who invoked "the bitter blasts of glaciers and the Pennine host of demons" on the violaters of the charters he was employed to draft. The examples on the other side have been comparatively neglected. It seems time they were insisted on.

The view I hold firmly, and which I wish to place before you to-day, is that this popular belief that the love of mountains is a taste, or, as some would say, a mania, of advanced civilisation, is erroneous. On the contrary, I allege it to be a healthy, primitive, and almost universal human instinct. I think I can indicate how and why the opposite belief has been fostered by eminent writers. They have

taken too narrow a time-limit for their investigation. They have compared the nineteenth century not with the preceding ages, but with the eighteenth. They have also taken too narrow a space-limit. They have hardly cast their eyes beyond Western Europe. Within their own limits I agree with them. The eighteenth century was, as we all know, an age of formality. It was the age of Palladian porticoes, of interminable avenues, of formal gardens and formal style in art, in literature, and in dress. Mountains, which are essentially romantic and Gothic, were naturally distasteful to it. The artist says "they will not compose," and they became obnoxious to a generation that adored composition, that thought more of the cleverness of the artist than of the aspects of Nature he used as the material of his work. There is a great deal to be said for the century; it produced some admirable results. It was a contented and material century, little stirred by enthusiasms and aspirations and vague desires. It was a phase in human progress, but in many respects it was rather a reaction than a development from what had gone before. Sentiment and taste have their tides like the sea, or, we may here perhaps more appropriately say, their oscillations like the glaciers. The imagination of primitive man abhors a void, it peoples the regions it finds uninhabitable with aery sprites, with "Pan and father Sylvanus and the sister Nymphs," it worships on high places and reveres them as the abode of Deity. Christianity came and denounced the vague symbolism and personification of Nature in which the pagan had recognised and worshipped the Unseen. It found the objects of its devotion not in the external world but in the highest moral qualities of man. Delphi heard the cry "Great Pan is dead!" But the voice was false. Pan is immortal. Every villager justifies etymology by remaining more or less of a pagan. Other than villagers have done the same. The monk driven out of the world by its wickedness fell in love with the wilderness in which he sought refuge, and soon learnt to give practical proof of his love of scenery by his choice of sites for his religious houses. But the literature of the eighteenth century was not written by monks or countrymen, or by men of world-wide curiosity and adventure like the Italians of the Renaissance or our Elizabethans. It was the product of a practical commonsense epoch which looked on all waste places, heaths like Hindhead, or hills like the Highlands, as blemishes in the scheme of the universe, not having yet recognised their final purpose as golf links or gymnasiums. Intellectual life was concentrated in cities and courts, it despised the country. Books were written by townsmen, dwellers in towns which had not grown into vast cities, and whose denizens therefore had not the longing to escape from their homes into purer air that we have to-day. They abused the Alps frankly. But all they saw of them was the comparatively dull carriage passes, and these they saw at the worst time of year. Hastening to Rome for Easter, they traversed the Maurienne while the ground was still brown with frost and patched untidily with half-melted snowdrifts. It is no wonder that Gray and Richardson, having left spring in the meadows and orchards of Chambéry, grumbled at the wintry aspect of Lanslebourg.

That at the end of the eighteenth century a literary lady of Western Europe preferred a Paris gutter to the Lake of Geneva is an amusing caricature of the spirit of the age that was passing away, but it is no proof that the love of mountains is a new mania, and that all earlier ages and peoples looked on them with indifference or dislike. Wordsworth and Byron and Scott in this country, Rousseau and Goethe, De Saussure and his school abroad broke the ice, but it was the ice of a winter frost, not of a Glacial period.

Consider for a moment the literature of the two peoples who have most influenced European thought—the Jews and the Greeks. I need hardly quote a book that before people quarrelled over education was known to every child—the Bible. I would rather refer you to a delightful poem in rhyming German verse written in the seventeenth century by a Swiss author, Rebman, in which he relates all the great things that happened on mountains in Jewish history: how Solomon enjoyed his Sommerfrische on Lebanon, and Moses and Elias both disappeared on mountain tops; how kings and prophets found their help among the hills; how closely the hills of Palestine are connected with the story of the Gospels.

Consider, again, Greece, where I have just been wandering. Did the Greeks pay no regard to their mountains? They seized eagerly on any striking piece of hill scenery and connected it with a legend or a shrine. They took their highest mountain, broad-backed Olympus, for the home of the gods; their most conspicuous mountain, Parnassus, for the home of poetry. They found in the cliffs of Delphi a dwelling for their greatest oracle and a centre for their patriotism. One who has lately stood on the top of Parnassus and seen the first rays of the sun as it springs from the waves of the Ægean strike its snows, while Attica and Bœotia and Eubœa still lay in deep shadow under his feet, will appreciate the famous lines of Sophocles, which I will not quote, as I am uncertain how you may pronounce Greek in this University. You may remember, too, that Lucian makes Hermes take Charon, when he has a day out from Hell, to the twin-crested summit, and show him the panorama of land and sea, of rivers and famous cities. The Vale of Tempe, the deep gap between Olympus and Ossa, beautiful in its great red cliffs, fountains, and spreading plane-trees, was part of a Roman's classical tour. The superb buttresses in which Taygetus breaks down on the valley of the Eurotas were used by the Spartans for other purposes besides the disposal of criminals and weakly babies. The middle regions—the lawns above the Langada Pass, "virginibus bacchata Lacænis Taygeta"—are frequented to this day as a summer resort by Spartan damsels. The very top, the great rock that from a height of 8000 feet looks down through its woods of oaks and Aleppo pines on the twin bays of the southern sea, is a place of immemorial pilgrimages. It is now occupied by a chapel framed in a tiny court, so choked with snow at the beginning of June that I took the ridge of the chapel roof for a dilapidated stoneman. I have no time to-day to look for evidence in classical literature, to refer to the discriminating epithets applied in it to mountain scenes.

A third race destined apparently to play a great part in the world's history—the Japanese—are ancient mountain lovers. We are all aware that Fusiyama to the Japanese is (as Ararat to the Armenians) a national symbol; that its ascent is constantly made by bands of pilgrims; that it is depicted in every aspect. Those who have read the pleasant book of Mr. Watson, who, as English chaplain for some years at Tokio, had exceptional opportunities of travel in the interior, will remember how often he met with shrines and temples on the summits of the mountains, and how he found pilgrims who frequented them in the belief that they fell there more readily into spiritual trances. The Japanese Minister, when he attended Mr. Watson's lecture at the Alpine Club, told us that his countrymen never climbed mountains without a serious—that is to say, a religious—object.

India and China would add to my evidence had I knowledge and time enough to refer to their literature. I remember Tennyson pointing out to me in a volume of translations from the Chinese a poem, written about the date of King Alfred, in praise of a picture of a mountain landscape. But I must return to the sixteenth and seventeenth centuries in Europe; I may go earlier—even back to Dante. His allusions to mountain scenery are frequent; his Virgil had all the craft of an Alpine rock-climber. Read Leonardo da Vinci's "Notes," Conrad Gesner's "Ascent of Pilatus"; study the narratives of the Alpine precursors Mr. Coolidge has collected and annotated with admirable industry in the prodigious volume he has recently brought out.

It is impossible for me here to multiply proofs of my argument, to quote even a selection from the passages that show an authentic enthusiasm for mountains that may be culled from writers of various nations prior to A.D. 1600. I must content myself with the following specimens, which will probably be new to most of my hearers.

Benoît Marti was a professor of Greek and Hebrew at Bern, and a friend of the great Conrad Gesner (I call him great, for he combined the qualities of a man of science and a man of letters, was one of the fathers of botany as well as of mountaineering, and was, in his many-sidedness, a typical figure of the Renaissance). Marti, in the year 1558 or 1559, wrote as follows of the view from his native city:—

"These are the mountains which form our pleasure and delight" (the Latin is better—"deliciæ nostræ, nostrique

amores ") "when we gaze at them from the higher parts of our city and admire their mighty peaks and broken crags that threaten to fall at any moment. Here we watch the risings and settings of the sun and seek signs of the weather. In them we find food not only for our eyes and our minds but also for our bellies"; and he goes on to enumerate the dairy products of the Oberland and the happy life of its population. I quote again this good man: "Who, then, would not admire, love, willingly visit, explore, and climb places of this sort? I assuredly should call those who are not attracted by them mushrooms, stupid, dull fishes, and slow tortoises" ("fungos, stupidos insulsos pisces, lentosque chelones"). "In truth, I cannot describe the sort of affection and natural love with which I am drawn to mountains, so that I am never happier than on the mountain crests, and there are no wanderings dearer to me than those on the mountains." "They are the theatre of the Lord, displaying monuments of past ages, such as precipices, rocks, peaks and chasms, and never-melting glaciers"; and so on through many eloquent paragraphs.

I will only add two sentences from the preface to Simler's "Vallesiæ et Alpium Descriptio," first published in 1574, which seem to me a strong piece of evidence in favour of my view:—"In the entire district, and particularly in the very lofty ranges by which the Vallais is on all sides surrounded, wonders of Nature offer themselves to our view and admiration. With my countrymen many of them have through familiarity lost their attraction; but foreigners are overcome at the mere sight of the Alps, and regard as marvels what we through habit pay no attention to."

Mr. Coolidge, in his singularly interesting footnotes, goes on to show that the books that remain to us are not isolated instances of a feeling for mountains in the age of the Renaissance. The mountains themselves bear, or once bore, records even more impressive. Most of us have climbed to the picturesque old castle at Thun and seen beyond the rushing Aar the green heights of the outposts of the Alps, the Stockhorn, and the Niesen. Our friend Marti, who climbed the former peak about 1558, records that he found on the summit "tituli, rythmi, et proverbia saxis inscripta unà cum imaginibus et nominibus auctorum. Inter alia cujusdam docti et montium amœnitate capti observare licebat illud:

"Ὁ τῶν ὀρῶν ἔρως ἄριστος."

"The love of mountains is best." In those five words some Swiss professor anticipated the doctrine of Ruskin and the creed of Leslie Stephen, and of all men who have found mountains the best companions in the vicissitudes of life.

In the annals of art it would be easy to find additional proof of the attention paid by men to mountains three to four hundred years ago. The late Josiah Gilbert, in a charming but too little-known volume, "Landscape in Art," has shown how many great painters depicted in their backgrounds their native hills. Titian is the most conspicuous example.

It will perhaps be answered that this love of mountains led to no practical result, bore no visible fruit, and therefore can have been but a sickly plant. Some of my hearers may feel inclined to point out that it was left to the latter half of the nineteenth century to found Climbers' Clubs. It would take too long to adduce all the practical reasons which delayed the appearance of these fine fruits of peace and an advanced civilisation. I am content to remind you that the love of mountains and the desire to climb them are distinct tastes. They are often united, but their union is accidental, not essential. A passion for golf does not necessarily argue a love of levels. I would suggest that more outward and visible signs than are generally imagined of the familiar relations between men and mountains in early times may be found. The choicest spots in the Alpine region—Chamonix, Engelberg, Disentis, Einsiedlen, Pesio, the Grande Chartreuse—were seized on by recluses; the Alpine Baths were in full swing at quite an early date. I will not count the Swiss Baden, of which a geographer, who was also a Pope, Æneas Silvius (Pius II.) records the attractions, for it is in the Jura, not the Alps; but Pfäfers, where wounded warriors went to be healed, was a scene of dissipation, and the waters of St. Moritz were vaunted as superseding wine. I may be excused, since I wrote this particular passage myself a good many years ago, for quoting a few sentences bearing on this point from "Murray's Handbook to Switzerland." In the sixteenth century fifty treatises dealing with twenty-one different resorts were published. St. Moritz, which had been brought into notice by Paracelsus (died 1541), was one of the most famous baths. In 1501 Matthew Schinner, the famous Prince Bishop of Sion, built "a magnificent hotel" at Leukerbad, to which the wealthy were carried up in panniers on the backs of mules. Brieg, Gurnigel, near Bern, the Baths of Masino, Tarasp, and Pfäfers were also popular in early times. Leonardo da Vinci mentions the baths of Bormio, and Gesner went there.

It is not, however, with the emotional influences or the picturesque aspect of mountains that science concerns itself, but with their physical examination. If I have lingered too long on my preamble I can only plead as an excuse that a love of one's subject is no bad qualification for dealing with it, and that it has tempted me to endeavour to show you grounds for believing that a love of mountains is no modern affectation, but a feeling as old and as widespread as humanity.

Their scientific investigation has naturally been of comparatively modern date. There are a few passages about the effects of altitude, there are orographical descriptions more or less accurate in the authors of antiquity. But for attempts to explain the origin of mountains, to investigate and account for the details of their structure, we shall find little before the notes of Leonardo da Vinci, that marvellous man who combined, perhaps, more than anyone who has ever lived the artistic and the scientific mind. His ascent of Monte Boso about 1511, a mountain which may be found under this name on the Italian ordnance map on the spur separating Val Sesia and the Biellese, was the first ascent by a physical observer. Gesner with all his mountain enthusiasm found a scientific interest in the Alps mainly if not solely in their botany.

The phenomenon which first drew men of science to Switzerland was the Grindelwald glaciers—"miracles of Nature" they called them. Why these glaciers in particular, you may ask, when there are so many in the Alps? The answer is obvious. Snow and ice on the "mountain tops that freeze" are no miracle. But when two great tongues of ice were found thrusting themselves down among meadows and corn and cottages, upsetting barns and covering fields and even the marble quarries from which the citizens of Bern dug their mantelpieces, there was obviously something outside the ordinary processes of Nature, and therefore miraculous.

Swiss correspondents communicated with our own Royal Society the latest news as to the proceedings of these unnatural ice-monsters, while the wise men of Zürich and Bern wrote lectures on them. Glacier theories began. Early in the eighteenth century Hottinger, Cappeller, Scheuchzer, that worthy man who got members of our Royal Society to pay for his pictures of flying dragons, contributed their quota of crude speculation. But it was not until 1741 that Mont Blanc and its glaciers were brought into notoriety by our young countrymen, Pococke and Windham, and became an attraction to the mind and an object to the ambition of the student whose name was destined to be associated with them. Horace Benedict de Saussure, born of a scientific family, the nephew of Bonnet, the Genevese botanist and philosopher, who has become known to the world as a mountaineer and the climber of Mont Blanc, came twenty years later. In truth he was far more of a mountain traveller and a scientific observer, a geological student, than a climber. When looking at his purple silk frock-coat (carefully preserved in his country house on the shore of the Lake of Geneva), one realises the difference between the man who climbed Mont Blanc in that garment and the modern gymnast, who thinks himself *par excellence* the mountaineer.

De Saussure did not confine himself to Savoy or to one group, he wandered far and wide over the Alpine region, and the four volumes of his "Voyages" contain, besides the narratives of his sojourn on the Col du Géant and ascent of Mont Blanc, a portion of the fruit of these wanderings.

The reader who would appreciate De Saussure's claim as the founder of the Scientific Exploration of Mountains must, however, be referred to the List of Agenda on questions calling for investigation placed at the end of his last volume.

They explain the comparative indifference shown by De Saussure to the problems connected with glacial movement and action. His attention was absorbed in the larger question of earth-structure, of geology, to which the sections exposed by mountains offered, he thought, a key; he was bitten by the contemporary desire for "A Theory of the Earth," by the taste of the time for generalisations for which the facts were not always ready. At the same time, his own intellect was perhaps somewhat deficient in the intuitive faculty; the grasp of the possible or probable bearing of known facts by which the greatest discoverers suggest theories first and prove them afterwards.

The school of De Saussure at Geneva died out after having produced Bourrit, the tourist who gloried in being called the Historian of the Alps, a man of pleasant self-conceit and warm enthusiasm, and De Luc, a mechanical inventor, who ended his life as reader to Queen Charlotte at Windsor, where he flits across Miss Burney's pages as the friend of Herschel at Slough and the jest of tipsy Royal Dukes. Oddly enough, the first sound guess as to glacier movement was made by one Bordier, who had no scientific pretensions. I reprinted many years ago the singular passage in which he compared glacier ice to "cire amollie," soft wax, "flexible et ductile jusqu'à un certain point," and described it as flowing in the manner of liquids (*Alp. J.*, ix. 327). He added this remarkable suggestion foreshadowing the investigations of Prof. Richter and M. Forel: "It is very desirable that there should be at Chamonix someone capable of observing the glaciers for a series of years and comparing their advance and oscillations with meteorological records." To the school of Geneva succeeded the school of Neuchatel, Desor and Agassiz; the feat of De Saussure was rivalled on the Jungfrau and the Finsteraarhorn by the Meyers of Bern. They in turn were succeeded by the British school, Forbes and Tyndall, Reilly and Wills, in 1840-60.

In 1857 the Alpine Club was founded in this country. In the half-century since that date the nations of Western Europe have emulated one another in forming similar bodies, one of the objects of which has been to collect and set in order information as to the mountains and to further their scientific as well as their geographical exploration.

What boulders, or rather pebbles, can we add to the enormous moraine of modern Alpine literature—a moraine the lighter portions of which it is to be hoped for the sake of posterity that the torrent of Time may speedily make away with?

For fifty years I have loved and at frequent intervals wandered and climbed in the Alps. I have had something of a grand passion for the Caucasus. I am on terms of visiting acquaintance with the Pyrenees and the Himalaya, the Apennines and the Algerian Atlas, the mountains of Greece, Syria, Corsica, and Norway. I will try to set in order some observations and comparisons suggested by these various experiences.

As one travels east from the Atlantic through the four great ranges of the Old World the peaks grow out not only in absolute height but also in abruptness of form, and in elevation above the connecting ridges. The snow and ice region increases in a corresponding manner. The Pyrenees have few fine rockpeaks except the Pic du Midi d'Ossau; its chief glacier summits, the Vignemale, Mont Perdu, the Maladetta, correspond to the Titlis or the Buet in the Alps. The peaks of the Alps are infinite in their variety and admirable in their clear-cut outlines and graceful curves. But the central group of the Caucasus, that which culminates in Dykhtau, Koshtantau, and Shkara, 17,000 feet summits (Koshtantau falls only 120 feet below this figure) has even more stately peaks than those that cluster round Zermatt.

Seek the far eastern end of the Himalaya, visit Sikkim, and you will find the scale increased; Siniolchum, Jannu, and Kangchenjunga are all portentous giants. To put it at a low average figure, the cliffs of their final peaks are half as high again as those of Monte Rosa and the Matterhorn.

In all these chains you will find the same feature of watersheds or partings lying not in but behind the geological axis, which is often the line of greatest peak elevation. This is the case in the Alps at the St. Gothard, in the Caucasus for some forty miles west of the Dariel Pass, in the Himalaya, in Sikkim and Nepal, where the waters flowing from the Tibetan plateau slowly eat their way back behind Kangchenjunga and the Nepalese snows. The passes at their sources are found consequently to be of the mildest character, hills "like Wiltshire Downs" is the description given by a military explorer. It needs no great stretch of geological imagination to believe in the cutting back of the southern streams of Sikkim or the Alps, as for instance at the Maloya, but I confess that I cannot see how the gorges of Ossetia, clefts cut through the central axis of the Caucasus, can be ascribed mainly to the action of water.

I turn to the snow and ice region. Far more snow is deposited on the heights of the Central Caucasus and the Eastern Himalaya than on the Alps. It remains plastered on their precipices, forming hanging glaciers everywhere of the kind found on the northern, the Wengern Alp, face of the Jungfrau. Such a peak as the Weisshorn looks poor and bare compared with Tetnuld in the Caucasus or Siniolchum in the Himalaya. The plastered sheets of snow between their great bosses of ice are perpetually melting, their surfaces are grooved, so as to suggest fluted armour, by tiny avalanches and runnels.

In the Aletsch glacier the Alps have a champion with which the Caucasus cannot compete; but apart from this single exception the Caucasian glaciers are superior to the Alpine in extent and picturesqueness. Their surfaces present the features familiar to us in the Alps—icefalls, moulins, and earthcones.

In Sikkim, on the contrary, the glaciers exhibit many novel features due no doubt mainly to the great sun-heat. In the lower portion their surface is apt to be covered with the débris that has fallen from the impending cliffs, so that little or no ice is visible from any distance. In the region below the névé there are very few crevasses, the ice heaves itself along in huge and rude undulations, high gritty mounds, separated by hollows often occupied by yellow pools which are connected by streams running in little icy ravines; a region exceptionally tiresome, but in no way dangerous to the explorer. In steep places the Alpine icefall is replaced by a feature I may best compare with a series of earth-pillars such as are found near Evolena and elsewhere, and are figured in most text-books. The ice is shaped into a multitude of thin ridges and spires, resembling somewhat the Nieves Penitentes of the Andes—though formed in a different material.

Great sun-heat acting on surfaces unequally protected, combined in the latter case with the strain of sudden descent, is no doubt the cause of both phenomena. Generally the peculiarities of the great glaciers of Kangchenjunga may be attributed to a vertical sun, which renders the frozen material less liable to crack, less rigid, and more plastic.

A glacier, as a rule, involves a moraine. Now moraines are largely formed from the material contributed by subaërial denudation, in plain words by the action of heat and cold and moisture on the cliffs that border them. It is what falls on a glacier, not that which it falls over, that mainly makes a moraine. The proof is that the moraines of a glacier which flows under no impending cliffs are puny compared with those of one that lies beneath great rock-walls.

Take, for example, the Norwegian glaciers of the Jostedals Brae and compare them with the Swiss. The former, falling from a great névé plain or snowfield, from which hardly a crag protrudes, are models of cleanliness. I may cite as examples the three fascinating glaciers of the Olden Valley. The Rosenlaui Glacier in Switzerland owed the cleanliness which gave it a reputation fifty years ago, before its retirement from tourists' tracks, to a similar cause—a vast snow-plateau, the Wetterkessel.

One peculiarity very noticeable both in the Himalaya and the Caucasus I have never found satisfactorily accounted for. I refer to the long grassy trenches lying between the lateral moraine and the hillside, which often seem to the mountain explorer to have been made by Providence to form grass paths for his benefit. They may possibly be due to the action of torrents falling from the hillside, which, meeting the moraine and constantly sweeping along its base, undermine it and keep a passage open for themselves. There are remarkable specimens of this formation on both sides of the Bezingi Glacier, in the Caucasus, and on the north side of the Zemu Glacier, in Sikkim.

Water is one of the greatest features in mountain scenery.

in Norway it is omnipresent. In this respect Scandinavia is a region apart; the streams of the more southern ranges are scanty compared with those of a region where the snowfall of two-thirds of the year is discharged in a few weeks. Greece stands at the opposite pole. By what seems a strange perversity of Nature, its slender streams are apt to disappear underground, to re-issue miles away in the great fountains that gave rise to so many legends. Arcadia is, for the most part, a dry upland, sadly wanting in the two elements of pastoral scenery, shady groves, and running brooks.

The Alps are distinguished by their subalpine lakes—

> "Anne lacus tantos? te, Lari maxime, teque,
> Fluctibus et fremitu assurgens, Benace, marino?"

of Virgil. But perhaps even more interesting to the student are the lake basins that have been filled up, and thus suggest how similar lakes may have vanished at the base of other ranges.

I know no more striking walk to anyone interested in the past doings of glaciers than that along the ridge of the mighty moraine of the old glacier of Val d'Aosta, which sweeps out, a hill 500 feet high, known as "La Serra," from the base of the Alps near Ivrea into the plain of Piedmont. Enclosed in its folds still lies the Lago di Viverone; but the Dora has long ago cut a gap in the rampart and drained the rest of the enclosed space, filling it up with the fluvial deposit of centuries.

It is, however, the tarns rather than the great lakes of the Alps which have been the chief subjects of scientific disputation. Their distribution is curious. They are found in great quantity in the Alps and Pyrenees, hardly at all in the Caucasus, and comparatively rarely in the part of the Himalaya I am acquainted with.

A large-scale map will show that where tarns are most thickly dotted over the uplands the peaks rise to no great height above the ridges that connect them. This would seem to indicate that there has been comparatively little subaërial denudation in these districts, and consequently less material has been brought down to fill the hollows. Again, it is in gneiss and granitic regions that we find tarns most abundant—that is, where the harder and more compact rocks make the work of streams in tapping the basins more lengthy. The rarity of tarns in the highlands behind Kangchenjunga, perhaps, calls for explanation. We came upon many basins, but, whether formed by moraines or true rockbasins, they had for the most part been filled up by alluvial deposits.

In my opinion, the presence of tarns must be taken as an indication that the portion of the range where they are found has until a comparatively recent date been under snow or ice. The former theory, still held, was that the ice scooped out their basins from the solid rock. I believe that it simply kept scoured pre-existing basins. The ice removed and the surrounding slopes left bare, streams on the one hand filled the basins with sediment, or, on the other, tapped them by cutting clefts in their rims. This theory meets, at any rate, all the facts I have observed, and I may point out that the actual process of the destruction of tarns by such action may be seen going on under our eyes in many places, notably in the glens of the Adamello group. Prof. Garwood has lately employed his holidays in sounding many of the tarns of the St. Gotthard group, and his results, I understand, tend to corroborate the conclusions stated.

I desire here to re-affirm my conviction that snow and ice in the High Alps are conservative agents: that they arrest the natural processes of subaërial denudation; that the scouring work done by a glacier is insignificant compared with the hewing and hacking of frost and running water on slopes exposed to the open sky without a roof of névé and glacier.

The contrast between the work of these two agents was forced upon me many years ago while looking at the ground from which the Eiger Glacier had then recently retreated. The rocks, it is true, had had their angles rubbed off by the glacier, but through their midst, cut as by a knife, was the deep slit or gash made by the subglacial torrent. There is in the Alps a particular type of gorge, found at Rosenlaui, at the Lower Grindelwald Glacier, at the Kirchet above Meiringen, and also in the Caucasus, within the curves of old terminal moraines. It is obviously due to the action of the subglacial torrent, which cuts deeper and deeper while the ice above protects the sides of the cutting from the effects of the atmosphere.

One more note I have to make about glaciers. It has been stated that glaciers go on melting in winter. Water, no doubt, flows from under some of them, but that is not the same thing. The end of the Rosenlaui Glacier is dry in January; you can jump across the clear stream that flows from the Lower Grindelwald glacier. That stream is not meltings, but the issue of a spring which rises under the glacier and does not freeze. There is another such stream on the way to the Great Scheideck, which remains free when frost has fettered all its neighbours.

I should like to direct your attention before we leave glaciers to the systematic efforts that are being made on the Continent to extend our knowledge of their peculiarities. The subject has a literature of its own, and two Societies—one in France, one in other countries—have been constituted to promote and systematise further investigations, especially with regard to the secular and annual oscillations of the ice. These were initiated by the English Alpine Club in 1893, while I was its president. Subsequently, through the exertions of the late Marshall Hall, an enthusiast on the subject, an International Commission of Glaciers was founded, which has been presided over by Dr. Richter, M. Forel, and others; and more recently a French Commission has been created with the object of studying in detail the glaciers of the French Alps. A number of excellent reports have been published, embodying information from all parts of the globe. There has been, and is, I regret to say, very great difficulty in obtaining any methodical reports from the British possessions oversea. The subject does not commend itself to the departmental mind. Let us hope for improvement: I signalise the need for it. Of course, it is by no means always an easy matter to get the required measurements of retreat or advance in the glacial snout, when the glacier is situated in a remote and only casually visited region. Still, with good-will more might be done than has been. The periods of advance and retreat of glaciers appear to correspond to a certain extent throughout the globe. The middle of the last century was the culmination of the last great advance. The general estimate of their duration appears to be half a century. The ice is now retreating in the Alps, the Caucasus, and the Himalaya, and I believe in North America. We live in a retrogressive period. The minor oscillation of advance which a few years ago gave hopes to those who, like myself, had as children seen the glaciers of Grindelwald and Chamonix at their greatest, has not been carried on.

Attempts are made to connect the oscillations of glaciers with periods of sun-spots. They are, of course, connected with the rain or snow-fall in past seasons. But the difficulty of working out the connection is obvious.

The advance of the ice will not begin until the snows falling in its upper basin have had time to descend as ice and become its snout; in each glacier this period will vary according to its length, bulk, and steepness, and the longer the glacier is, the slower its lower extremity will be to respond. Deficiency in snowfall will take effect after the same period. It will be necessary, therefore, to ascertain (as has been done in a tragic manner on Mont Blanc by the recovery in the lowest portion of the Glacier des Bossons of the bodies of those lost in its highest snows) the time each glacier takes to travel, and to apply this interval to the date of the year with which the statistics of deposition of moisture are to be compared. If the glacier shows anything about weather and climate, it is past, not contemporary, weather it indicates.

Another point in which the Asiatic ranges, and particularly the Himalaya, differ from the Alps is in the frequency of snow avalanches, earthfalls, and mud-slides. These are caused by the greater deposition of snow and the more sudden and violent alternations of heat and cold, which lead to the splitting of the hanging ice and snows by the freezing of the water in their pores. I have noticed at a bivouac that the moment of greatest cold—about the rising of the morning star—is often hailed by the reports of a volley of avalanches.

The botanist may find much to do in working out a comparison of the flora of my four ranges. I am no

botanist: I value flowers according, not to their rarity, but to their abundance, from the artist's, not the collector's, point of view. But it is impossible not to take interest in such matters as the variations of the gentian in different regions, the behaviour of such a plant as the little Edelweiss (once the token of the Tyrolese lover, now the badge of every Alp-trotter), which frequents the Alps, despises the Caucasus, reappears in masses in the Himalaya, and then, leaping all the isles of the tropics, turns up again under the snows of New Zealand. I may mention that it is a superstition that it grows only in dangerous places. I have often found it where cows can crop it; it covers acres in the Himalaya, and I believe it has been driven by cows off the Alpine pastures, as it is being driven by tourists out of the Alps altogether.

The Italian botanists, MM. Levier and Sommier, have given a vivid account of what they call the Makroflora of the Central Caucasus—those wild-flower beds, in which a man and horse may literally be lost to sight, the product of sudden heat on a rich and sodden soil composed of the vegetable mould of ages. Has any competent hand celebrated the Mikroflora of the highest ridges, those tiny, vivid forget-me-nots and gentians and ranunculuses that flourish on rock-island "Jardins" like that of Mont Blanc, among the eternal snows, and enamel the highest rocks of the Basodano and the Lombard Alps? A comprehensive work on a comparison of mountain flora and the distribution of Alpine plants throughout the ranges of the Old World would be welcome. We want another John Ball. Allied to botany is forestry, and the influence of trees on rainfall, and consequently the face of the mountains, a matter of great importance, which in this country has hardly had the attention it deserves.

From these brief suggestions as to some of the physical features of mountains I would ask you to turn your attention to the points in which mankind come in contact with them, and first of all to History.

I fancy that the general impression that they have served as efficient barriers is hardly in accordance with facts, at any rate from the military point of view. Hannibal, Cæsar, Charles the Great, and Napoleon passed the Alps successfully. Hannibal, it is true, had some difficulty, but then he was handicapped with elephants. The Holy Roman Emperors constantly moved forwards and backwards. Burgundy, as the late Mr. Freeman was never weary of insisting, lay across the Alps. So until our own day did the dominions of the House of Savoy. North Italy has been in frequent connection with Germany; it is only in my own time that the Alps have become a frontier between France and Italy. But questions of this kind might lead us too far. Let me suggest that some competent hand should compose a history of the Alpine passes and their famous passages, more complete than the treatises that have appeared in Germany. Mr. Coolidge, to whom we owe so much, has, in his monumental collection and reprint of early Alpine writers, just published, thrown great light on the extensive use of what I may call the by-passes of the Alps in early times. Will he not follow up his work by treating of the Great Passes? I may note that the result of the construction of carriage roads over some of them was to concentrate traffic; thus the Monte Moro and the Gries were practically deserted for commercial purposes when Napoleon opened the Simplon. The roads over the Julier and Maloya ruined the Septimer. Another hint to those engaged in tracing ancient lines of communication. In primitive times, in the Caucasus to-day, the tendency of paths is to follow ridges, not valleys. The motives are on the spot obvious—to avoid torrents, swamps, ravines, earthfalls, and to get out of the thickets and above the timberline. The most striking example is the entrance to the great basin of Suanetia, which runs not up its river, the Ingur, but over a ridge of nearly 9000 feet, closed for eight months in the year to animals.

From the military point of view mountains are now receiving great attention in Central Europe. The French, the Italians, the Swiss, the Austrians have extensive Alpine manœuvres every summer, in which men, mules, and light artillery are conveyed or carried over rocks and snow. Officers are taught to use maps on the spot, the defects in the official surveys are brought to light. It is not likely, perhaps, except on the Indian frontier, that British troops will have to fight among high snowy ranges. But I feel sure that any intelligent officer who is allowed to attend such manœuvres might pick up valuable hints as to the best equipment for use in steep places. Probably the Japanese have already sent such an envoy and profited by his experience.

A word as to maps, in which I have taken great interest, may be allowed me. The ordnance maps of Europe have been made by soldiers, or under the supervision of soldiers. At home when I was young, it was dangerous to hint at any defects in our ordnance sheets, for surveyors in this country are a somewhat sensitive class. Times have altered, and they are no longer averse from receiving hints and even help from unofficial quarters. Since the great surveys of Europe were executed, knowledge has increased so that every country has had to revise or to do over again its surveys. In three points that concern us there was great room for improvement, the delineation of the upper region as a whole, and the definition of snow and glaciers in particular, and in the selection of local names. In the two former the Federal Staff at Bern has provided us with an incomparable model. The number of local names known to each peasant is small, his pronunciation is often obscure, and each valley is apt to have its own set of names for the ridges and gaps that form its skyline. Set a stranger, speaking another tongue than the local *patois*, to question a herdsman, and the result is likely to be unsatisfactory. It has often proved so. The Zardezan is an odd transcription of the Gias del Cian of *patois*, the Gîte du Champ in French. The Grand Paradis is the last term an Aostan peasant would have used for the Granta Parei, the great screen of rock and ice of the highest mountain in Italy. The Pointe de Rosablanche was the Roesa Bianca, or white glacier. Monte Rosa herself, though the poet sees a reference to the rose of dawn, and the German professor detects "the Keltic *ros*, a promontory," is a simple translation of the Gletscher Mons of Simler, or rather Simler's hybrid term is a translation of Monte della Roesa. Roesa, or Ruize, is the Val d'Aostan word for glacier, and may be found in De Saussure's "Voyages."

An important case in this matter of mountain nomenclature has recently come under discussion—that of the highest mountain in the world. Most, if not all, mountaineers regret that the name of a Surveyor-General, however eminent, was fifty years ago affixed to Mount Everest. The ground for this action on the part of the Survey was the lack of any native name. Some years ago I ventured to suggest that the 29,002-feet peak (No. XV. of the Survey) was probably visible from the neighbourhood of Katmandu, even though the identifications of it by Schlagintweit and others might be incorrect, and that since some at least of the summits of the snowy group east of that city are apparently known in Nepal as Gaurisankar, that name might, following the practice which gave its name to Monte Rosa in the Alps, legitimately be applied to the loftiest crest of the mountain group of which the Nepalese Gaurisankar formed a part.

Recently, by the kindness of Lord Curzon, acting on a suggestion of my own, Captain Wood, a Survey officer, has been deputed to visit Katmandu and ascertain the facts. He has found that, contrary to the opinion of the late General Walker and the assertion of Major Waddell, Peak XV. is visible from the hills round the capital, and that the two highest snowpeaks visible from the city itself in the same direction were known to the Nepalese "nobles" as Gaurisankar.

These latter peaks or peak are about 36 miles distant from Peak XV., but are connected with it by a continuous line of glaciers. According to the principles that have prevailed in the division of the Alps, they would undoubtedly be considered as part of the same group, and the name, which, according to Captain Wood, is applied to a portion of the group, might legitimately be adopted for its loftiest peak.

But the chiefs of the Indian Survey take, as they are entitled to, a different view. They have decided to confine the name Gaurisankar to one of the peaks seen from Katmandu itself. I do not desire to raise any further protest against this decision. For since, in 1886, I first raised the question its interest has become mainly academical. A local Tibetan name for Peak XV., Chomo-Kankar, the Lord of Snows, has been provided on excellent native authority, confirmed by that competent Tibetan scholar, Major

Waddell, and I trust this name may in the future be used for the highest mountain in the world.[1] The point at issue is mainly one of taste. Indian surveyors may see no incongruity in naming after one of their own late chiefs the highest mountain in the world. But in this view they are, I believe, in a small minority.

I would urge mountain explorers to attempt in more distant lands what the late Messrs. Adams-Reilly and Nichols, Mr. Tuckett, and Lieut. Payer (of Arctic fame) did forty years ago with so much success in the Alps, what the Swiss Alpine Club have done lately, take a district, and working from the trigonometrically fixed points of a survey, where one exists, fill it in by planetabling with the help of the instruments for photographic and telephotographic surveying, in the use of which Mr. Reeves, the map curator to the R.G.S., is happy to give instruction. An excellent piece of work of this kind has been done by Mr. Stein in Central Asia.

There are, I know, some old-fashioned persons in this country who dispute the use of photography in mountain work. It can only be because they have never given it a full and fair trial with proper instruments.

Lastly, I come to a matter on which we may hope before long to have the advantage of medical opinion, based for the first time on a large number of cases. I refer to the effects of high altitudes on the human frame and the extent of the normal diminution in force as men ascend. The advance to Lhasa ought to do much to throw light on this interesting subject. I trust the Indian Government has taken care that the subject shall be carefully investigated by experts. The experience of most mountaineers (including my own) in the last few years has tended to modify our previous belief that bodily weakness increases more or less regularly with increasing altitude. Mr. White, the Resident in Sikkim, and my party both found on the borders of Tibet that the feelings of fatigue and discomfort that manifested themselves at about 14,000 to 16,000 feet tended to diminish as we climbed to 20,000 or 21,000 feet. I shall always regret that when I was travelling in 1899 on the shoulders of Kangchenjunga the exceptional snowfall altogether prevented me from testing the point at which any of our ascents were stopped by discomforts due to the atmosphere. Owing to the nature of the footing, soft snow lying on hard, it was more difficult to walk uphill than on a shingly beach; and it was impossible for us to discriminate between the causes of exhaustion.

Here I must bring this, I fear, desultory Address to an end. I might easily have made it more purely geographical, if it is geography to furnish a mass of statistics that are better and more intelligibly given by a map. I might have dwelt on my own explorations in greater detail, or have summarised those of my friends of the Alpine Club. But I have done all this elsewhere in books or reviews, and I was unwilling to inflict it for a second time on any of my hearers who may have done me the honour to read what I have written. Looking back, I find I have been able to communicate very little of value, yet I trust I may have suggested to some of my audience what opportunities mountains offer for scientific observations to mountaineers better qualified in science than the present speaker, and how far we scouts or pioneers are from having exhausted even our Alpine playground as a field for intelligent and systematic research.

And even if the value to others of his travels may be doubtful, the Alpine explorer is sure of his reward. What has been said of books is true also of mountains—they are the best of friends. Poets and geologists may proclaim—

> "The hills are shadows, and they flow
> From form to form, and nothing stands!"

But for us creatures of a day the great mountains stand fast, the Jungfrau and Mont Blanc do not change. Through all the vicissitudes of life we find them sure and sympathetic companions. Let me conclude with two lines which I found engraved on a tomb in Santa Croce at Florence:

> "Huc properate, viri, salebrosum scandite montem,
> Pulchra laboris erunt præmia, palma, quies."

SECTION G.

ENGINEERING.

OPENING ADDRESS BY HON. CHARLES A. PARSONS, M.A., F.R.S., M.INST.C.E., PRESIDENT OF THE SECTION.

On this occasion I propose to devote my remarks to the subject of invention.

It is a subject of considerable importance, not only to engineers but also to men of science and the public generally.

I also propose to treat invention in its wider sense, and to include under the word discoveries in physics, mechanics, chemistry, and geology.

Invention throughout the Middle Ages was held in little esteem. In most dictionaries it receives scant reference except as applied to poetry, painting, and sculpture.

Shakespeare and Dryden describe invention as a kind of muse or inspiration in relation to the arts, and when taken in its general sense to be associated with deceit, as "Return with an invention, and clap upon you two or three plausible lies."

As to the opposition and hostility to scientific research, discovery, and mechanical invention in the past, and until comparatively recent times, there can be no question, in some cases the opposition actually amounting to persecution and cruelty.

The change in public opinion has been gradual. The great inventions of the last century in science and the arts have resulted in a large increase of knowledge and the powers of man to harness the forces of Nature. These great inventions have proved without question that the inventors in the past have, in the widest sense, been among the greatest benefactors of the human race. Yet the lot of the inventor until recent years has been exceptionally trying, and even in our time I scarcely think that anyone would venture to describe it as altogether a happy one. The hostility and opposition which the inventor suffered in the Middle Ages have certainly been removed, but he still labours under serious disability in many respects under law as compared with other sections of the community. The change of public feeling in favour of discovery and invention has progressed with rapidity during the last century. Not only have private individuals devoted more time and money to the work, but societies, institutions, colleges, municipalities, and Governments have founded many research laboratories, and in some instances have provided large endowments. These measures have increased the number of persons trained to scientific methods, and also provided greatly improved facilities for research; but perhaps one of the most important results to engineers has been the direct and indirect influence of the more general application of scientific methods to engineering.

Sir Frederick Bramwell, in his Presidential Address to this Association in 1888, emphasised the interdependence of the man of science and the civil engineer, and described how the work of the latter has been largely based on the discoveries of the former; while the work of the engineer often provides data and adds a stimulus to the researches of the man of science. And I think his remarks might be further appropriately extended by adding that since the man of science, the engineer, the chemist, the metallurgist, the geologist, all seek to unravel and to compass the secrets of Nature, they are all to a great extent interdependent on each other.

But though research laboratories are the chief centres of scientific invention, and colleges, institutions, and schools train the mind to scientific methods of attack, yet in mechanical, civil, and electrical engineering the chief work of practical investigation has been carried on by individual engineers, or by firms, syndicates, and companies. These not only have adapted discoveries made by men of science to commercial uses, but also in many instances have themselves made such discoveries or inventions.

To return to the subject, let us for a moment consider in what invention really consists, and let us dismiss from our minds the very common conception which is given in dictionaries and encyclopædias that invention is a happy thought occurring to an inventive mind. Such a conception would give us an entirely erroneous idea of the formation of the great steps in advance in science and engineering that have been made during the last century; and, further, it would lead us to forget the fact that almost all important

inventions have been the result of long training and laborious research and long-continued labour. Generally, what is usually called an invention is the work of many individuals, each one adding something to the work of his predecessors, each one suggesting something to overcome some difficulty, trying many things, testing them when possible, rejecting the failures, retaining the best, and by a process of gradual selection arriving at the most perfect method of accomplishing the end in view.

This is the usual process by which inventions are made.

Then after the invention, which we will suppose is the successful attempt to unravel some secret of Nature, or some mechanical or other problem, there follows in many cases the perfecting of the invention for general use, the realisation of the advance or its introduction commercially; this after-work often involves as great difficulties and requires for its accomplishment as great a measure of skill as the invention itself, of which it may be considered in many cases as forming a part.

If the invention, as is often the case, competes with or is intended to supersede some older method, then there is a struggle for existence between the two. This state of things has been well described by Mr. Fletcher Moulton. The new invention, like a young sapling in a dense forest, struggles to grow up to maturity, but the dense shade of the older and higher trees robs it of the necessary light. If it could only once grow as tall as the rest all would be easy, it would then get its fair share of light and sunshine. Thus it often occurs in the history of inventions that the surroundings are not favourable when the first attack is made, and that subsequently it is repeated by different persons, and finally in different circumstances it may eventually succeed and become established.

We may take in illustration almost any of the great inventions of undoubted utility of which we happen to have the full history—for instance, some of the great scientific discoveries, or some of the great mechanical inventions, such as the steam-engine, the gas-engine, the steamship, the locomotive, the motor-car, or some of the great chemical or metallurgical discoveries. Are not most, if not all, of these the result of the long-continued labour of many persons, and has not the financial side been, in most cases, a very important factor in securing success?

The history of the steam-engine might be selected, but I prefer on this occasion to take the internal-combustion engine, for two reasons—firstly, because its history is a typical one; and secondly, because we are to hear a paper by that able exponent and great inventor in the domain of the gas-engine, Mr. Dugald Clerk, describing not only the history, but the engine in its present state of development and perfection, an engine which is able to convert the greatest percentage of heat units in the fuel into mechanical work, excepting only, as far as we at present know, the voltaic battery and living organisms.

The first true internal-combustion engine was undoubtedly the cannon, and the use in it of combustible powder for giving energy to the shot is strictly analogous to the use of the explosive mixture of gas or oil and air as at present in use in all internal-combustion engines; thus the first internal-combustion engine depended on the combination of a chemical discovery and a mechanical invention, the invention of gunpowder and the invention of the cannon.

In 1680 Huygens proposed to use gunpowder for obtaining motive power in an engine. Papin, in 1690, continued Huygens's experiments, but without success. These two inventors, instead of following the method of burning the powder under pressure, as in the cannon, adopted, in ignorance of thermodynamic laws, an erroneous course. They exploded a small quantity of gunpowder in a large vessel with escape valves, which after the explosion caused a partial vacuum to remain in the vessel. This partial vacuum was then used to actuate a piston or engine and perform useful work. Subsequently several other inventors worked on the same lines, but all of these failed on account of two causes which now are very evident to us. Firstly, gunpowder was then, as it still is, a very expensive form of fuel, in proportion to the energy liberated on explosion; secondly, the method of burning the powder to cause a vacuum involves the waste of nearly the whole of the available energy, whereas had it been burned under pressure, as in the cannon, a comparatively large percentage of the energy would have been converted into useful work. But even with this alteration, and however perfect the engine had been, the cost of explosives would have debarred its coming into use, except for very special purposes.

We come a century later to the first real gas-engine. Street, in 1794, proposed the use of vapour of turpentine in an engine on methods closely analogous to those successfully adopted in the Lenoir gas-engine of eighty years later, or thirty years ago. But Street's engine failed from crude and faulty construction. Brown, in 1823, tried Huygens's vacuum method, using fuel to expand air instead of gunpowder, but he also failed, probably on account of the wastefulness of the method.

Wright, in 1833, made a really good gas-engine, having many of the essential features of some of the gas-engines of the present day, such as separate gas and water pumps, and water-jacketed cylinder and piston.

Barnett, in 1839, further improved on Wright's design, and made the greatest advance of any worker in gas-engines. He added the fundamental improvements of compression of the explosive mixture before combustion, and he devised means of lighting the mixture under pressure, and his engine conformed closely to the present-day practice as regards fundamental details. No doubt Barnett's engine, so perfect in principle, deserved commercial success, but either his mechanical skill or his financial resources were inadequate to the task, and the character of the patents would seem to favour this conclusion, both as regards Barnett and other workers at this period. Up to 1850 the workers were few, but as time went on they gradually increased in numbers; attention had been attracted to the subject, and men with greater powers and resources appear to have taken the problem in hand. Among these numerous workers came Lenoir, in 1860, who, adopting the inferior type of non-compression engine, made it a commercial success by his superior mechanical skill and resources. Mr. Dugald Clerk tells us: "The proposals of Brown (1823), Wright (1833), Barnett (1838), Bansanti and Matteucci (1857), show gradually increasing knowledge of detail and the difficulties to be overcome, all leading to the first practicable engine in 1866, the Lenoir." This stage of the development being reached, the names of Siemens, Beaude Roches, Otto Simon, Dugald Clerk, Priestman, Daimler, Dowson, Mond, and others, appear as inventors who have worked at and added something to perfect the internal-combustion engine and its fuel, and who have helped to bring it to its present state of perfection.

In the history of great mechanical inventions there is perhaps no better example of the interdependence of the engineer, the physicist, and the chemist than is evinced in the perfecting of the gas-engine. The physicist and the chemist together determine the behaviour of the gaseous fuel, basing their theory on data obtained from the experimental engines constructed by the mechanical engineer, who, guided by their theories, makes his designs and improvements; then, again, from the results of the improvements fresh data are collected and the theory further advanced, and so on until success is reached. But though I have spoken of the physicist, the chemist, and the engineer as separate persons, it more generally occurs that they are rolled into one, or at most two, individuals, and that it is indispensable that each worker should have some considerable knowledge of all the sciences involved to be able to act his part successfully.

Now let us ask, Could not this very valuable invention, the internal-combustion engine, have been introduced in a much shorter time by more favouring circumstances, by some more favourable arrangement of the patent laws, or by legislation to assist the worker attacking so difficult a problem? I think the answer is that a great deal might be done, and I will endeavour to indicate some changes and possible improvements.

The history of this invention brings before our minds two important considerations. Firstly, let us consider the patentable matter involved in the invention of the gas-engine, the utilisation for motive-power purposes of the then well known properties of the explosive energy of gunpowder or of mixtures of gas and oil with air. Are not these obvious inferences to persons of a mechanical turn of mind and who had seen guns fired, or explosions in bottles containing spirits of turpentine when slightly heated

and a light applied to the neck? Surely no fundamental patent could have been granted under the existing patent laws for so obvious an application of known forces. Consequently, patent protection was sought in comparative details, details in some cases essential to success which were evolved or invented in the process of working out the invention. In this extended field of operations a slight protection was in some instances obtained. But in answer to the question whether such protection was commensurate with the benefits received by the community at large, there can, I think, be only one reply. Generally, those who did most got nothing, some few received insufficient returns, and in very few cases indeed can the return be said to have been adequate. The second important consideration is that of the methods of procedure of the patentees, for it appears that very few of them had studied what had been suggested or done before by others before taking out their own patent. We are also struck by the number of really important advances that have been suggested and have failed to fructify, either from want of funds or other causes, to be forgotten for the time and to be re-invented later on by subsequent workers.

What a waste of time, expense, and disappointment would be avoided if we in England helped the patentee to find out easily what had been done previously, on the lines adopted by the United States and German Patent Offices, who advise the patentee after the receipt of his provisional specification of the chief anticipatory patents, dead or alive! And ought we in England to rest content to see our patentees awaiting the report of the United States and German Patent Offices on their foreign equivalent specifications before filing their English patent claims? Ought not our Patent Office to give more facilities and assistance to the patentee?

Before proceeding further to discuss some of the possible improvements for the encouragement and protection of research and invention, I ask you further to consider the position of the inventor—the man anxious to achieve success where others have hitherto failed. To be successful he must be something of an enthusiast; and usually he is a poor man, or a man of moderate means, and dependent on others for financial assistance. Generally the problem to be attacked involves a considerable expenditure of money; some problems require great expenditure before any return can thereby accrue, even in the most favourable circumstances. In the very few cases where the inventor has some means of his own they are generally insufficient to carry him through, and there have unfortunately been many who have lost everything in the attempt. In nearly all cases the inventor has to co-operate with capital: the capitalist may be a sleeping partner, or the capital may be held by a firm or syndicate, the inventor in such cases being a partner—a junior partner—or a member of the staff. The combination may be successful and lasting, but unfortunately the best inventors are often bad men of business. The elements of the combination are often unstable, and the disturbing forces are many and active; especially is this so when the problem to be attacked is one of difficulty, necessitating various and successive schemes involving considerable expenditure, generally many times greater than that foreshadowed at the commencement of the undertaking. In such circumstances, unless the capitalist or the senior partner or board be in entire sympathy with the inventor or exercise great forbearance, stimulated by the hope of ultimate success and adequate returns, the case becomes hopeless, disruption takes place, and the situation is abandoned. Further, in the majority of cases, after some substantial progress has been made it is found that under the existing patent laws insufficient protection can be secured, and the prospect of a reasonable return for the expenditure becomes doubtful. In such circumstances the capitalist will generally refuse to proceed further unless the prospect of being first in the field may tempt him to continue.

Very many inventors, as I have said, avoid the expense of searching the patent records to see how far their problem has been attacked by others. In some cases the cost of a thorough search is very great indeed; sometimes it is greater than the cost of a trial attack on the problem. In the case of young and inexperienced inventors there sometimes exists a disinclination to enter on an expensive search; they prefer to spend their money on the attack itself. There are some, it is true, who have a foolish aversion to take steps to ascertain if others have been before them, and who prefer to remain in ignorance and trust to chance. It will, however, be said that the United States and German Patent Office reports ought to suffice to warn or protect the English patentee; but my own experience has been that such protection is not entirely satisfactory. There is, firstly, a considerable interval before such reports are received, and the life of a patent is short. Then, if the patent is upon an important subject, attracting general attention, the search is vigorous and sometimes overwrought, and the patent unjustly damaged or refused altogether. If, however, the patent is on some subject not attracting general attention, it receives too little attention and is granted without comment.

In some few instances it may be said that ignorance has been a positive advantage, and that if the patentee had realised how much of his patentable work was honeycombed by previous publications and patents, he would have lost heart and given up the task. It is, I think, a case of the exception proving the rule; and the patentee ought, as far as possible, in all cases to know his true position, and make his choice accordingly. The present patent law has some curious anomalies. Let us suppose some inventor has the good fortune to place the keystone in the arch of an invention, to add some finishing touch which makes the whole invention a complete success, and valuable. Then, success having been proved possible, others try to reap the results of his labour and good fortune, and, as often happens, it is discovered after laborious search that someone else first suggested the same keystone in some long-forgotten patent or obscure publication, but for some reason or other the public were none the better for his having done so. What does the law do? It says this is an anticipation, and instead of apportioning to all parties reasonable and equitable shares in the perfected invention, to which no one could object, it says that the patent is injured or perhaps rendered useless by the anticipation, and that its value to everyone concerned is thereby diminished or destroyed, as the case may be, and thrown open to the public. Until a few years ago, any anticipations, however old, might be cited; but recently the law has been amended, and at present none rank as anticipations which are more than fifty years old.

The perfecting of inventions and their introduction into general use require capital, as we have seen—sometimes a considerable amount, as in the introduction of the Bessemer process for steel, or the linotype system of printing—before any commercial success can be realised.

Capital having been found, the next difficulty is in the conservatism of persons and communities who are the buyers of the invention. There is always present in their minds the risk of failure and its consequent loss and worry to themselves, and in the event of success the advantage, in their estimation, may not be sufficient to counterbalance the risk. In large departments and companies the management of which is conducted by officials receiving fixed salaries, acting under non-technical supervision, there is a strong tendency among the officials to leave well alone, the organisation being such that the risk of failure, even though it be remote, more than counterbalances, in their estimation, the advantages that would result in the event of success. Next is the opposition of those who are financially interested in competing trades or older inventions; and if the invention is a labour-saving appliance, then the active opposition of the displaced labour is a serious, though generally only a temporary, barrier.

Fortunately, however, for the community, for research, and for invention, there is always to be found a considerable percentage of persons who, apart from the inventor, are able and willing to risk, and indeed to sacrifice, their personal interests in the cause of progress for the benefit of the community at large; and were it not for such persons the task of the introduction of most inventions would be an impossible one.

There are many problems of the highest importance in physics, engineering, chemistry, geology, and the arts, of which the investigation might probably prove of great benefit to the human race, and of which the probable monetary cost of the attack would be considerable, and of some very great indeed. Let us, then, inquire how the necessary funds could be raised. It is possible in the case of some of the more attractive problems that a group of

rich philanthropists might be found, but in most cases it would be impossible to form a company on business lines, under the existing laws of this and other countries, as I shall endeavour to show.

In the case of many of the problems, no patents will give adequate protection; in some cases there is no subject-matter of novelty and importance involved. In other cases the probable duration of the investigation is so long that any initial patents would have expired before a commercial result was reached, and in either of these circumstances there would be no inducement to business men or financiers to undertake the risk.

As an illustration of my meaning I will take two investigations that have doubtless occurred to the minds of most of those present, though many others of greater or less importance might be cited. One is the thorough investigation of the problem of aërial navigation, with or without the assistance of flotation by gas. This problem could undoubtedly be successfully solved by an organised attack of skilled and properly trained engineers and the expenditure of a large sum of money. Assuming the problem solved, and commercially successful, it appears to be impossible under the existing patent laws to secure any adequate monopoly so as to justify the expectation of a reasonable return on the capital expended on the invention. For in view of the multitude of suggestions that have been made and the experiments that have been carried out, the practical solution of the problem would appear to rest on a judicious selection of old ideas by means of exhaustive experiments.

Another and perhaps more important investigation which has not, as yet, been attacked to any material extent is the exploration of the lower depths of the earth. At present the deepest shaft is, I believe, at the Cape, of a little more than one mile in depth, and the deepest bore-hole is one made in Silesia, by the Austrian Government, of about the same depth. What would be found at greater depths is at present a matter for conjecture, founded on the dip and thicknesses of strata observed on or near the surface. Much money and many valuable lives have been devoted to exploration of the polar regions, but there can be no comparison between the scientific interest and the possible material results of such exploration and the one I have chosen for illustration of the inadequate protection afforded by law—namely, a great engineering attack on a problem of geology.

I would ask you to consider the commercial aspect of this engineering geological enterprise, as compared with exploration into new or unknown areas on the surface of the earth.

An exploring expedition into a new country has before it generally the probability of the acquisition of territorial and mineral rights or possessions bringing material gain to the undertakers. The rights of such enterprises are well known, and capital can be obtained with or without national support, as the case may be. On the other hand, the explorer into the depths of the earth has no rights or monopolies beyond the mineral rights of the land he has purchased over his boring; further, it is improbable that he can obtain any patent of substantial value for his methods of boring to great depths. To succeed in the undertaking a great expenditure of money must be incurred, an expenditure far greater than that of an exploring expedition, and analogous to that of a military expedition or a small invading army, and to raise this sum the pioneers have practically no security to offer. For if they succeed in finding rich deposits of precious minerals in greater abundance, or succeed in making some geological discovery associated with deep borings, they gain no exclusive title to these under existing laws. Any other person or syndicate acting upon the experience gained, could sink other shafts in other places or countries, and, benefiting by the experience gained by the pioneers, could probably carry out the work more advantageously, and thus depreciate the first undertaking or render it valueless, as has often occurred before.

Let us consider more closely some of the essential features of sinking a shaft to a great depth, for I think it will be seen that it presents no unsurmountable difficulties beyond those incidental to an enterprise of considerable magnitude involving the ordinary methods of procedure and the ordinary methods adopted by mining engineers. That there would be some departures from ordinary practice on account of the great depth is true, but these are more of the character of detail. On the design of this boring I have consulted Mr. John Bell Simpson, the eminent authority on mining in the North of England. The shaft would be sunk in a locality to avoid as far as possible water-bearing strata and the necessity of pumping. It would be of a size usual in ordinary mines or coal-pits. The exact position of such shaft would require some consideration as to whether it should commence in the primary or secondary strata. It would be sunk in stages, each of about half a mile in depth, and at each stage there would be placed the hauling and other machinery, to be worked electrically, for dealing with each stage. The depth of each stage would be restricted to half a mile in order to avoid a disproportionate cost in the hauling machinery and the weight of rope, as well as increased cost in the cooling arrangements arising from excessive hydraulic pressures. At each second or third mile in depth there would be air-locks to prevent the air-pressure from becoming excessive owing to the weight of the superincumbent air, which at from two to three miles would reach about double the atmospheric pressure at the surface. A greater rise of pressure than this would be objectionable for two reasons—firstly, from the inconvenience to the workmen; secondly, from the rise of temperature due to the adiabatic compression of the circulating air for ventilating purposes. The air-pressure immediately above each air-lock would thus reach to about two atmospheres, and beneath to one atmosphere. In order to carry on the transfer of air through the air-locks for ventilating purposes pumps coupled to air-engines would be provided, the energy to work the pumps being obtained from electro-motors. To maintain the shaft at a reasonable temperature at the greater depth powerful means of carrying the heat to the surface would be provided.

The most suitable arrangement for cooling would probably consist of large steel pipes, an upcast and a downcast pipe, connected at the top and bottom of each half-mile section in a closed ring. This ring would be filled with brine, which by natural circulation would form a powerful carrier of heat; but the circulation, assisted by electrically driven centrifugal pumps, would be capable of carrying an enormous quantity of heat upwards to the surface. At each half-mile stage there would be a transfer of the heat from the ring below to the ring above by means of an apparatus similar in construction to a feed-water heater, or to a regenerator constructed of small steel tubes, through which the brine in the ring above would circulate, and around the outside the brine in the ring below could also circulate, the heat being transmitted through the metal of the tubes from brine ring to brine ring.

We have now presented to us two alternative arrangements for cooling. One arrangement would be to cool the brine to a very low temperature in the top ring at the mouth of the shaft by refrigerating machinery, so as to provide a sufficient gradation of temperature in the whole brine system, to ensure the necessary flow of heat upwards from brine ring to brine ring, and overcome all the resistances of heat-transfer, and so maintain the lowest ring at the temperature necessary for effectual cooling of the lowest section of the shaft. But a better arrangement would be to place powerful refrigerating machinery at certain of the lower stages, the function of this machinery being to extract heat from the ring below and deliver it to the ring above. This latter method would increase to a very great extent the heat-carrying power of the system, which in the first arrangement is limited by the freezing temperature of brine in the descending column and the highest temperature admissible in the ascending brine column. The amount of heat conducted inwards through the rock-wall and requiring to be absorbed and transferred to the surface depends on the temperature and conductibility of the strata. But there is no doubt that the methods I have indicated would be capable of maintaining a moderate temperature in the shaft to depths of twelve miles.

During the process of sinking at the greater depths the shaft bottom would require the application of a special cooling process in advance of the sinkers, similar to the Belgian freezing system of M. Poesche used for sinking through water-bearing strata and quicksands, and now in general use. It consists in driving a number of bore-holes in a circle outside the perimeter of the shaft to be sunk;

through these bore-holes very cold brine is circulated, thus freezing the rocks and quicksands and the water therein, and when this process is completed the sinking of the shaft is easily accomplished.

In our case this process would be maintained not only on the shaft bottom, but also for some time on the newly-pierced shaft sides, until the surrounding rock had been cooled for some distance from the face.

As to the cost, rate of boring, and normal temperature of the rock, an approximate estimate has been made, based on the experience gained on the Rand, but including the extra costs for air-locks and cooling:—

	Cost £	Time in Years	Temp. of Rock
For 2 miles depth from the surface.	500,000	10	122° F.
,, 4 ,, ,, ,, ,, ,, .	1,100,000	25	152°
,, 6 ,, ,, ,, ,, ,, .	1,800 000	40	182
,, 8 ,, ,, ,, ,, ,, .	2,700,000	55	212°
,, 10 ,, ,, ,, ,, ,, .	3,700,000	70	242°
,, 12 ,, ,, ,, ,, ,, .	5,000,000	85	272°

I hope I have succeeded in showing in the short time at our disposal that an exploration to great depths is not an impossible undertaking. But my main object in discussing the enterprise at some length has been to show that a pioneer company would not acquire any subsequent monopoly of similar works under the existing patent laws or the laws of any country.

In the scheme as I have described it, there appears to be nothing that could be patented; but let us suppose that some good patent could have been found that was absolutely essential to the success of the undertaking, it would certainly have expired before the pioneer company could have reaped any substantial return, and probably before the first enterprise had been completed. It follows therefore that at the present time there is no adequate protection, or indeed any protection at all, for the promoters of many great and important pioneer enterprises, some of which might prove of immense benefit to mankind.

Let us ask what change in the laws would place great pioneer research works on a sound financial basis. A Government grant, except for very special purposes, seems to be out of the question, seeing that the benefits to be derived are generally not confined to any one country. An extension of the life of patents, which is now from fourteen to sixteen years in different countries, would be undoubtedly a step in the right direction. It would be of great benefit generally if some scale of duration of patents could be fixed internationally, the scale being fixed according to the subject-matter, the difficulty of the attack, and the past history of the subject, but more especially in view of the utility of the invention.

One of the chief objections raised by the Privy Council against the extension of patents in this country has rightly been that undue prolongation is unfair to the British public, seeing that abroad no prolongations are granted. Therefore, if the duration of patents for important matters is to be extended at home it must also be extended abroad. In other words, such prolongations, to be effective, should necessarily extend to other countries. They should be international, and concurrent in all the countries interested.

One possible solution of this difficult question would be to place such matters under the jurisdiction of a Central International Committee, who would have the apportionment of the life and privileges of patents and of the extension or curtailment of their duration, according to their handling by the owners. I would ask, Why has a patent a life of only fourteen to sixteen years, while copyright is for forty-two years? Why has a pioneer company making a railway under Act of Parliament generally rights for ever unless it abuses its privileges, or the requirements of the district necessitate the construction of competing lines, while a patent has in comparison a life of infinite shortness?

I might also cite gas companies, electrical supply companies, under Act of Parliament, or provisional orders of forty-two years' duration; and this reminds us of the fact that until the term of life for electric supply companies had been extended from twenty-one years to forty-two years by the bill of 1884, it was impossible to find capital for such undertakings.

Now, it may be urged that the grant of a patent is a different thing from the grant of power to a railway company, a gas or electric supply company. But the object of this Address has been to show that a patent, to be fair to the patentee, ought in many cases to be analogous to an Act of Parliament or a provisional order. Would it not place matters in a fairer position, especially in the case of expensive and lengthy researches, to grant to those who pledge themselves to spend a suitable and minimum sum within a stated period on the research a reasonable and fair monopoly, so that such person or syndicate might in the event of success be in the position to reap a reasonable return for their expenditure and risk?

Some such measure would unquestionably give an immense stimulus to research and invention by enabling capital to be raised and works started on commercial lines in fields of great promise at present almost untouched.

I pass over the disadvantages to the British inventor of the hostile patent tariffs of Continental nations and of the protective patent laws of some of the British dependencies, disadvantages greater than those imposed by protective tariffs on the ordinary British manufacturer.

There is, however, another aspect of the question to which I would briefly allude: it is the great benefits that the world at large has derived from the work of inventors in the past.

Think of the multitude and power of the great steam-engines and gas-engines that drive our factories, and pump the water out of our mines, and supply our cities with water, light, and power; of the great steamships scattered over the ocean and the locomotives on the railways.

Think of the billions of tons of steel that have been made by the Bessemer, Siemens-Martin, and Thomas Gilchrist processes, and of the great superiority and less cost of the material over the puddled iron which it superseded.

Think of the vast work performed by the electric telegraphs and telephones; and we must not fail to include the great chemical and metallurgical processes carried on all over the world, besides the countless other inventions and labour-saving appliances.

Can we form any idea of the commercial value of all these gigantic tools that past inventors have left as a heritage to the human race, and can we venture to place any order of magnitude on so vast a sum?

If we take as our unit of value the whole of the money spent on all inventions, both successful and unsuccessful, I think we shall be much below the mark if we assume that the value of the benefits has on the average exceeded by ten-thousandfold the money spent on making and introducing the inventions.

If this is so, let us see what it means. It means that for every unit of capital spent by the inventors and their friends on invention they have in some cases received nothing back. In some cases they have just got their capital back, in some cases two or threefold, occasionally tenfold, very rarely a hundredfold. Whereas the world at large has received a present of ten-thousandfold greater value than all the money spent and misspent by the small band of past inventors.

In conclusion, let us hope that the inventor will in the future receive more encouragement and support, that the patent laws will be further modified and extended, that the people at large will consider these matters more closely and recognise that they are of first importance to their progress and welfare, and that in the future it may be easier, nay in some cases possible, to carry on many great researches into the secrets of Nature.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS BY HENRY BALFOUR, M.A., PRESIDENT OF THE SECTION.

IT has frequently been remarked, and not without some justification, that Anthropology is an exceedingly diffuse science, and that it lacks the compactness and relatively well-defined field of enterprise enjoyed by most other sciences. This characteristic has even been employed by many as an argument against regarding Anthropology as a subject of any considerable value for educational purposes, the suggested lack of cohesion being thought to militate against

this science ever being allowed to occupy a similar position in the educational curricula and examination systems of this country as that to which the older sciences have for the most part been admitted. For my own part, I cannot but consider the validity of this argument as open to question. The term Anthropology, used in its unrestricted and, as I venture to think, proper sense, does, I readily admit, embrace a vast and varied field, and it inevitably overlaps, and even wanders far and at times freely into the domains of, other sciences. How should it and how can it be otherwise? We, surely, would be guilty of grievously undervaluing and paying scant respect to our genus were we to imagine that the science devoted to its comprehensive study could be otherwise than far-reaching—call it diffuse if you will—and that it could be expected to avoid driving its roots deeply into other sciences the chief practical interest of which lies, after all, in their adaptability to the service of Man.

In admitting the partial justice of the accusation as regards diffuseness, Anthropology, it seems to me, is really pleading guilty to the possession of an educational quality of which it may rather boast than feel ashamed. A science which is so far-reaching, and yet the nucleus or focussing point of which is so well defined, seems of itself to furnish the materials in great part for a liberal education, if properly handled, and to lend itself to the preparation of the inevitable syllabuses, adapted to the different grades both of general education and of higher scholarship.

I readily admit that the *word* Anthropology is unfortunately cumbersome; but it would seem to be inevitable, since no one has yet provided the science with a compact general name which may serve as an efficient substitute; and, since we must retain it, we may at least expect the word to work for its polysyllabic existence, by covering a wide area and serving as the most general term denoting the study of Man in a wide and all-embracing sense.

It is not my purpose to discuss here the educational value of Anthropology, but frankly and even gladly to admit that Anthropology, in spite of its late recognition as a distinct science worthy of encouragement, has in recent years progressed with rapid strides, and has already reached a stage of developmental progress at which it is necessary to differentiate the several branches of study which are included under the general science, and to adopt a classification which is ever becoming more complex as the various divisions become unwieldy and require subdividing. An extensive terminology has been growing up for the purpose of assigning appropriate names to the already fairly numerous divisions of the main subject. Anthropology is passing through the developmental stages which have been followed by the older sciences, and is merely following normal routine in advancing from the simple to the complex. With the increase of knowledge the elements which together constitute a given science necessarily develop individually as well as collectively, and the original science loses its primitive unity by becoming an ever-increasing aggregation of sub-sciences. This process of subdivision or branching is inseparable from the life-history of an active and progressive science.

The genesis, growth, and maturity of Section H reflects to some extent the development of the study of Anthropology. If we look back nearly sixty years, to a meeting of the Association held in Cambridge in 1845, we see that Ethnology was not mentioned at all in the programme and list of Sections, though one ethnological paper does certainly figure amongst those of the Zoological-Botanical group. We may, however, assume that at this meeting a start was made, and give to Cambridge due credit for having a distinct claim to the parentage of Section H. For, in the following year, 1846, we find in the list of Sections a definite *sub-Section* of Ethnology. Indeed, were we in doubt as to the parentage of the infant sub-Section, there is circumstantial evidence clearly indicating this ancient University city, in the subtle influence apparently exercised upon the mind of the parent by overpowering leanings towards applied mathematics, as manifested by the interesting and otherwise unaccountable fact that the "sub-Section of Ethnology" was in that year humbly parasitic upon Section G, which was then, as now, devoted to "Mechanics"!

From 1847 to 1850 the Ethnological sub-Section came under Section D (Zoology, Botany, and Physiology). In 1851 Ethnology appears in conjunction, and, apparently, on nearly equal terms, with Geography; and so it remained in the year 1862, when the Association again had the privilege of meeting in Cambridge, that profound and ingenious student of Man, Mr. Francis Galton, being president of the dual Section. The Geographico-Ethnological combination lasted until 1868, after which, and until 1880, we find the prospective Section H replaced under the charge of Section D—Biology (which included Zoology, Botany, Anatomy, and Physiology).

The steadily growing vitality of the study of Man is very evident through all these years, from the list of papers read, and one may gather, from the way in which the sub-Section was transferred from Section to Section, that the infant was rapidly outgrowing its nurses, and becoming a troublesome handful. Typographical signs of adolescence, coupled with a yearning for independence, appear in 1883, when, glancing at the list of Sections, we see that, although Anthropology is still a "Department of Biology," not only is it the only "department" specially announced under Section D, but the heading is printed in type of the same magnitude as that used for the Section itself. The printer proved to be a good prophet; for in the following year, 1884, at the meeting in Montreal, the inevitable occurred, and Anthropology blossomed out into the adult stage, and received the emancipation afforded by the assignment of an entire Section to itself, the "Section H," which has, I venture to think, thoroughly justified its existence ever since.

It may be doubted whether we have as yet reached the limit of expansion. The time is likely to come when Section H will be the parent of one or more vigorous sub-Sections, which, again, may repeat the developmental sequence, reaching at length maturity and discretion, and being perhaps allowed to set up for themselves as semi-independent Sections. The original title of a Section of the British Association may disappear entirely as such, after the sub-Sections comprised under it have received their full emancipation. This has happened in the case of Biology, which for some thirty years gave its name to Section D, but which finally gave way before the growth of its enterprising and very progressive offshoots (Zoology, Anthropology, Physiology, and Botany), which one after the other developed into independent Sections. With this segregation of the various component elements of Biology, the old generalised title ceased to appear on the list of the British Association. This, perhaps, will be the fate of the term "Anthropology," as the growth of the subjects which have developed under the wing of this very comprehensive science gradually causes, for the sake of practical convenience, a number of subordinate titles to replace the time-honoured and inclusive term. Should it thus happen, in response to the growth of the science, that this term is destined to follow the far wider term "Biology" into a position of dignified ease, we shall be wise to bear continually in mind that Anthropology is the main stem from which the various branches have sprung, and to the nourishment and growth of which it should be the principal aim of their individual activities to contribute. In an age of ever-increasing specialisation we may from time to time require a reminder of the fact that the true value of researches in the special fields of a science must be estimated by the degree to which their relationship to the whole can be and is rendered manifest. The work of specialists will necessarily lose half its value if there is a dearth of generalists who will gather together the threads and weave them into a substantial fabric, which shall show the importance of each individual piece of work to the progress of the science as a whole.

Once Anthropology became recognised as a definite science, and one worthy of encouragement, the number of its devotees increased steadily and apace, and the range of its work widened rapidly. Indeed, it would appear as though there were an almost feverish desire to make up for time lost through the phenomenal tardiness of the discovery of a seemingly obvious fact, which is that "Man" is in very truth a "proper study for mankind." Energy is not wanting, though this feverishness is kept in rigid subjection by the chilling and reducing effect of starvation for want of funds. The lack of adequate financial support is painfully apparent in Great Britain when we compare the

conditions prevailing here with those obtaining in other countries.

I will not endeavour to cope with the many and varied aspects of Anthropology and its complex ramifications, nor will I attempt to enumerate the many distinguished men of science to whose stimulating work we chiefly owe the progress already achieved in Anthropology; the more prominent pioneers are well known to you, and several, I am glad to say, are yet with us. Their works remain as important landmarks in the developmental record of the Science of Man. I have, instead, selected as my principal theme one branch of the subject. My main object is to review, necessarily briefly, *one* of the factors which have played a part in stimulating scientific inquiry into the past and present conditions of Man, and in furthering the development both of the scientific and the popular interests of Anthropology. I wish to confine myself to the consideration of the contribution of one man towards the subject, a contribution which is the more valuable since it deals with wide principles, and thus affords a basis upon which a vast army of students may found valuable work. It amounted to the establishment of a particular school of research into the history of human culture, into which fresh workers are constantly being attracted, and which has stood the test of time through half a century.

It was about the middle of last century that an officer in Her Majesty's Army began to apply the lessons which he had learnt in the course of some of his professional experimental work to studies pursued by him as a hobby in a far wider field of science. The story of the famous ethnographical collection of Colonel Lane Fox is well known, and I need but briefly refer to it. During his investigations, conducted with a view to ascertaining the best methods whereby the service firearms might be improved, at a time when the old Tower musket was being finally discarded, he was forcibly struck by the extremely gradual changes whereby improvements were effected. He observed that every noteworthy advancement in the efficiency, not only of the whole weapon but also of every individual detail in its structure, was arrived at as a cumulative result of a succession of very slight modifications, each of which was but a trifling improvement upon the one immediately preceding it. Through noticing the unfailing regularity of this process of gradual *evolution* in the case of firearms, he was led to believe that the same principles must probably govern the development of the other arts, appliances, and ideas of mankind. With characteristic energy and scientific zeal Colonel Lane Fox began at once, in the year 1851, to illustrate his views and to put them to a practical test. He forthwith commenced to make the ethnological collection with which his name will always be associated, and which rapidly grew to large proportions under his keen search for material which should illustrate and perhaps prove his theory of progress by evolution in the arts of mankind.

Although as a collector he was somewhat omnivorous, since every artefact product fell strictly within his range of inquiry, his collection, nevertheless, differed from the greater number of private ethnological collections, and even public ones of that day, inasmuch as it was built up *systematically* with a definite object in view. It is unnecessary for me to describe in detail the system which he adopted in arranging his collection. His principles are well known to ethnologists, either from the collection itself or from his writings, more especially from the series of lectures which he gave at the Royal United Service Institution, in the years 1867–69, upon "Primitive Warfare"; from his paper read before the Anthropological Institute in 1874 on "The Principles of Classification," as adopted in the arrangement of his anthropological collection, which was then exhibited at the Bethnal Green Museum; from that portion of the *catalogue raisonné* of his collection which was published in 1877; and from numerous other papers dealing with special illustrations of his theory. Suffice it to say that, in classifying his ethnological material, he adopted a *principal* system of groups into which objects of like form or function from all over the world were associated to form series, each of which illustrated as completely as possible the varieties under which a given art, industry, or appliance occurred. Within these main groups objects belonging to the same region were usually associated together in *local* sub-groups. And wherever amongst the implements or other objects exhibited in a given series there seemed to be suggested a *sequence of ideas*, shedding light upon the probable stages in the evolution of this particular class, these objects were specially brought into juxtaposition. This special grouping to illustrate sequence was particularly applied to objects from the same region as being, from their local relationships, calculated better to illustrate an actual continuity. As far as possible the seemingly more primitive and generalised forms—those simple types which usually approach most nearly to *natural* forms, or the use of which is associated with primitive ideas—were placed at the beginning of each series, and the more complex and specialised forms were arranged towards the end.

The primary object of this method of classification by series was to demonstrate, either actually or hypothetically, the origin, development, and continuity of the material arts, and to illustrate the variations whereby the more complex and specialised forms belonging to the higher conditions of culture have been evolved by successive slight improvements from the simple, rudimentary, and generalised forms of a primitive culture.

The *earlier* stages in these sequence series were more especially the object of investigation, the later developments being in the greater number of cases omitted or merely suggested. It was necessary for Colonel Lane Fox to restrict the extent of the series, any one of which, if developed to the full extent, would easily have filled a good-sized museum. The earlier stages, moreover, were less familiar, and presented fewer complications. The general principles of his theory were as adequately demonstrated by the ruder appliances of uncivilised races as by the more elaborate products of peoples of higher culture; and, moreover, there was doubtless a great attraction in attacking that end of the development series which offered a prospect at least of finality, inasmuch as there was always a chance of discovering the absolute origin of a given series. Hence the major part of his collection consisted in specimens procured from savage and barbaric races, amongst whom the more rudimentary forms of appliances are for the most part to be found.

The validity of the general views of Colonel Lane Fox as to evolution in the material arts of Man was rapidly accepted by a large number of ethnologists and others, who were convinced by the arguments offered and the very striking evidence displayed in their support. I have heard people object to the use of the term "evolution" in connection with the development of human arts. To me the word appears to be eminently appropriate, and I think it would be exceedingly difficult to find one which better expresses the succession of extremely minute variations by means of which progress has been effected. That the successive individual units of improvement, which when linked together form the chain of advancement, *are* exceedingly small is a fact which anyone can prove for himself if he will study *in detail* the growth of a modern so-called "invention." One reason why we are apt to overlook the greater number of stages in the growth of still living arts is that we are not as a rule privileged to watch behind the scenes. Of the numberless slight modifications, each but a trifling advance upon the last, it is but comparatively few which ever meet the eye of the public, which only sees the more important stages; those, that is to say, which present a sufficiently distinct advance upon that which has hitherto been in use to warrant their attracting attention, or, shall we say, having for a time a marketable value. The bulk of the links in the evolutionary chain disappear almost as soon as they are made, and are known to few, perhaps none, besides their inventors. Even where the history of some invention is recorded with the utmost care it is only the more prominent landmarks which receive notice; the multitude of trifling variations which have led up to them are not referred to, for, even if they be known, space forbids such elaborately detailed record. The smaller variations are, for the most part, utterly forgotten, their ephemeral existence and their slight individual influence upon the general progress being unrecorded at the time, and lost sight of almost at once. The immediately succeeding stage claims for the moment the attention, and it again in its turn becomes the stepping-stone upon which the next raises itself, and so on.

Before proceeding further, let me give as briefly as I can an example of a development series worked out, in the main,

upon the general line of inquiry inaugurated by Colonel Lane Fox. It is commonly accepted as a fact, which is borne out by tradition, both ancient and modern, that certain groups of stringed instruments of music must be referred for their origin to the bow of the archer. The actual historical record does not help us to come to a definite conclusion on this point, nor does the direct testimony of archæology, but from other sources very suggestive evidence is forthcoming. A comparative study of the musical instruments of modern savage and barbaric peoples makes it very clear to one that the greater portion of the probable chain of sequences which led from the simple bows to highly specialised instruments of the harp family may be reconstructed from types still existing in use among living peoples, most of the well-defined early stages being represented in Africa at the present day.[1] The native of Damaraland, who possesses no stringed instrument proper, is in the habit of temporarily converting his ordinary shooting-bow into a musical instrument. For this purpose he ties a small thong loopwise round the bow and bow-string, so as to divide the latter into two vibrating parts of unequal length. When lightly struck with a small stick the tense string emits a couple of notes, which satisfy this primitive musician's humble cravings for purely rhythmic sound. Amongst many other African tribes we find a slight advance, in the form of special rather slightly made bows constructed and used for musical purposes only. In order to increase the volume of sound, it is frequently the custom amongst some of the tribes to rest the bow against some hollow, resonant body, such as an inverted pot or hollow gourd. In many parts, again, we find that the instrument has been further improved by *attaching* a gourd to the bow, and thus providing it with a permanent resonating body. To achieve greater musical results, it would appear that somewhere in Africa (in the West, I suspect) two or more small bows were attached to a single gourd. I have, so far, been unable to trace this particular link in Africa itself, but, curiously enough, this very form has been obtained from Guiana. It may be thought that I am applying a breaking strain to the chain of evidence when I endeavour to work an instrument from South America into an African developmental series. But, when we recall the fact that evidence of the existence of *indigenous* stringed instruments of music in the New World has yet to be produced, coupled with the certain knowledge that a considerable number of varieties of musical instruments, stringed and otherwise, accompanied the enforced migration of African natives during the days of the slave trade, and were thus established in use and perpetuated in many parts of the New World, including the north-east regions of South America, we may, I think, admit with some confidence that in this particular instance from Guiana to Guinea is no very far cry, and that the more than probable African origin of this instrument from South America gives it a perfect claim to take its place in the African sequence. I still anticipate that this type of instrument will be forthcoming from some hinterland region in West Africa. Were *no* evidence at all forthcoming of such a form, either in past or present, we should be almost compelled to infer that such a one had existed, as this stage in the sequence appears to be necessary to prevent a break in the continuity of forms leading to what is apparently the next important stage, represented by a type of instrument common in West Africa, having five little bows, each carrying its string, and all of which are fixed by their lower ends into a box-like wooden resonator. This method of attaching the bows to the now improved body of the instrument necessitates the lower attachment of the strings being transferred from the bows to the body, so that the bow-like form begins to disappear. The next improvement of which there is evidence from existing types consists in the substitution of a single, stouter, curved rod for the five little "bows," all the five strings being serially attached to the upper end of the rod, their lower ends to the body as before. This instrument is somewhat rare now, and it may well be a source of wonder to us that it has survived at all (unless it be to assist the ethnologist), since it is an almost aggressively inefficient form, owing to the row of strings being brought into two different planes at right angles to one another. The structure of this rude instrument gives it a quaintly composite appearance, suggesting that it is a banjo at one end and a harp at the other. This is due to the strings remaining, as in the preceding form, attached to the resonating body in a line disposed *transversely*, while the substitution of a single rod for the five "bows" has necessitated the disposal of their upper attachments in a *longitudinal* series as regards the longer axis of the instrument. Inefficient though it be, this instrument occupies an important position in the apparent chain of evolution, leading on as it does through some intermediate types to a form in which the difficulty as regards the strings is overcome by attaching their *lower* ends in a longitudinal series, and so bringing them into the same plane throughout their length. In this shape the instrument has assumed a harp-like form—a rude and not very effective one, it is true, but it is none the less definitely a member of the harp family. The modern varieties of this type extend across Africa from west to east, and the harps of ancient Egypt, Assyria, Greece, and India were assuredly elaborations of this primitive form. The Indian form, closely resembling that of ancient Egypt, still survives in Burma, while elsewhere we find a few apparently allied forms. In all these forms of the harp, from the rudest Central and West African types to the highly ornate and many-stringed examples of Egypt and the East, one point is especially noteworthy. This is the invariable *absence of the fore-pillar*, which in the modern harps of Western Europe is so important, nay, essential, a structural feature. In spite of the skill and care exercised in the construction of some of the more elaborate forms, none were fitted with a fore-pillar, the result being that the frame across which the strings were stretched was always weak and disposed to yield more or less to the strain caused by the tension of the strings. This implied that, even when the strings were not unduly strained, the tightening up of one of them to raise its pitch necessarily caused a greater or less slackening of all the other strings, since the free end of the rod or "neck" would tend to be drawn slightly towards the body of the instrument under the increased tension. One can picture the soul-destroying agonies endured by two performers upon these harps when endeavouring, if they ever did so, to bring their refractory instruments into unison, while, as for the orchestral music of the old Assyrian days—well, perhaps we had better not attempt to picture *that!* The mere addition of a simple, strut-like support between the free end of the "neck" and the "body" would have obviated this difficulty and rendered the instrument relatively efficient and unyielding to varying tension. And yet, even in Western Europe, this seemingly obvious and invaluable addition did not appear, as far as I can ascertain, until about the seventh or eighth century A.D.; and even then it seems to have been added somewhat half-heartedly, and a very long time had yet to elapse before the fore-pillar became an integral part of the framework and was allotted its due proportion in the general design.

I have purposely selected this particular series for my illustration, not because it is something new—indeed, it is already more or less familiar, and maybe has even some merit in its lack of newness, since, in accordance with a popular dictum, it may urge a greater claim to be regarded as true—nor because it is specially striking, but rather for the reason that it illustrates suitably several of the points upon which I wish briefly to touch. Even in the severely condensed form in which I have been obliged to present this series of developments from bow to harp, there is, I think, demonstrated the practical application of several of the general principles upon which is based the theory whereby Colonel Lane Fox sought to elucidate the phenomena of human progress.

A series of this kind serves, in the first place, to demonstrate that the absence of historical and archæological evidence of the *actual* continuity in development from simple to complex does not preclude investigations into the early history of any product of human ingenuity, nor prevent the formation of a suggestive and plausible if largely hypothetical series, illustrating the probable chain of sequences along which some highly specialised form may be traced back link by link to its rudimentary prototypes, or even to its absolute origin, which in this particular instance is the ordinary shooting bow *temporarily* converted into a musical instrument. Where an actual chronological series is not forthcoming, a comparative study of such types as are

[1] "The Natural History of the Musical Bow." By H. Balfour. Clarendon Press, Oxford.)

available, even though they be *modern* examples, reveals the fact that, if classified according to their apparent morphological affinities, these types show a tendency to fall into line, the gap between the extreme forms—that is, the most simple and the most advanced—being filled by a succession of intermediate forms, more or less completely linked together, according to the number of varieties at our disposal. We are thus, at any rate, in possession of *a* sequence series. Is it unreasonable for us to conclude that this reflects, in great measure, *the* actual chronological sequence of variations through which in past times the evolutionary history of the instrument was effected from the earliest rudimentary form?

It is difficult to account at all for the existence of many of the forms such as I have briefly described, except on the supposition that they are *survivals* from more or less *early stages* in a series of progressive evolution; and, for myself, I do not believe that so inefficient and yet so elaborate an instrument as, to take an example, the harp of ancient Egypt, Assyria, and India could have come into being by any sudden inventive process, by "spontaneous generation," as it were, to use a biological term; whereas, the innate conservatism of the human species, which is most manifest among the lower and more primitive races (I use the term conservatism, I need hardly say, in a non-political sense) amply accounts for such forms having been arrived at, since the rigid adherence to traditional types is a prevailing characteristic of human culture, and only admits of improvement by very slight and gradual variations upon existing forms. The difficulty experienced by man in a primitive condition of culture of emancipating himself from the ideas which have been handed down to him, except by a very gradual and lengthy process, causes him to exert somewhat blindly his efforts in the direction of progress, and often prevents his seeing very obvious improvements, even when they are seemingly forced upon his notice. For instance, the early Egyptian, Assyrian, and Greek harps, as I have already stated, were destitute of a fore-pillar, and this remained the case for centuries, in spite of their actually existing in an environment of other instruments, such as the lyre and *trigonon*, which in their rigid, unyielding frames possessed and even paraded the very feature which was so essential to the harp, to enable it to become a really efficient instrument. The same juxtaposition of similar types, without mutual influence, may be seen in modern Africa among ruder forms of these instruments.

And yet, in spite of instances such as this—where a valuable feature suggested by one instrument has not been adopted for the improvement of another, even though the two forms are in constant use side by side—we must recognise that progress in the main is effected by a process of bringing the experience gained in one direction to bear upon the results arrived at in another. This process of grafting one idea upon another, or, as we may call it, the hybridisation of ideas and experience, is a factor in the advancement of culture the influence of which cannot be overestimated. It is, in fact, the main secret of progress. In the animal world hybridisation is liable to produce *sterile* offspring; in the world of ideas its results are usually far different. A fresh stimulus is imparted, which may last through generations of fruitful descendants. The *rate* at which progress is effected increases steadily with the growth of experience, whereby the number of ideas which may act and react upon one another is augmented.

It follows, as a corollary, that he who would trace out the phylogenetic history of any product of human industry will speedily discover that, if he aims at doing so *in detail*, he must be prepared for disappointments. The tangle is too involved to be completely unravelled. The sequence, strictly speaking, is not in the form of a simple chain, but rather in that of a highly complex *system* of chains. The time-honoured simile afforded by a river perhaps supplies the truest comparison. The course of the *main stream* of our evolution series may be fairly clear to us, even as far as to its principal source; we may even explore and study the general effect produced by the more important tributaries; but to investigate in detail the contributions afforded in present and past of the innumerable smaller streams, brooks, and runlets is clearly beyond anyone's power, even supposing that the greater number had not changed their course at times, and even, in many cases, run dry. While we readily admit that important effects have been produced by these numberless tributary influences, both on the course and on the volume of the river, it is clear that we must in general be content to follow the main stream. A careful study of the series of musical instruments, of which I gave but a scanty outline, reveals very clearly that numberless ideas borrowed from outside sources have been requisitioned and have affected the course of development. In some cases one can see fairly clearly whence these ideas were derived, and even trace back in part their own phylogenetic history; but a complete analysis must of necessity remain beyond our powers and even our hopes.

It will have been observed that, in the example of a sequence series which I have given, the early developmental stages are illustrated entirely by instruments belonging to *modern savage races*. It was a fundamental principle in the general theory of Colonel Lane Fox that in the arts and customs of the still living savage and barbaric peoples there are reflected to a considerable extent the various strata of human culture in the past, and that it is possible to reconstruct in some degree the life and industries of Man in prehistoric times by a study of existing races in corresponding stages of civilisation. His insistence upon the importance of bringing together and comparing the archæological and ethnological material, in order that each might serve to throw light upon the other, has proved of value to both sciences. Himself a brilliant and far-seeing archæologist as well as ethnologist, he was eminently capable of forming a conclusion upon this point, and he urged this view very strongly.

The earth, as we know, is peopled with races of the most heterogeneous description, races in all stages of culture. Colonel Lane Fox argued that, making due allowance for possible instances of degradation from a higher condition, this heterogeneity could readily be explained by assuming that, while the progress of some races has received relatively little check, the culture development of other races has been retarded to a greater or less extent, and that we may see represented conditions of at least partially arrested development. In other words, he considered that in the various manifestations of culture among the less civilised peoples were to be seen more or less direct *survivals* from the earlier stages or strata of human evolution; vestiges of ancient conditions which have fallen out at different points and have been left behind in the general march of progress.

Taken together, the various living races of Man seem almost to form a kind of living genealogical tree, as it were, and it is as an epiphyte upon this tree that the comparative ethnologist largely thrives; while to the archæologist it may also prove a tree of knowledge the fruit of which may be eaten with benefit rather than risk.

This certainly seems to be a legitimate assumption in a general way; but there are numerous factors which should be borne in mind when we endeavour to elucidate the past by means of the present. If the various gradations of culture exhibited by the condition of living races—the savage, semi-civilised, or barbaric, and the civilised races—could be regarded as accurately typifying the successive stages through which the higher forms of culture have been evolved in the course of the ages; if, in fact, the different modern races of mankind might be accepted as so many sections of the human race the intellectual development of which has been arrested or retarded at various definite stages in the general progression, then we should have, to all intents and purposes, our genealogical tree in a very perfect state, and by its means we could reconstruct the past and study with ease the steady growth of culture and handicrafts from the earliest simple germs, reflecting the mental condition of primæval man up to the highest manifestations of the most cultured races.

These ideal conditions are, however, far from being realised. Intellectual progress has not advanced along a single line, but, in its development, it has branched off in various directions, in accordance with varying environment; and the tracing of lines of connection between different forms of culture, as is the case with the physical variations, is a matter of intricate complexity. Migrations with the attendant climatic changes, change of food, and, in fact, of general environment, to say nothing of the crossing of different stocks, transmission of ideas from one people to another, and other factors, all tend to increase the tangle.

Although in certain instances savage tribes or races show obvious signs of having *degenerated* to some extent from conditions of a higher culturedom, this cannot be regarded as the general rule, and we must always bear in mind the seemingly paradoxical truth that degradation in the culture of the lower races is often, if not usually, the direct result of contact with peoples in a far higher state of civilisation.

There can, I think, be little doubt that Colonel Lane Fox was well justified in urging the view that most savage races are in large measure strictly *primitive*, survivals from early conditions, the development of their ideas having from various causes remained practically stationary during a very considerable period of time. In the lower, though not degenerate, races signs of this are not wanting, and while few, possibly none, can be said to be absolutely in a condition of arrested development, their normal progress is at a slow, in most cases at a *very* slow, rate.

Perhaps the best example of a truly primitive race existing in recent times, of which we have any knowledge, was afforded by the native inhabitants of Tasmania. This race was still existing fifty years ago, and a few pure-blooded survivors remained as late as about the year 1870, when the race became extinct, the benign civilising influence of enlightened Europeans having wiped this extremely interesting people off the face of the earth. The Australians, whom Colonel Lane Fox referred to as being "the lowest amongst the existing races of the world of whom we have any accurate knowledge," are very far in advance of the Tasmanians, whose lowly state of culture conformed thoroughly with the characteristics of a truly primitive race, a survival not only from the Stone Age in general, but from almost the earliest beginnings of the Stone Age. The difference between the culture of the Tasmanians and that of the Australians was far greater than that which exists between man of the "River Drift" period and his Neolithic successors. The objects of every-day use were but slight modifications of forms suggested by Nature, involving the exercise of merely the simplest mental processes. The stone implements were of the rudest manufacture, far inferior in workmanship to those made by Palæolithic man; they were never ground or polished, never even fitted with handles, but were merely grasped in the hand. The *varieties* of implements were very *few in number*, each, no doubt, serving a number of purposes, the function varying with the requirements of the moment. They had no bows or other appliances for accelerating the flight of missiles, no pottery, no permanent dwellings; nor is there any evidence of a previous knowledge of such products of higher culture. They seem to represent a race which was isolated very early from contact with higher races; in fact, before they had developed more than the merest rudiments of culture—a race continuing to live under the most primitive conditions, from which they were never destined to emerge.

Between the Tasmanians, representing in their very low culture the one extreme, and the most civilised peoples at the other extreme, lie races exhibiting in a general way intermediate conditions of advancement or retardation. If we are justified, as I think we are, in regarding the various grades of culture observable among the more lowly of the still existing races of man as representing to a considerable extent those vanished cultures which in their succession formed the different stages by which civilisation emerged gradually from a low state, it surely becomes a very important duty for us to study with energy these living illustrations of early human history in order that the archæological record may be supplemented and rendered more complete. The material for this study is vanishing so fast with the spread of civilisation that opportunities lost now will never be regained, and already even it is practically impossible to find native tribes which are wholly uncontaminated with the products, good or bad, of higher cultures.

The arts of living races help to elucidate what is obscure in those of prehistoric times by the process of reasoning from the known to the unknown. It is the work of the zoologist which enables the palæontologist to reconstruct the forms of extinct animals from such fragmentary remains as have been preserved, and it is largely from the results of a comparative study of living forms and their habitats that he is able, in his descriptions, to equip the reconstructed types of a past fauna with environments suited to their structure, and to render more complete the picture of their mode of life.

In like manner, the work of the ethnologist can throw light upon the researches of the archæologist: through it broken sequences may be repaired, at least suggestively, and the interpretation of the true nature and use of objects of antiquity may frequently be rendered more sure. Colonel Lane Fox strongly advocated the application of the reasoning methods of biology to the study of the origin, phylogeny, and etionomics of the arts of mankind, and his own collection demonstrated that the products of human intelligence can conveniently be classified into families, genera, species, and varieties, and *must* be so grouped if their affinities and development are to be investigated.

It must not be supposed—although some people, through misapprehension of his methods, jumped at this erroneous conclusion—that he was unaware of the danger of possibly mistaking mere accidental resemblances for morphological affinities, and that he assumed that *because* two objects, perhaps from widely separated regions, appeared more or less identical in form, and possibly in use, they were necessarily to be considered as members of one phylogenetic group. On the contrary, in the grouping of his specimens according to their form and function, he was anxious to assist as far as possible in throwing light upon the question of the monogenesis or polygenesis of certain arts and appliances, and to discover whether they are exotic or indigenous in the regions in which they are now found, and, in fact, to distinguish between mere analogies and true homologies. If we accept the theory of the monogenesis of the human race, as most of us undoubtedly do, we must be prepared to admit that there prevails a condition of unity in the tendencies of the human mind to respond in a similar manner to similar stimuli. Like conditions beget like results; and thus instances of independent invention of similar objects are liable to arise. For this very reason, however, the arts and customs belonging to even widely separated peoples may, though apparently unrelated, help to elucidate some of the points in each other's history which remain obscure through lack of the evidence required to establish *local* continuity.

I think, moreover, that it will generally be allowed that cases of "independent invention" of similar forms should be considered to have established their claim to be regarded as such only after exhaustive inquiry has been made into the possibilities of the resemblances being due to actual relationship. There is the alternative method of assuming that, because two like objects are widely separated geographically, and because a line of connection is not immediately obvious, therefore the resemblance existing between them is fortuitous, or merely the natural result of similar forms having been produced to meet similar needs. Premature conclusions in matters of this kind, though temptingly easy to form, are not in the true scientific spirit, and act as a check upon careful research, which, by investigating the case in its various possible aspects, is able either to prove or disprove what otherwise would be merely a hasty assumption. The association of similar forms into the same series has therefore a double significance. On the one hand, the sequence of related forms is brought out, and their geographical distribution illustrated, throwing light, not only upon the evolution of types, but also upon the interchange of ideas by transference from one people to another, and even upon the migration of races. On the other hand, instances in which two or more peoples have arrived independently at similar results are brought prominently forward, not merely as interesting coincidences, but also as evidence pointing to the phylogenetic unity of the human species, as exemplified by the tendency of human intelligence to evolve independently identical ideas where the conditions are themselves identical. Polygenesis in his inventions may probably be regarded as testimony in favour of the monogenesis of Man.

I have endeavoured in this Address to dwell upon some of the main principles laid down by Colonel Lane Fox as a result of his special researches in the field of Ethnology, and my object has been twofold. First, to bear witness to the very great importance of his contribution to the scientific study of the arts of mankind and the development of culture in general, and to remind students of Anthropology of the debt which we owe to him, not only for the results of his

very able investigations, but also for the stimulus which he imparted to research in some of the branches of this comprehensive science. Secondly, my object has been to reply to some criticisms offered in regard to points in the system of classification adopted in arranging his ethnographical collection. And, since such criticisms as have reached me have appeared to me to be founded mainly upon misinterpretation of this system, I have thought that I could meet them best by some sort of restatement of the principles involved.

It would be unreasonable to expect that his work should hold good in all details. The early illustrations of his theories were to be regarded as tentative rather than dogmatic, and in later life he recognised that many modifications in matters of detail were rendered necessary by new facts which had since come to light. The crystallisation of solid facts out of a matrix which is necessarily partially volatile is a process requiring time. These minor errors and the fact of our not agreeing with all his details in no way invalidate the general principles which he urged, and we need but cast a cursory glance over recent ethnological literature to see how widely accepted these general principles are, and how they have formed the basis of, and furnished the inspiration for, a vast mass of research by ethnologists of all nations.

It appears more than probable that Cambridge will be much involved in the future advancement of anthropological studies in Great Britain, if we may judge from the evident signs of a growing interest in the science, not the least of which is the recent establishment of a Board of Anthropological Studies, an important development upon which we may well congratulate the University. Within my own experience there have been many proofs of the existence in Cambridge of a keen sympathy with the principles of ethnological inquiry developed by Colonel Lane Fox, and I feel that, as regards my choice of a theme for the main topic of my address, no apology is needed. For my handling of this theme, on the other hand, I fear it must be otherwise. I would gladly have done fuller justice to the work of Colonel Lane Fox, but, while I claim to be among the keenest of his disciples, I must confess to being but an indifferent apostle.

I have been obliged, moreover, to pass over many interesting features in the work of this ingenious and versatile man of science. I have made no attempt to touch upon his archæological researches, since it has been necessary for me to restrict myself to a portion only of his scientific work. In this field, as in his ethnological work, his keen insight, ingenuity, and versatility were manifested, while the close attention which he bestowed upon matters of minute detail has rendered classical his work as a field archæologist. While the greater part of his ethnological work is associated with the name Lane Fox, by which he was known until 1880, most of his researches into the remains of prehistoric times were conducted after he had in that year assumed the name of Pitt Rivers, on inheriting an important estate which, by the happiest of coincidences, included within its boundaries a considerable number of prehistoric sites of the highest importance. That he made full use of his opportunities is amply manifested in his published works. In his archæological work are repeated the characteristics of his ethnological researches, and one may with confidence say of his contributions to both fields of inquiry that, if he advanced science greatly through his results he furthered its progress even more through his methods. By his actual achievements as a researcher he pushed forward the base of operations; by his carefully-thought-out systems for directing research he developed a sound strategical policy upon which to base further organised attacks upon the Unknown.

NOTES.

THE Hugh Miller Memorial Institute at Cromarty was opened on Friday last by Mr. Andrew Carnegie. The institute, which had its inception at the Hugh Miller centenary celebrations two years ago, is a short distance from the house where the geologist was born, and the accommodation provided includes a public library. The site was given by Colonel Ross, of Cromarty; the cost of the building, amounting to 1200*l.*, was defrayed by Mr. Carnegie, and the public subscribed 400*l.* for an endowment fund.

THE director of the Paris Museum of Natural History has been authorised to accept a gift made by M. Durand of a collection of herbaria and a botanical library, a sum of 5000 francs to pay the expense of transporting and installing these collections, and a further sum of 50,000 francs to be invested with a view to provide a fund for the upkeep of the herbaria and the purchase of plants and of works on botany.

THE International Congress of Physiologists was opened at the Solvay Institute in Brussels on Tuesday.

THE fourth congress of the International Aëronauts Committee, convened by the Imperial Academy of Sciences, was opened at St. Petersburg on Monday.

IT is reported that Mr. Henry Phipps has given 4000*l.* to the Johns Hopkins University, for the study of tuberculosis.

IT is announced that the late Mr. John Innes bequeathed the sum of 300,000*l.* for the erection of a museum at Merton, Surrey.

THE committee appointed by the Texas Legislature to investigate methods for the extermination of the boll weevil and pay a reward of 10,000*l.* to the discoverer of any such method, has decided, says *Science*, that no one has earned this reward.

THE Lancashire and Western Sea Fisheries Joint Committee has appointed Dr. J. T. Jenkins, professor of biology in Hartley University College, Southampton, to be superintendent of sea fisheries in place of the late Captain Dawson.

MR. W. I. LAST, senior keeper in the science division of the Victoria and Albert Museum, has been appointed director of that division of the museum in succession to Major-General Festing, C.B., F.R.S., who has recently retired at the age of sixty-four on the operation of the age limit. Mr. Last was senior Whitworth scholar in 1877, and a Watt medallist of the Institution of Civil Engineers in 1887, and has been for the last few years senior keeper in the science division of the museum, with the special charge of the engineering collections.

THE second International Congress on the History of Religions was opened at Basel on Tuesday. Prof. von Orelli, president of the organising committee, read an address, in the course of which he pointed out that the objects of the conference were purely scientific, and that a propaganda in favour of a particular sect and controversies on the lines of religious discussions during the Middle Ages would not be allowed.

WITH the view to obtain further information on the growth and migrations of salmon (including sea-trout, salmon-trout, peal, sewin, &c.), the Board of Agriculture and Fisheries had had a number of such fish "marked" by attaching a small oblong silver label (oxidised, or blackened, and bearing distinctive letters and numbers) to the dorsal or large back fin. Small rewards will be paid for the recovery of fish bearing such labels or other "marks," or for information respecting them. The Board has prepared lists of persons in the south and west of England, in Wales and Monmouthshire, and in the north of England, who will receive marked fish. The experiments will be continued during a series of years, and the cooperation of net-fishermen, anglers, fishmongers, and all interested in the improvement of the salmon fisheries, is invited in order that the fullest possible results may be secured.

THE value and possibilities of wireless telegraphy as a journalistic adjunct are described in Saturday's *Times* by the special correspondent who established a wireless telegraph system at the theatre of war operations in the Far East with such success that both the belligerents regarded the enterprise as dangerous to their interests. The Japanese Government placed such limitations upon the free movements of the *Haimun*—the vessel chartered by the *Times* for its wireless telegraph service—that this means of communication was discontinued of necessity; and there seems little doubt that in future the use of all systems of wireless communication will be controlled by international law. The De Forest system, with its telephonic receiver, was adopted by the *Times* correspondent as most suitable for war messages, as it will allow the operators to record twenty to thirty words a minute, and its usefulness is not impaired by the working of other systems in the vicinity. The land station was at Wei-hai-wei, where a mast 170 feet high was erected. Even with a mast 90 feet high and 102 feet exposure of wire on board the moving ship, there was not the slightest difficulty in keeping up intercommunication at a distance of 100 sea miles. With the 170 feet mast on land, perfect communication was established over a distance of 180 sea miles, and on one occasion over 210 miles. A long message sent from a point 155 miles from the land station had to cross 30 miles of the mountainous corner of the Shan-tung promontory, the hills of which vary from 200 feet to 1860 feet in height, yet the message reached its destination. As soon as the apparatus was in working order, both Russian and Japanese messages were received by the operator, who could easily recognise the difference in the systems employed, and by this means it was possible approximately to tell the distance of the *Haimun* from the various ships. Moreover, the operator began to recognise the notes of various ships, that is to say, he could tell if a Russian ship was at sea by listening for the answering communication from the shore. He could also detect whether the Japanese messages were being transmitted by relay to the naval base or whether the fleet itself was at sea. The information thus obtained guided the movements of the correspondent, and thus assisted the enterprise, which has had to be abandoned on account of the restrictions placed upon it.

IN NATURE of June 2, Dr. H. A. Wilson pointed out (p. 101) that Prof. Rutherford's value for the absorption coefficient of α rays is nearly 2000 times greater than Lenard's value for the absorption coefficient of β rays of the same speed. He suggested, as an explanation, that the α rays consist of positive electrons having a radius 2000 times smaller than negative electrons. Prof. W. H. Bragg, of the University of Adelaide, in a letter which the limitations of space prevent us from publishing, gives reasons for believing that the α rays penetrate further than β rays of the same speed because they do not suffer from deflection by collision, whereas β radiation of this speed is very much affected thereby.

THE results of an attempt to derive formulæ by which the effect of wind and atmospheric pressure on the tides could be calculated were given by Mr. F. L. Ortt in NATURE several years ago (1897, vol. lvi. pp. 80–84). Dr. Wegemann informs us that these formulæ are printed in the *Getijtafels* for 1904, though they are only true for the deep water at the Hook of Holland and Ymuiden. Theoretical considerations have shown that the tables are not applicable to shallow water (Wegemann, *Annalen der Hydrogr.*, 1904, v.). Dr. Wegemann suggests that in deriving a general formula it would be desirable to name the directions of the wind, not according to the compass, but to the angle at which they touch the coast. The places should also be grouped according to depth, coast-line, and formation of the sea floor.

DURING each of the months April to June last, the usual scientific balloon ascents have taken place in the countries which generally participate in these useful experiments. Some of the flights have attained great altitudes, *e.g.* three registering balloons sent up by Baron v. Bassus, from Munich, averaged more than 19,000 metres. Two ascents, from Pavlovsk and from Itteville (near Paris), attained 17,600 metres or more, and one from Trappes reached 16,540 metres. Kite ascents were also made each month by Mr. Rotch at Blue Hill (U.S.), and in May and June by Mr. Dines at Oxshott (Surrey). The value of these researches is recognised by the Royal Academy of Sciences of Amsterdam, which has awarded the Buys-Ballot medal for 1903 to Messrs. R. Assmann, director of the Aëronautical Observatory at Tegel (near Berlin), and A. Berson, of the same institution, for "the great services they have rendered to the development of meteorology" by means of daily observations of the upper air, and as editors of, and contributors to, an elaborate work on scientific balloon ascents.

FROM a report which we have received, it is seen that the present Meteorological Service in Japan is highly organised and more centralised than in this country. It is placed under the direction of the Central Observatory at Tokio, and under the supervision of the Minister of Education, who determines the sites of the provincial stations; any persons who desire to erect meteorological stations (except for rainfall only) must obtain the necessary sanction from the Minister. All provincial stations of the first and second orders have to forward monthly and annual registers to the Central Observatory, while stations of the third order (of which there are more than 1200) send their observations to the "provincial" stations to which they belong. The method of taking observations and the reductions are made in accordance with the regulations of the International Meteorological Committee, and each station is inspected once in three or four years. The principal publications are the daily weather map, monthly and annual reports, and a monthly weather review. The text of the daily weather map is given in English and Japanese. Storm warning telegrams are issued to some 360 stations, and signals are hoisted by day and night. The average success of weather forecasts is 82 per cent., and that of storm warnings 70 per cent. Maritime meteorology has been carried on since 1888; all ships with a tonnage exceeding 100 tons forward logs to the Central Observatory. Much attention is given to earthquake phenomena and to magnetic observations, and since 1880 several expeditions have been made from time to time to high mountains in various portions of the Empire to investigate the processes of the higher strata of the atmosphere. The present director of the service is K. Nakamura.

THE first part of a new serial, *Memoirs of Natural Sciences of the Brooklyn Museum*, is devoted to an account of the medusas of the Bahamas, by Mr. A. G. Mayer. Numerous new forms are described, and the author directs special attention to the difference between the medusa-fauna of the Bahamas and that of the Tortugas—a difference correlated with physical differences in the two areas.

WE have received the July issues of the *Emu* and the *Victorian Naturalist*, the contents of both of which are chiefly devoted to matters of local interest, although a new kestrel from Western Australia is described in the former.

ORNITHOLOGICAL subjects constitute the contents of the August number of the *Zoologist*, so far at least as the separate articles are concerned, the measurements and weights of the eggs of the commoner members of the plover tribe being recorded in the first article by the Messrs. Buchanan. A photograph of the new Orkney vole, in juxtaposition with one of the common vole, forms the frontispiece to the number.

A BICAUDATE specimen of the king-crab is described by Mr. F. F. Smith in No. 8 of *Tuft's College Studies*, while Mr. G. Winslow records three cases of structural abnormalities in tailed amphibians. The origin of the hypophysis cerebri in the salamander, Amblystoma, especially in connection with the dispute as to whether it is an endodermal or ectodermal structure, is discussed at considerable length by Messrs. Kingsley and Thyng, and the histology of the digestive tract of the same creature receives attention at the hands of Mr. G. A. Bates. In a list of the mammals in the Barnum Museum of Tuft's College, by Mr. A. E. Preble, it is somewhat curious to find the African elephant "Jumbo" figuring as *Elephas indicus*; it is sincerely to be hoped that this is an error, and not the result of a discovery that *E. indicus* is the proper title of the African elephant.

IN the *American Journal of Science* for August, Dr. C. R. Eastman discusses the nature of the limb-like appendages in the fish-like creatures collectively known as Osteostraci, as exemplified in the family Asterolepididæ. Five theories have been propounded to explain the nature of these structures. They have been likened, firstly, to arthropod limbs; secondly, they have been regarded as produced and jointed extensions of the head-angles of forms like Cephalaspis; thirdly, they have been derived from a fixed body-spine like that of Acanthaspis; fourthly, they have been considered to be the degenerate development from the lobate fins of the fringe-finned (crossopterygian) ganoids; while, fifthly, they may be *sui generis*. The first two hypotheses Dr. Eastman dismisses as being founded upon misconceptions. The third he regards as presupposing impossible or anomalous conditions. Against the fourth, which was suggested by Mr. C. T. Regan in his paper on the phylogeny of the Teleostomi, recently noticed in our columns, the author advances a number of objections, while he pins his faith on the fifth. Dr. Eastman also takes occasion to record his dissent from Mr. Regan's views as to the existence of a close affinity between the Osteostraci (Cephalaspis, Asterolepis, &c.) and the Arthrodira (Coccosteus); and also as to the alleged relationship between the latter and the fringe-finned ganoids.

IN the same issue Mr. E. H. Sellards publishes an important contribution to our knowledge of Palæozoic cockroaches. Hitherto these insects have been chiefly known by the wings. It is now demonstrated that in bodily organisation they conform essentially to the modern Orthoptera, this agreement also extending to their development, as exemplified by the resemblance of the young to the adult, and by the growth taking place by means of a succession of moults, during which the wings are gradually evolved.

THE fourth volume of the new series of the *Proceedings* of the Aristotelian Society, containing the papers read before the society during the twenty-fifth session, 1903–4, has been published by Messrs. Williams and Norgate. Dr. Shadworth Hodgson contributes two papers dealing respectively with method in philosophy and with reality. Prof. G. F. Stout deals with primary and secondary qualities, and Dr. E. Westermarck has a paper entitled "Remarks on the Subjects of Moral Judgments." Miss E. E. C. Jones recapitulates the main points of Prof. Sidgwick's ethical view, and attempts to answer some of the objections to it that have been brought forward in recent criticisms.

IN vol. xxiv., part iv., of *Notes* from the Leyden Museum, Madame C. M. L. Popta describes as new a number of species of cat-fishes (Siluroids) collected by Dr. Nieuwenhaus in Central Borneo in 1898 and 1900. In the same issue Dr. Jentink records the plantain-bat (*Cerivoula picta*) from Sumatra.

MESSRS. PATTEN AND HART have found that the soluble phosphorus of wheat-bran is organic in nature, existing as the magnesium-calcium-potassium salt of a phospho-organic acid having the formula $C_2H_8P_2O_9$, and probably identical with Posternak's anhydro-oxymethylene diphosphoric acid (*Bull.* No. 250, New York Agricult. Exper. Station). This acid and its salts seem to be of wide distribution in the vegetable kingdom, having already been isolated from peas, beans, pumpkin and lupine seeds, and from the potato and other tubers and bulbs.

IN the July number of the *Gazzetta Chimica Italiana*, a convenient and practical method for the preparation of nitrosyl chloride is described by Francesconi and Bresciani. It is found that carefully prepared animal charcoal exerts a very considerable catalytic influence on the combination of nitric oxide and chlorine, the temperature most favourable for the reaction being 40° to 50° C. Below 35° and above 70° C. the influence of the catalyser is much less marked.

SEVERAL observations are to be found in the literature which indicate that hydrobromic acid at 1000° C. and hydrochloric acid at 2000° C. are perceptibly dissociated into the elements. The direct quantitative measurement of the extent of dissociation at these high temperatures has not yet been found possible. In the *Zeitschrift für physikalische Chemie* (vol. xlix. p. 70), Messrs. Bodenstein and Geiger have, however, calculated the percentage dissociation from known experimental data, the numbers obtained being :—

	1000° abs.	2000° abs
Hydrobromic acid	0·18 per cent.	6·0 per cent.
Hydrochloric acid	0·002 ,,	0·8 ,,

IN the current number (vol. xlix. p. 162) of the *Zeitschrift für physikalische Chemie*, Dr. P. P. Fedotieff gives an account of an investigation of the ammonia-soda process from the standpoint of the phase rule. According to the experimental data, it is theoretically possible to convert 80 per cent. of the sodium chloride used into bicarbonate, and in practice the yield under favourable conditions should not fall below 70 per cent. It is interesting to note that, from a purely chemical standpoint, the Solvay process, in which ammoniacal brine is treated with carbonic acid, is not the best form of the process. The author concludes from his measurements that the treatment of sodium chloride solution with solid ammonium bicarbonate is to be preferred.

AN account of milk investigations at Garforth is given by Dr. C. Crowther in the *Transactions* of the Highland and Agricultural Society of Scotland for 1904. It is found that change from a highly nitrogenous diet to one relatively poor in nitrogen causes secretion of a larger quantity of milk, but the milk is poorer in fat, the change in the fat-content being much more pronounced in the morning than in the evening milk. During the summer months of 1901, 1902, and 1903, the average percentage of fat in the morning milk of the Garforth herd was found on most days to fall below the standard of 3 per cent. embodied in the regulations for the sale of milk at present in force.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN SEPTEMBER :—

Sept. 2. 11h. 55m. to 12h. 34m. Moon occults σ^2 Tauri (mag. 4·8).
6. Saturn. Major axis of outer ring=42″·96. Minor axis of outer ring=11″·67.
,, 9h. 53m. Minimum of Algol (β Persei).
9. Total eclipse of the Sun, invisible at Greenwich.
15. Venus. Illuminated portion of disc=0·947, of Mars=0·972.
23. Sun enters Libra: autumn commences.
,, 12h. 18m. Neptune's satellite at eastern elongation.
26. 10h. Jupiter in conjunction with Moon. Jupiter 1° 52′ N.
,, 10h. 42m. Neptune's satellite at western elongation.
,, 11h. 36m. Minimum of Algol (β Persei).
29. 8h. 25m. Minimum of Algol (β Persei).
,, 9h. 17m. to 10h. 2m. Moon occults γ Tauri (mag. 3·9).
,, 12h. 33m. to 13h. 8m. Moon occults 71 Tauri (mag. 4·6).
,, 13h. 40m. to 14h. 57m. Moon occults θ^1 Tauri (mag. 3·9).
,, 13h. 50m. to 15h. 0m. Moon occults θ^2 Tauri (mag. 3·6).
,, 18h. 42m. to 19h. 10m. Moon occults α Tauri (mag. 1·1).
30. 11h. 15m. Inferior conjunction of Sat. IV. with Jupiter.

CATALOGUE OF STARS NEAR THE SOUTH POLE.—No. 1, vol. liii., of the Harvard College Observatory *Annals* contains the results obtained during a photographic investigation of the positions of about 200 stars, all of which are situated within half a degree of the South Pole. The positions were measured on negatives enlarged six times from the originals, and nine stars from Gilliss's "Catalogue of 16,478 Southern Stars" were taken as standards.

During the discussion of the results it was found that the values of the residuals exhibited marked gradation, depending on the magnitudes of the stars; the differences were seen to be serious in the final results, and were not eliminated by reversing the plate during the measurements.

A table of magnitude corrections was therefore prepared by graphical methods, and, when applied, reduced the average deviation of the value of the x coordinate from the normal, from $\pm 0''{\cdot}68$ to $\pm 0''{\cdot}36$.

This result was so important that the corrections were also applied to the results given in a similar catalogue for stars near the North Pole, which was published in No. 1, vol. xlviii., of the *Annals*. The resulting corrections are now published in No. 2 of vol. liii.

ANNUAL REPORT OF THE PARIS OBSERVATORY (1903).—The annual report of the Paris Observatory for 1903 was presented to the council by M. Loewy, the director, on March 22.

Among other matters it gives a detailed account of the work accomplished last year in connection with the International Chart and the Eros observations for the re-determination of the solar parallax.

In connection with the former work, thirty-five charts, showing the triple images of some 47,300 stars, have been distributed, and it is hoped that the second volume of the photographic catalogue will be published during the present year.

For the Eros campaign, 10,858 photographic observations of comparison stars and *étoiles de repère*, 284 photographic determinations of the equatorial positions of the planet, and 281 visual micrometric measures, were made during last year.

The seventh part of the "Atlas de la Lune" was published, and the plates show very plainly the marked inferiority of eye observations, as compared with photographs, of our satellite. Several interesting points in selenography, such as the absence of water and the presence of an atmosphere at a remote period, were deducible from the photographs.

The report also gives the details of the large amount of routine work done in the different departments during the past year, and concludes with a bibliography of the published results.

Three important pieces of work, based on novel methods, are to be undertaken in the near future. The first will deal with the determination of latitude and its variations, the second with precise measures of the constant of aberration, and the third with the application of M. Lippman's photographic telescope to meridian observations.

PHOTOGRAPHIC MAGNITUDES AND PLACES OF 350 PLEIADES STARS.—Mr. Dugan publishes the magnitudes and places of 350 stars situated in the Pleiades, which he has obtained from measurements of several plates of the region, in No. 3964 of the *Astronomische Nachrichten*. The star-places are given for 1900, and a chart showing the catalogue number placed against each star image accompanies the paper.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. F. C. WILLCOCKS, demonstrator in entomology and botany at the South-Eastern Agricultural College, Wye, has been appointed entomologist to the Khedivial Agricultural Society at Cairo.

MR. A. LAUDER, assistant lecturer and demonstrator in chemistry at the University College of North Wales, Bangor, has been appointed lecturer in agricultural chemistry at the Edinburgh and East of Scotland College of Agriculture; and Mr. F. E. Rees, assistant lecturer and demonstrator in physics, has been appointed inspector of secondary and technical schools under the Glamorganshire County Council.

IT has been resolved by the Senate of the University of London that the Preliminary Scientific Examination be in future designated the "Preliminary Scientific Examination, Part i.," and the examination in organic chemistry for medical students be designated the "Preliminary Scientific Examination, Part ii." Students are to be permitted to present themselves for Part ii. after an interval of not less than six months from the date of passing Part i. Internal and external students in the Faculty of Medicine who have passed in physics, or chemistry, or botany and zoology, at the final B.Sc. examination will be exempted from examination in the subjects in which they have already passed. Such students, if they have passed in chemistry at the B.Sc. examination, will be excused inorganic chemistry in Part i. and also Part ii. of the Preliminary Scientific Examination. No exemption in biology at the preliminary examination will be granted to students who have not passed in botany and in zoology either at an intermediate examination in science or agriculture, or at the final B.Sc. examination. In future internal and external candidates for Part i. will be required to present themselves for examination either in inorganic chemistry and physics taken together, or in biology, or in all three subjects; but if they fail in any one subject they will be permitted to present themselves for re-examination in that subject taken alone.

MR. FREDERICK SODDY has concluded a series of university extension lectures in Western Australia. The last lecture was delivered on July 23, and on this occasion the Premier of the colony, Mr. Walter James, in proposing a vote of thanks to Mr. Soddy, referred to the desirability of establishing a university in Western Australia. During the course of the last twelve months one distinct step has been taken in advancing the movement by the passage of the University Endowment Act. Endowment trustees have been appointed, and in these trustees some 700 or 800 acres of land have been vested, which promise to give the future university the richest endowment enjoyed by any university in Australia. They were very apt to think, Mr. James continued, that no university could be established unless they first expended a large sum of money in an elaborate building. He wished only they could convince the residents of Western Australia that so long as they had efficient workshops for their professors, the sooner they commenced to get their professors the sooner could they begin the work of the university, without money overburdening it in the first instance. Mr. Soddy's visit has done good in bringing home more thoroughly than before how necessary it is that the establishment of this university should be commenced without undue delay.

SOCIETIES AND ACADEMIES.

EDINBURGH.

Royal **Society**, July 4.—Prof. Geikie in the chair.—Prof. Cunningham read an obituary notice of the late Prof. His, honorary fellow.—Dr. J. **Halm**, in a note on the structure of the series of line spectra, gave an interesting extension of Balmer's formula for the distribution of lines in a spectrum. Various other formulæ have been given by Rydberg, Kayser and Runge, and others, but none are satisfactory in the sense of being applicable to all substances. Balmer's formulæ for the two hydrogen series may be put in the forms $1/n=am^2$, and $1/n=a(m-\frac{1}{2})^2$, where a is a constant and n is the difference of the oscillation frequencies of the last line of the series and of the mth line in the spectrum. Dr. Halm finds that the series of any other substance can be represented with great accuracy by either of the formulæ $1/n=am^2+b$, $1/n=a(m-\frac{1}{2})^2+b$, where b is a constant characteristic of the particular substance. The whole sets of series for all substances may be represented very concisely by a geometric figure consisting of one set of radiants and a set of transversals each one of which corresponds to the line spectrum of a substance.—Mr. J. R. **Milne** described some of the modifications of his new form of spectrophotometer for measuring the light absorption of dilute solutions. The main feature considered was the use of a Wollaston prism so as to act in the reverse way, that is, to bring together two different rays, instead of separating one ray into two.—The Rev. F. H. **Jackson** communicated a paper giving the complete solution of the differential equation satisfied by his generalised form of Bessel function.

July 18.—Sir John Murray in the chair.—Dr. T. H. **Bryce** read a paper on the histology of the blood of the larva of Lepidosiren (part ii., histogenesis). The paper dealt with the development of the blood corpuscles, and was fully illustrated with lime-light projections. One of the most important results concerned the origin of the leucocytes. They were found arising *in situ*, before the appearance of thymus or spleen, in specialised tracts of the mesenchyme, first in the splanchnic layer and slightly later in the tissue round the nephric tubules.—Mr. J. R. **Milne**, in some notes on experiments in spectrophotometry, gave an account of his method for obtaining what might be called an artificial line spectrum, and so enabling him to use a powerful and steady source of light. In front of the photographic plate an opaque screen with a series of fine transparent slits was set. Only the parts of the continuous spectrum corresponding in position to these slits were photographed on the plate. When a solution of an absorbent substance was introduced, the spectrum photographed was shortened and a fewer number of lines were photographed; but by widening the slit and so increasing the intensity of light it was possible to obtain the original length of spectrum. In this way, in terms of the intensities of light, an estimate of the absorbing power of different solutions could be obtained, probably quite as accurate as by any of the other known methods.—In a note on the magnetic condition of nickel demagnetised by decreasing reversals, Mr. J. **Russell** discussed the production of magnetisation at right angles to a magnetising force which is made to act upon a toroidal tube of nickel after the metal has been demagnetised by reversals. The force was applied at various orientations relatively to the direction of the original magnetisation, which was apparently destroyed by the reversals. Results for iron have already been published, and the results for nickel are similar, though differing considerably in detail. Thus in nickel the transverse induction is much smaller than in iron, being roughly speaking about a twentieth. Also the maximum, which in the case of iron is obtained when the applied field makes an angle of 45° with the original direction of magnetisation, is obtained in the case of nickel at other orientations.—Prof. **Chrystal** read a paper on some particular results in the theory of seiches. The differential equation of free oscillations of a lake of water was found to be capable of a comparatively simple solution when the longitudinal section of the lake was bounded below by a parabola, either concave or convex upwards. The solution was obtained in the form of series which were particular cases of hypergeometric series, but which do not seem to have been discussed. They had properties which were analogous to the properties of sines and cosines, and the functions were accordingly named the seiche-sine, the seiche-cosine, and the hyperbolic seiche-sine and seiche-cosine. In a particular case of special interest in the seiche problem the roots of the cosine and sine are the products 1·2, 3·4, 5·6, &c., and 2·3, 4·5, 6·7, &c., respectively, and this corresponds to the case of the concave parabolic bottom. The roots for the hyperbolic function are not so easily found. They correspond to the case of the convex parabolic bottom, that is, a lake with a shallow in the middle and deeper parts towards the ends. Some promising applications of the investigations have already been made, and it is hoped that when more experimental data are accumulated in regard to the periods of the uni-nodal, bi-nodal, tri-nodal, &c., oscillations, a real explanation of the seiche phenomena will be obtained.

PARIS.

Academy of Sciences, August 22.—M. Mascart in the chair.—The flow of underground water: J. **Boussinesq**. A continuation of preceding papers on the same subject.—On stelliform or ramefied cartilage: Joannes **Chatin**. This type of cartilage has been found in the larynx of a mammal.—Thermoelectric inversion and the neutral point: G. **de Metz**. Previous researches have indicated two simple relations between the temperature of inversion and the neutral point. The author has examined the behaviour of several couples at temperatures down to −185° C., and has found that these equations hold only for the platinum-zinc couple. This couple is therefore valuable for the measurement of low temperatures.—The study and synthetical preparation of some symmetrical cyclic thio-ureas: Emm. **Pozzi-Escot**. The primary amines react with carbon bisulphide in alcoholic solution in presence of caustic potash, with evolution of sulphuretted hydrogen. Details are given of the properties of several of these thio-ureas.—On the freezing point of milk in health and disease: MM. **Giraud** and **Lasserre**. Milk from healthy subjects has a freezing point of −0°·55 to −0°·56. In the case of diseased subjects the freezing point is slightly lower, −0°·58 to −0°·61.

SOCIAL TYPES AND SOCIAL SELECTION.

Aspects of Social Evolution. First Series. Temperaments. By J. Lionel Tayler, M.R.C.S. Pp. xxviii+297; illustrated. (London: Smith, Elder and Co.) Price 7*s.* 6*d.*

ARE they not methodologically equivalent, the three systems of classification—(*a*) of plants into herbs, shrubs and trees; (*b*) of animals into birds, beasts and fishes; and (*c*) of humans into the sanguine, the lymphatic, the bilious and the melancholy? Why, then, is it that science, having long ago given us a *Systema Naturae* and a *nomenclature botanicus and zoologicus,* still leaves us almost without the rudiments of a *Systema Hominis* and a *nomenclature sociologicus?* It may be asked in reply, What of the anthropologists and their half century of taxonomic labours in the name of science? But the anthropological classifications belong, in appearance at least, to natural and not human history. They do not rise through psychology into sociology. It is true the biologist rejects them, and must continue to do so, as long as the anthropologist cannot formulate his fundamental concept—that of race—in biological terms. Of late the anthropologist has shown signs of attaching himself to the psychologist; and this suggests another form of the initial question, Why have anthropologists not endeavoured to formulate even a provisional classification of psychological types? Why have they, with unconscious naïvete, been content to accept implicitly the popular classification that traditionally survives from early Greek thought? To this question the positivist will be ready with his answer, but perhaps it were wiser to leave it as a shameful reminder to the laggard sociologist.

During the past few years there have appeared, notably in France and in America, a considerable number of systematic studies of psychological types. Dr. Tayler's book is the first systematic endeavour towards taxonomic psychology in this country. Written without reference to foreign sources, it testifies the more convincingly to the presence of a general movement of thought. Though tardily manifesting itself here in systematic form, yet the movement is conspicuously marked by British initiative. By postulating (in "Hereditary Genius," 1869) the variability of psychological type and the correlation of this variability with national history, Francis Galton made a pioneer advance of the first importance in linking psychology with sociology and both with biology. A way was thus opened for several new lines of research, of which some have been considerably developed. Of these two only call for reference here—(*a*) taxonomic studies of character and temperament, alluded to above as being prosecuted mainly by French psychologists like Paulhan, Ribèry and Fouillée, and by American sociologists like Giddings, Patten and Adams; and (*b*) evolutionist studies seeking to decipher selective processes in history and in contemporary civilisation whereby certain types are eliminated and others encouraged. Of these latter investigators, notable examples are Lapouge, Seeck, Ammon, Hansen, &c.

Dr. Tayler's book belongs to both these lines of research, and contributes original material—both observational and speculative—to each. To the more taxonomic side, Dr. Tayler contributes (*a*) studies of several selected types affirmed to be of a highly representative social character; (*b*) the suggestion that the functioning of certain glands (especially the sexual ones) is a main factor in determining temperaments, and hence the idea that from this source are derivable principles of division for a natural classification of temperaments. To the more evolutionist side Dr. Tayler contributes the conceptions of domestic selection and occupational selection as dominant factors in that complex of historical processes which collectively are increasingly described as social selection in contradistinction to natural selection.

The salient feature of the book is the contrast set up between two opposed series of types. The one series is composed of variants on the type generalised by popular observation in the "John Bull" concept. The other series, in contrast to the first, is characterised by (*a*) a more delicate and complex physiological organisation attuned to an increasing complexity of environment; (*b*) a more complete and subtle sexual differentiation, both physical and psychical; (*c*) a relatively greater subordination of carnal to culture interests; and (*d*) readier response to the social ideals created by art, sanctioned by religion, formulated by science. For these two contrasted series of sociological types observable in contemporary western civilisation, Dr. Tayler uses the titular designation of "primitive" and "evolved." While remaining true as a general characterisation, yet these words will need to be supplemented by more specific designations should a sound working hypothesis result from Dr Tayler's observations. Mr. Galton's coinage, eugenics, having been widely accepted, suggests further utilisation. In respect of the robuster, coarser, more carnal and materialist type, the word palæogenic would at once resume its observational basis and leave scope for further terminological development in the study of type variants and their social environment. In the same way the correlative word neogenic would designate the contrasted order, whether of environment or of organism, characterised by the finer, subtler, more cultural and idealist type.

Grant the conception of the two contrasted series of palæogenic and neogenic types as a fundamental principle of division in the classification of human types of character, and the centre of interest shifts to other than taxonomic issues. What, we ask, is or can be known of the historical development of these types in individual and racial evolution; what of the interaction between themselves as individuals and as groups; what of their environmental interrelationships; what of their future phases of evolution; what modification may be consciously devised; what ideals consciously promoted? And, moreover, each of these

questions has to be asked alike on many planes—biological, psychological, economic, ethical, &c. Thus does every initiative in science open up a whole system of new lines of investigation. The student who gives himself to Dr. Tayler's guidance will be carried no little distance along several of these new lines of research; and, moreover, it will be surprising if, after that initiation, the student does not himself acquire the momentum of original investigation, for evolutionist conceptions are applied by Dr. Tayler with a fertility and a novelty as courageous as their results are inspiring.

His evolutionist doctrines cannot be adequately summarised in the space here available. But two of his main contentions may be noted. Looking at western civilisation from the environmental point of view, he sees two large formative processes at work. There is a process which operates in the direction of selecting the palæogenic types and eliminating the neogenic; and there is a process which sociologically runs counter to this, and operates in the contrary direction, tending to select the neogenic types and eliminate the palæogenic. The social environment which, in its characteristic domestic and occupational phases, pertains to the plutocratic and the aristocratic scheme of life is, in point of selective efficacy, stated to be the sociological equivalent of the disease and poverty, the crime and vice of the urban slums. In contrast to the social selection exercised alike by impoverished and luxurious environments, Dr. Tayler finds the counter process in the cultural activities associated with most professional and some artisan occupations.

Such being the speculative foundations, it will be readily seen that Dr. Tayler's practical policy of social progress lies in environmental modification consciously planned by the scientific sociologist. The immediate practical question thus resolves itself into asking who and where is the scientific sociologist and what are his credentials? The human control of environmental modification has hitherto—at any rate since the Reformation—lain with the statesman and politician, and such theoretical guidance as the practical reformer has received from theologian and historian, and in later times from economist and journalist, has not been without a certain element of scientific foundation. But the guidance of a new spiritual order is appearing. Indications of this are visible on all sides. To say nothing of Mr. Wells and other competent popularists, examples may readily be drawn from more recondite sources. By the president of the Scottish College of Physicians, medical men were recently exhorted, with missionary fervour, to organise a crusade for the development of a hygienic conscience. From the rostrum of the Sociological Society Mr. Galton has preached a eugenic conscience. A recent presidential address of the Anthropological Institute came very near to preaching an ethnic conscience; and have not the psychologists for half a generation or more been preaching a pedagogic conscience?

It is indeed manifest that we are here in contemplation of that most thrilling spectacle of human drama—the birth-throes of a new spiritual power. And in the new spiritual orders there will be, as always in the past there have been, individuals of the militant type—brethren not content with crook and cassock, book and bell, but demanding the sword of temporal power. In this respect the observation may be made that great as is the theoretical and scientific interest of Dr. Tayler's book, yet its practical symptomatic interest is perhaps still greater; for it is diffused with the militant spirit, and thus it becomes a matter of political concern to ascertain how many fighting brothers of Dr. Tayler's calibre are to be found in the order of the Neo-æsculapians.

ELECTRICITY, OLD AND NEW.

Propagation de l'Electricité. By Marcel Brillouin. Pp. vi+398. (Paris: A. Hermann.) Price 15 francs.

IN this book we have a reproduction of a course of lectures delivered by Prof. Brillouin at the Collège de France during the session 1902–03. They were presumably addressed to an audience possessing already a fair knowledge of electrical theory. The author, therefore, does not aim at giving a complete and connected account of the subject, but, with a freedom which less fortunate teachers will envy, selects those parts which seem to him most interesting from a historical or theoretical point of view. The subject matter of the course now published falls under two heads; first, an exposition of fundamental principles, characterised by great fulness in the historical setting and originality in the order adopted, and second, a detailed discussion of certain special problems. The style is admirably clear, and the whole book is written with a freshness which makes it very interesting reading.

The title is taken to cover steady as well as varying currents. Accordingly, the first four chapters are devoted to an account of the work of the pioneers, beginning with Cavendish—that wonderful human electrometer who estimated P.D. by the kick in his elbows—and coming down to Kirchhoff and Clausius. The author traces very clearly the gradual progress towards definiteness in the ideas of the magnitudes which figure in Ohm's law. Of Ohm's work a specially full account is given; stress is laid upon the fact that Ohm, in formulating his theories, was influenced constantly by the desire to coordinate experimental results, and was not, as is sometimes represented, guided merely by an *a priori* analogy between thermal and electrical phenomena.

Following this historical introduction we have the development of the theory of conduction in three dimensions. Among the special cases dealt with are the resistance of a circular cylinder treated by Bessel's functions, and the "end-correction" for a wire by Lord Rayleigh's method of approximations.

The discussion of varying currents is next taken up, beginning with the case in which the influence of capacity only needs to be considered. An excellent account is given of Lord Kelvin's theory of the cable.

The author, here and elsewhere, keeps in close touch with the actual experimental conditions, and makes frequent reference to the historic controversies of the early days of long-distance signalling. This chapter is followed by an account of the author's investigation of the electrostatic field associated with a given current system. An interesting special case is worked out in detail, viz., the two-dimensional field produced by a current sheet flowing round an infinitely long cylinder, an impressed E.M.F. being localised in a generator.

In the treatment of induced currents which follows, Prof. Brillouin departs widely from the order of ideas now usually adopted. He confines the discussion to fixed circuits in a uniform non-magnetic medium, and takes as starting point Felici's experiments on the induction of currents in a secondary circuit, by making or breaking a given current in a primary. Proceeding in the old action-at-a-distance manner, he gets first a formula for the inductive action of an element of the primary circuit on an element of the secondary, and from this obtains the coefficient of mutual induction and the vector potential. Some cases of induction coefficients are worked out, and then follows an exhaustive and critical analysis of Kirchhoff's great memoir of 1857, in which the finite rate of propagation of electric effects along a wire was established.

Perhaps the most novel feature of the book, at least to an English reader, is the way in which the question of open circuits is approached. The author begins by adding to his vector potential a term which goes out on integrating round a closed path. This term is affected by an arbitrary constant which appears also in the complete electric force derived from the new vector potential. The value of this constant is then chosen so as to make the divergence of the electric force still equal to 4π times the charge. This preserves what the author calls the "unity of the electric force," *i.e.*, it makes the ponderomotive force on unit charge identical with the current-producing force which enters into Ohm's law. When we have reached this point we find that the new term in the vector potential has given us Maxwell's displacement current. It is then shown that its identification as a true current makes all currents closed, and is justified by its electromagnetic effects. The magnetic force is then introduced "pour la commodité de langage," as the vector the time-rate of which is the curl of electric force; and such things as magnet-poles need not exist at all.

To readers brought up on Maxwell and Heaviside this electrostatic method of arriving at things will come as a sharp disturbance to the "normal piling" of their electrical ideas. A similar disturbance would be produced in the theory itself by the introduction of a little iron into its system. We shall probably understand the reason for the adoption of this procedure if we remember that Prof. Brillouin wrote when "l'affaire Crémieu" was at its height, and before Pender crossed the Atlantic to see what the matter was. An exposition which linked Maxwell's views to the earlier theories was specially natural at that time, in view of the doubts suggested touching relations which had come to be regarded as the "solid ground of Nature." If a revision of belief had been shown to be necessary, some such harking-back to earlier positions as is displayed in the present book would have become essential.

The concluding section of the lectures is occupied with a discussion of the problems of the Hertz oscillator and of the oscillations proper to spherical and spheroidal conductors. A full account is given of the recent work of Prof. Pearson and Miss Lee on the field of the Hertzian doublet as modified by the damping of the oscillations. In the discussion of the spheroid the author supplements the work of Abraham and Maclaurin, specially in the direction of numerical evaluation of the functions involved.

W. B. M.

MILK IN RELATION TO DISEASE.

Bacteriology of Milk. By Harold Swithinbank, of the Bacteriological Research Laboratory, Denham, and George Newman, M.D., D.P.H., Medical Officer of Health of the Metropolitan Borough of Finsbury, and formerly Demonstrator of Bacteriology in King's College, London. With special chapters also by Dr. Newman on the Spread of Disease by Milk and the Control of the Milk Supply. Pp. xx+605; illustrated. (London: John Murray, 1903.) Price 25*s.* net.

THE public is beginning to recognise the importance of milk and its products from the dietetic and hygienic point of view, and public authorities are becoming alive to the necessity for safeguarding the milk supply from adulteration, from the addition of preservatives, and from contamination with filth and the germs of disease. The appearance of this work, a large volume of 600 pages, is therefore opportune. It is a treatise on milk in its relation to disease rather than, as its title implies, an account of the general bacteriology of milk, for while such subjects as the souring of milk and the various fermentations it undergoes are dealt with in 55 pages, tuberculosis in relation to milk, epidemics of disease due to infected milk, the legal enactments regulating milk supply, &c., occupy some 350 pages.

As a general criticism, in the reviewer's opinion some of the matter introduced might without detriment have been omitted, thereby giving more space to certain subjects that at present receive somewhat scant treatment. Thus an attempt has been made to deal generally with bacteriological technique, the preparation of culture media, and examination of water and air, instead of limiting the matter in these directions to that special to the subject. The pages on the agglutination reaction, on preventive inoculation in enteric fever, and on the bacteriological diagnosis of diphtheria seem to be quite unnecessary. The chapter on the description of species of milk bacteria, occupying some 60 pages, also gives for the majority

of species so few details that in its present form it is of little value. This may be the fault of the subject rather than of the authors, but had an attempt been made to give a key-index to the species and their recognition, this would have been of much use. With these reservations, the authors are to be congratulated on having produced a work which must for some time to come remain the standard one on the subject.

The tubercle and acid-fast bacilli met with in milk and the biology of the tubercle bacillus are fully and adequately treated, and a number of coloured and other illustrations of cultures and colonies are given which will be of the greatest service to those who are unable to consult original papers. As regards the relation of bovine and human tuberculosis, a judicial and judicious summary is given, and the authors express the provisional opinion "that tuberculosis in all animals is generally one and the same disease, but that it differs in various ways in different animals and according to the strain and virulence of the infecting bacillus. That human tuberculosis can be transmitted in certain circumstances to animals we do not doubt. There is also *prima facie* evidence to show that the reverse proposition is true, namely, that under certain conditions bovine tuberculosis is transmissible to man. We therefore look upon the two diseases as different species or varieties of one and the same generic disease and intercommunicable. Whilst we hold this view in respect to the communicability of tubercle, we do not for one moment suppose that its transmission through milk is very frequent or very widespread. The great field of infection in tuberculosis is from animal to animal, and from man to man, and cross-infection is probably less common than is generally supposed."

This opinion practically coincides with that expressed in the recent report of the Royal Commission on Tuberculosis. Dealing with outbreaks of epidemic disease due to an infected milk supply, scarlatina, enteric fever, diphtheria, epidemic diarrhœa, cholera, &c., receive attention, and the details of many of the principal outbreaks are summarised. As regards the celebrated Hendon outbreak of scarlatina, the whole of the facts is stated, and not a portion only, as is generally the case, and the authors conclude, "we are of opinion that the exact origin of the London epidemic at that time has not yet been, and now probably never will be, demonstrated." It is to be hoped that future writers on the subject will note this.

The last portion of the book deals with the control of the milk supply (*a*) by the State, and (*b*) by private enterprise, with useful appendices on legal enactments and model regulations for dairies, &c. The summary on milk legislation in the various countries of the world is especially to be commended. Tuberculin is touched upon, and the old and the new tuberculins are described, but no mention is made that it is the *old* tuberculin which is employed for cattle testing. The sections dealing with pasteurised and sterilised milk are very brief, and might well be expanded in a future edition, while condensed milks seem to be unnoticed. The book is well produced and illustrated, but the index might with advantage be fuller.

R. T. HEWLETT.

OUR BOOKSHELF.

Handbook to the Natural History of Cambridgeshire. Edited by J. E. Marr and A. E. Shipley. Pp. viii+260: (Cambridge: University Press, 1904.) Price 4s. net.

THE little volume before us affords an excellent example of the thorough-going and careful manner in which every detail connected with the late meeting of the British Association at Cambridge was thought out and worked out by the responsible executive. As a matter of fact, the volume in question is likely to be much more than a mere ephemeral production, and will probably take its place as one of the standard text-books in the scientific teaching of the university; for it will scarcely be disputed that a thorough knowledge of the natural history of the district in which the student resides is one of the very best aids towards attaining a comprehensive grasp of biology and geology in general. The term natural history, it should be mentioned, is employed in this work in its very widest and most extensive sense, embracing not only zoology and botany, but likewise geology and palæontology; while the scope of the undertaking is still further increased by an excellent chapter on prehistoric archæology.

For the planning and supervision of a work of this nature no better editors could possibly have been found than Messrs. Marr and Shipley, the one gentleman being an eminent authority on geology in general, and that of the district in particular, while the other is no less distinguished as a biologist. Dr. Marr, in collaboration with Mr. Fearnsides, has contributed the introductory chapter on physiography, but Mr. Shipley has contented himself with purely editorial functions. For the other chapters of the work the editors have been fortunate in securing the (gratuitous) services of a number of specialists, at least two of whom happened to be engaged on the natural history of Cambridgeshire for the "Victoria County History," and were permitted by the council of that undertaking to make use of their labours for the benefit of the volume before us. Hitherto no complete lists of the fauna of Cambridgeshire appear to have been published, and Mr. H. H. Evans's account of the birds of the county may be cited as an excellent example of the manner in which such local faunas should be described. It was somewhat unfortunate that in the account of the vertebrate palæontology of the county the introduction of a personal element was unavoidable; but the proposal contained therein, to name a species after the well known palæontologist whose work is criticised, may be taken as an indication of the absence of any trace of ill-feeling on the part of the writer.

Both editors and authors are to be congratulated on the production of such an excellent and comprehensive local "natural history" in such a smal compass, the permanent value of the work being largely increased by the beautifully coloured geological map of the county.

R. L.

Theorie der Elektrizität und des Magnetismus. By Dr. I. Classen. Band i. Electrostatik und Electrokinetik. Pp. x+184. (Leipzig: G. J. Göschen, 1903.)

THE conventional text-book of electricity starts with the supposition that the forces exhibited by electrified bodies can be attributed to a something called electricity which resides on material bodies. Quantitative laws are developed, and we are led up to the Faraday-Maxwell conception of the medium as the real seat of electrical action.

Prof. Classen, like many others, finds this method unsatisfactory. The first view presented is too narrow; its arbitrary character cannot always be realised, the

development is often hap-hazard, and the mental revolution required before Faraday's idea can be assimilated generally proves troublesome to the student.

The author's view, then, so far as we can gather, is that the subject should be developed from Faraday's standpoint. With this we are in complete sympathy. But the problem of writing a text-book from a new order of thought is no easy matter, and the first portion of the volume is distinctly disappointing. There are frequent relapses to the old method, the treatment is somewhat laboured, and the result, so far from being inspiring, is confusing and inconclusive.

In the latter part of the volume the author treats of electrical currents, and the fundamental laws are developed without the introduction of the magnetic properties. This is distinctly good, and, although not quite new, will commend itself favourably to those who take an interest in the philosophical and logical presentation of the subject.

We cannot help thinking that the author is somewhat misguided in pushing a hydrodynamical analogue to the extent he does. It is difficult to reconcile the suppositions that velocity corresponds to electrical force, and pressure to electrical potential. Chapter x. is devoted to "an extension of this hydrodynamical picture." We are of opinion that when an analogy becomes so troublesome that a chapter is required to expound its additional artificial properties, it has ceased to be of any assistance, and the sooner it is dropped the better.

Die Keimpflanzen der Gesneriaceen. By Dr. Karl Fritsch. Pp. iv+188. (Jena: G. Fischer, 1904.) Price 4.50 marks.

The Gesneriaceæ are generally familiar to horticulturists and others, since the order includes several favourite greenhouse plants, to mention only Ramondia, Saintpaulia, Achimenes, Streptocarpus, and Sinningia, of which one species passes as Gloxinia. The morphological peculiarities of these and other less known genera are not so familiar, in fact, it has been the object of Dr. Fritsch to find their correct interpretation by the aid of cultivation and examination of such seedlings as he was able to obtain. Some of the principal morphological features are the tuber-bearing plants of which Sinningia is a type; vegetative scale-covered runners which propagate the plant, characteristic of Achimenes and Kohleria (Isoloma); and the unequal development of cotyledons which is well known to cultivators of *Streptocarpus Wendlandi*. The unequal development of the cotyledons is regarded by the writer as a special case of *anisophylly*, for which he proposes the term *anisocotyly*; in this connection there is a discussion of the views put forward by Wiesner and Goebel on anisophylly, and it is shown that some modification is required in order to explain anisocotyly. A further irregularity in the case of *Klugia Zeylanica* and some species of Streptocarpus is the displacement of the cotyledons from the opposite to an alternate position; this is attributed to the intercalary development of an internode between the cotyledons, to which the name of *mesocotyl* is given.

The scale-bearing runners have been variously described; they resemble bulbs in so far as the leaves are swollen into food reservoirs, but they differ therefrom because the stem is elongated and also contains reserve food material, and the swollen leaves may be closely packed, when the runner resembles a pine cone, or the leaves may be loosely arranged; on this account Dr. Fritsch prefers to call them *bulbshoots* (Zwiebelsprosse), and he would include under this designation the similar bodies which are found on species of Epilobium, Oxalis, Saxifraga, and Dicentra.

Dr. Fritsch confirms Lubbock's statement that the tubers of Corytholoma (Gesnera of gardeners) and *Sinningia speciosa* (Gloxinia) are produced by the thickening of the hypocotyl, and adds that in the case of *Corytholoma cardinalis* the epicotyl also takes part in its formation. It is not possible to mention, much less to pass in review, the various morphological details, but enough has been said to show that the Gesneriaceæ, as an order, will repay careful study, and it should be added that this account of the seedlings is characterised by clearness and breadth of treatment, and the German is simple enough to suit the veriest tyro.

Das Leben im Weltall. By Dr. L. Zehnder. Pp. 125. (Leipzig: J. C. B. Mohr, 1904.) Price 2.50 marks.

Man and animals and plants all live, each in its degree. Lower than these is matter itself. Does it live? Do crystals live in their mother-liquid? In general, is the universe itself a living thing? These are the questions which a professor of physics of Munich attempts to answer in this small volume. We learn that the variations of matter, and those variations of plants and animals which are taken as special evidence of their vitality, are linked together in an unbroken chain. On the other hand, an exception is made in respect to the ultimate structure of the atom itself. In fact, a well defined boundary is found to separate substances of which inorganic bodies consist from substances which are necessary for the formation of organic bodies.

We can by no means pretend to have followed all the arguments put forward, even when they have purely physical reference. Thus, the author concludes that the æther has an atomic structure merely on the ground that, having decided that it is a substance, there is neither sense in nor justification for attributing to it any properties except those which other substances possess. This dogmatic style of reasoning is characteristic of the whole argument; and it certainly does not conduce to confidence when matters are discussed with which we are not so familiar.

First Stage Steam. By J. W. Hayward, M.Sc. Pp. 230. (London: W. B. Clive, University Tutorial Press, Ltd., 1904.) Price 2s.

Mr. Hayward is very happy in the treatment of his subject in his "First Stage Steam," written to meet the requirements of the examination of the Board of Education at South Kensington. After a short introductory chapter on mensuration and squared paper work, drawings of a simple horizontal steam engine are given, and the functions of the various parts are described in detail. This description occupies considerable space, and at appropriate intervals is made the occasion for the introduction of experiments and calculations bearing on the subject. The Lancashire boiler with its mountings is then well described, and this leads naturally to the consideration of combustion and the heat properties of steam. The reader is introduced to these by simple and striking experiments which he can make himself, and not until after this has been done is the student informed of the results of classical experiments on which heat calculations of the steam engine are based. The writer then, by the help of good illustrations, touches on the salient points connected with the design and working of modern locomotives, marine engines, internal combustion engines, and steam turbines. The reader is left with the impression that there is very much in the subject worthy of attentive study. A special feature of the book is the encouragement given to quantitative experimental work with simple apparatus which the student can make and use himself. The book is not free from slight defects, but is sure to give satisfaction wherever used.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On the Secondary Radiation due to the γ Rays of Radium.

IN a recent communication to the *Annalen der Physik* (4 and 5, 1904), Paschen described experiments showing that a thick lead block containing radium emits negatively electrified particles which can be deviated in a magnetic field. He concluded that he had deflected the γ rays, thus differing from previous experimenters.

I have found that particles having a negative charge are projected, and are readily deflected magnetically. However, these are not γ rays, but differ from them inasmuch as they are completely absorbed by about a millimetre of lead.

In order to prove this, an electroscope with a thin aluminium face was mounted on a lead platform (1·2 cm. thick) above a block of lead 10 cm. high, at the centre of which was placed 30 mg. of radium. On applying a magnetic field to bend the rays towards the electroscope, the electroscope readings were doubled, but this increase was reduced to half value by a screen of lead (0·1 mm. thick) placed in front of the aluminium face. Since negatively charged particles are thus projected from the lead surface, it is clear that, as Paschen observed, a block of lead, placed in a vacuum and well insulated, would acquire a positive charge, and would continue to do so as long as the radium emitted γ rays, even if these penetrated two or three inches of lead.

The effect which Paschen observed was due not to the primary γ rays, but to the diffuse secondary radiation caused by the γ rays in the lead. This may be shown to be mainly a surface effect, for the secondary radiation from a greater depth than one or two millimetres is absorbed by the lead itself. The curvature of the rays, necessarily implied by Paschen's second experiment, is so large that other experimenters could not have failed to detect it by direct methods had the effect been due to γ primary rays.

This deflection of γ secondary radiation by a magnetic field is similar to Becquerel's result, obtained photographically, when he deflected the β secondary rays. Curie and Sagnac have also shown that Röntgen rays striking a metal cause it to emit negative electricity and to acquire a positive charge; Dorn has proved that such rays can be deflected by a magnet.

Any experiment designed to prove that the primary γ rays can be affected by a magnetic field must involve evidence that the effect produced is not due to the easily deviated γ secondary radiation. A. S. EVE.

McGill University, Montreal, August 22.

A Source of the Ionisation of the Atmosphere.

IT is perhaps not very generally known that human breath has a considerable power of discharging an electrified conductor. This fact can be strikingly shown by an experiment easily carried out. If the discharging knobs of a Wimshurst electrical machine are drawn apart so far that a spark just refuses to pass, then on breathing across the gap the spark is instantly precipitated.

The discharging power of the breath is more conclusively demonstrated, however, by breathing through a metal tube into which an insulated metal rod projects axially, the insulation of the rod being out of reach of the breath. If the rod is connected to the cap of a graduated gold-leaf electroscope, comparative observations show that the rate of discharge of the electrified rod and gold leaves is 60 per cent. to 70 per cent. greater when air from the lungs is passing through the tube than when ordinary air fills it. Again, the rate of leak of a charged electroscope in a small, badly ventilated class-room, was found to be 50 per cent. more rapid when the room was full of students than when it was empty. Incidentally, this explains in part why experiments on electrostatics are often troublesome to carry out in a room crowded with a large audience.

The point of interest, however, in these experiments is the fact that the slow low-temperature combustion going on in the lungs ionises the air in the same way as the rapid high-temperature combustion of flames. And if this slow ionisation of the air can take place in the lungs of living animals, it may also go on less markedly in the chemical interaction between the air and living plants, and in some cases between the air and inorganic matter, at ordinary temperatures, so that there is here a continual source of atmospheric ionisation apart from any possible radio-active processes. J. R. ASHWORTH.

Rochdale, August 27.

Celtic Place-names.

THE review of Mr. Johnston's "Place-names of Scotland" in your number of July 28 explains a problem that has been for a long time a puzzle to me in reference to the existence in County Leitrim alone, of the thirty-two counties in Ireland, of the word "allt" in common parlance.

To North Leitrim there came over from Stirlingshire about the year 1608, as followers and soldiers of Sir Frederick Hamilton, grandson of the second Earl of Arran, a strong Scotch colony. From them we took in a great measure our English or Scotch-English. Here is a trace of it. A half-dozen others of our distinctive Leitrimisms I have already traced back to Scotland; others to elsewhere.

In odd words and odd uses of them, and in odd pronunciations, are found "helpful and interesting sidelights for the historian" (to use the reviewer's expression) all through Ireland. Indeed, the "Irish plantations," and the parts of England and of Scotland the planters came from, might be plotted out by a careful observation of such peculiarities. They are disappearing. Before it is too late, or it becomes too difficult, it would be well worth while for someone who knows the rural districts of both countries intimately to attempt the task. It should well repay the historian or the philologist. I have been trying something like it, but I have had slight opportunity for making the acquaintance of any English dialects except the Yorkshire and the Lancashire, and I cannot accordingly push it very far.

I have to thank the reviewer; but permit me to say that the Leitrim use of "allt" (or "alt") corresponds rather with that given by Mr. Johnston than with that claimed by him. With us an "alt" is not "a streamlet passing through a ravine," but a narrow, deep glen or hollow through which, as a rule, of course, a stream or streamlet flows; but that a stream should do this is not essential for the chasm to be so termed. Joyce, too, would support this. The word *alt*, he states ("Irish Names of Places," p. 353, 1869 edition), is found in townland names in Ireland, and in its topographical application it is generally understood to mean a cliff or the side of a glen.

I should be much interested in knowing if Mr. Johnston would subscribe to our precise application of the word. It is evidently a primitive word of Aryan origin. The meaning of all allied words in any language I am familiar with favours our interpretation, and it is hard to see how it could come by the meaning of "streamlet," however flowing. JOSEPH MEEHAN.

Creevelea, Drumkeeran, Co. Leitrim, August 5.

I HAVE read with much interest your correspondent's letter, and can well understand his difficulty with regard to the Scottish usage of the word *allt*. Here it is applied, as I have stated, to a stream passing through a ravine or hollow; never, so far as I am aware, to a glen or dry chasm.

The Irish *alt*, which is slightly different in spelling, is also apparently different in application. Your correspondent may be interested in the various Celtic usages of the word as given by Dr. Macbain in his "Etymological Dictionary of the Gaelic Language":

"Allt, a stream; Ir. alt, height, (topographically) glen-side or cliff; O. Ir. alt, shore, cliff; O. W. allt, cliff; Cor. als; Br. aot, shore, all allied to Lat. altus. The Gaelic form and meaning are possibly of Pictish origin."

Looking down or up the precipitous sides of many a

mountain stream, it is not hard to see how this epithet came to be associated with, and applied to, the stream itself, which is not regarded apart from its peculiar surroundings. The steep sides are, in fact, the characteristic feature of the ordinary Highland *allt*. THE REVIEWER.

The Striped Hawk-Moth.

WITH reference to the paragraph in NATURE of August 18 (p. 389) on the striped hawk moth, on May 23 this year I found a specimen alive in a thick bed of lily-of-the-valley; it had just emerged, and had never flown. Warmwell is two miles from the sea as the crow flies; possibly the parent was a migrant, but the moth I found had passed through its metamorphosis in this country. The insect lived twelve hours after capture, and is now in the collection of Mr. O. Picard-Cambridge, of Bloxworth.

Warmwell, Dorchester. ROSE HAIG THOMAS.

Mountains and Mankind.

I SHALL be obliged if you will allow me to correct the following errata in my address to Section E of the British Association. For "Watson" and "Tokio" read Weston and Kobi (p. 429, column 2).

September 5. DOUGLAS W. FRESHFIELD.

[The errors occur in the copy of the address reprinted in NATURE.—EDITOR.]

BRITISH CHEMICAL EXHIBIT AT THE ST. LOUIS EXHIBITION.[1]

THE Royal Commission appointed to arrange the British exhibits for the St. Louis Exhibition have evidently, from the catalogue before us, carried out their difficult task with great care and in a most successful manner. We would that all catalogues were written in the extremely interesting and vivid style of the one to which we have referred. The products treated of in the catalogue are drawn up in alphabetical order, and at the end of the description of each substance, or group of substances, the names of the exhibitors are placed; the exhibitors are also arranged in alphabetical order at the end of the book.

The catalogue is written in the form of a history of the various manufacturing processes described therein. First and foremost we come to a most interesting and detailed account of the alkali industry, from the time of its inception to the present day. The reader is carried historically through the building up of the Le Blanc process—and the tragic fate of Le Blanc, its founder—the ammonia soda process, Chance's sulphur recovery process, and so on. Many details, which are not the common property of text-books, as to the difficulties and failures and final success are included, which makes the narrative of exceptional interest. Before Solvay's time, several patents had been taken out which embodied the principles of his ammonia soda process, but he, unaware that others had worked upon the subject, experimented and patented the process, and we are shown in his own words what a blow he received on discovering that he was not the first in the field:—

"What was our astonishment in discovering . . . I was no longer the inventor of the reaction and its industrial use had already tempted other investigators. It was a hard blow to me."

Here the narrator intervenes with the pertinent words: "Happily Solvay was young," and finally success attended his efforts. In so far as the ammonia soda process affects the British exhibits, we have to thank the indefatigable energy of Dr. Mond.

As a natural sequence the manufacture of sulphuric acid is treated of in the same section as that devoted to the alkali industry, and after being informed that sulphuric acid was first made by Ward at Richmond in 1740, we are taken through the gradual development of the chamber process, and then introduced to the contact process, which may be said to have been originally founded on an experiment of Humphrey Davy in 1817.

The section on alum is very interesting, and one notices how greatly manufacturers in this country are indebted to the acumen of Peter Spence, of Manchester.

One of the most interesting and suggestive sections is that dealing with the coal-tar products. In his report on the 1862 Exhibition, Hofmann spoke with sanguine eloquence of the bright prospects before the coal-tar colour industry in this country. The brilliant anticipations which Hofmann made for England have, alas! not been substantiated, for where we have sown others have reaped. The writer of this section endeavours to trace some of the causes which underlie the loss of the colour industry to England—such as the inadequate patent laws, want of research, which really means want of sufficient capacity for looking ahead.

To the electrochemical industry are devoted nine pages of the catalogue, which, commencing with an historical survey of the foundation of electrochemistry, passes on to deal with hypochlorites, chlorates, caustic alkali, and sodium. Then follows a description of the copper refining processes, and on p. 87 we are told that other metals, such as gold and silver, have been purified by electrolytic processes. As these have not been done in the United Kingdom, this is evidently in the nature of a hint to British electrochemists. A passing reference is made to the manufacture of calcium carbide, which, we regret to say, is at present not manufactured in this country.

We have only picked out a few of the subjects treated of in the catalogue; there are, of course, many others, such, for example, as explosives, the candle industry, soap, oils and colours, and so on.

There are also a good many scientific exhibits, among which may be noted Sir James Dewar's low temperature research exhibit, in which the complete plant, as employed at the Royal Institution for the production of liquid and solid hydrogen, is shown. Photographs of spectra by Mr. E. C. C. Baly, exhibits from the Lister Institute of Preventive Medicine, also a very complete exhibit from the Wellcome Research Laboratories, and many others which space forbids us to mention.

We do not know whether the catalogue is on sale in this country, but we recommend all interested in the manufacturing and scientific advancement of the country to endeavour to procure a copy; because the exhibits demonstrate that, in spite of the keen competition of Germany and other nations, Great Britain can still claim to be high up in brilliant achievements in chemical and allied sciences. F. M. P.

[1] Catalogue of British Exhibits; International Exhibition St. Louis, 1904. Department C, Liberal Arts; Chemical and Pharmaceutical Arts. Issued by the Roya Commission.)

THE LIMNOLOGICAL STATIONS ON THE LAKE OF BOLSENA.

TWO years ago the executive committee of the Italian Geographical Society determined to undertake the desirable work of preparing an exhaustive monograph on one of the lakes of Italy, and they very naturally selected the Lake of Bolsena for the purpose. Its situation within easy reach of Rome,

its size, depth, and geological relations, the beauty of its environment, and the unique charm of the two picturesque volcanic islets Martana and Bisentina, all combine to render the lake attractive.

Before the preliminary operations of the Geographical Society, very little was known about the lake except with regard to the geology and morphology of its basin; the contours of the bottom had been carefully mapped by De Agostini, who had made no fewer than 3000 soundings. No regular observations of the seasonal temperatures of its waters or of the variations in their level, of *seiches* or of lacustrine plankton, had ever been carried out.

From a preliminary report prepared by Prof. Luigi Palazzo,[1] we learn that limnological stations equipped with Sarasin's limnograph and with other instruments have been established on opposite sides of the lake at Bolsena and at Marta, and that at chosen points in the immediate vicinity five meteorological stations are to yield continuous records of the rainfall and air temperature. A gauge for measuring the height of the water has also been fixed to a pier in the Fiume Marta.

One of the most interesting phenomena of which a continuous record will be kept are the *sesse* or *seiches*, the rhythmical oscillations of the surface of the lake,

FIG. 1.—Isola Martana.

which have a regular period of 12 to 15 minutes, and are more conspicuous at Marta than at Bolsena, apparently on account of the position of the former village nearer the major diameter of the lake, and on account of differences in the declivity of the bottom. A rise of the water of 7 inches at Marta was noticed to be correlated with a rise of only 4 inches at Bolsena. On occasions the rise of water may amount to a foot, and the seiches are then so noticeable that the common folk, in their expressive dialect, declare that the lake is panting (*trenfia*).

We hope that the full reports on the physical problems connected with the lake may soon appear, and that the investigation of the plankton will not be forgotten.

R. T. GÜNTHER.

NOTES.

IT is proposed to fix a standard time for use upon all Indian railways and telegraphs, which shall be exactly $5\frac{1}{2}$ hours in advance of Greenwich time, and to fix for Burma a standard $6\frac{1}{2}$ hours in advance of Greenwich. The Government of India has intimated that it is in favour of the adoption of the new standard for general as well as for railway and telegraphic purposes, and is prepared to cooperate in any movement with this end in view; but as the matter is one upon which the local communities should be consulted, the opinions of the Chambers of Commerce upon the proposals are being sought by the Government.

[1] "La Stazione Limnologica di Bolsena." Pp. 19; 9 figs. 1 pl. (*Boll. Soc. Geogr. Ital.*, v. 1904.)

THE death is announced of Dr. Petr Petrovic van der Vliet, emeritus professor of physics at the University of St. Petersburg, aged sixty-five.

AT the beginning of next month Prof. H. Battermann, observer at the Berlin Observatory, will take the position of professor of astronomy at Königsberg University, and director of the observatory there.

IN a message from Ponta Delgada (Azores) on September 1, Captain Scott states that the Antarctic ship *Discovery* may be expected to arrive at Spithead about September 10.

A LIFE-SIZED bronze bust of the late Sir Richard Temple was unveiled last week in the parish church of Kempsey, near Worcester, by the Earl of Coventry, Lord Lieutenant of Worcestershire. The inscription is as follows:—"The Right Hon. Sir Richard Temple, Bart., G.C.S.I., C.I.E., D.C.L., LL.D., F.R.S., sometime Governor of Bombay and Finance Minister of India, and M.P. for Evesham and Kingston."

THE Chancellor of the Exchequer has appointed the following gentlemen to serve as members of a committee to inquire into the use of duty-free alcohol for industrial purposes:—Sir Henry Primrose, K.C.B., C.S.I., chairman; Sir William Crookes, F.R.S.; Sir W. H. Holland, M.P.; the Hon. J. Scott-Montagu, M.P.; Mr. Lothian D. Nicholson; Dr. W. Somerville; Dr. T. E. Thorpe, C.B., F.R.S.; and Mr. Thomas Tyrer.

THE fifteenth annual general meeting of the Institution of Mining Engineers will be held at Birmingham on September 14. The following are among the papers to be read, or taken as read:—The mining department of the University of Birmingham, Prof. R. A. S. Redmayne; coal-mining in Asturias, Prof. Henry Louis; the problem of Gob-fires, Mr. George Farmer; an improved apparatus for laying the dust in coal-mines, Mr. J. Creswell Roscamp; mine-surveying instruments, part ii., Mr. Dunbar D. Scott; and the problem of dynamic balance, Mr. E. H. Roberton.

THE latest proceedings of the Indian Tea Association contain several items of interest in connection with the proposed scientific experimental station in Assam. We learn from the *Pioneer Mail* that the scientific adviser of the association recently explained his proposals for the permanent location of his assistant in Assam, for the provision of a laboratory for him, and the initiation of experiments in tea culture under his direct supervision and control. An offer has been made by the agents of the Scottish Assam Tea Company to provide a small bungalow and tea for experiment in the immediate neighbourhood of the bungalow, and further land for experiments as required. It was decided to accept the offer of the Scottish Assam Tea Company, and arrangements have been made for the erection of a laboratory.

IN connection with the recent announcement of the death of the Rev. George Pirie, LL.D., professor of mathematics in the University of Aberdeen, the following particulars may be of interest. Dr. Pirie was born at Dyce on July 19, 1843, being the eldest son of the Very Rev. Principal Pirie. His early years were spent at Aberdeen Grammar School,

and he afterwards studied at the university in the same town. In 1863 he entered at Queens' College, Cambridge, and three years later took the mathematical tripos, obtaining the degree of fifth wrangler. He was subsequently elected to a fellowship at Queens' College, where he also held office both as mathematical lecturer and as college tutor. In 1878 Dr. Pirie was elected to the chair of mathematics at Aberdeen University, which he held until his death. Dr. Pirie's interest in mathematics does not appear to have carried him much beyond ordinary routine work, as his name does not appear as the author of papers in the leading mathematical journals to which reference has been made in connection with the present notice. He, however, published one text-book, entitled "Lessons in Rigid Dynamics."

Most of our readers remember that the year 1903 was one of unusually heavy rainfall. "British Rainfall" for that year, recently published, contains tables of nearly 4000 stations, and supplies every possible information upon the subject that can be wished for. The work has been issued in practically the same form since 1861, a fact which, we consider, much enhances its value; but the materials have continually increased, and its size has been doubled in the last thirty years. The volume before us has, moreover, several important additions, *e.g.* a section dealing with the duration of rainfall, and rules for rainfall observers. Special articles deal with the extraordinary excess of precipitation in June (accompanied by useful maps) and with the three wettest years in the annals of "British Rainfall," viz. 1872, 1877, and 1903. Dr. Mill states that only one other year earlier in the nineteenth century can compare with them, and that is 1852. Whereas the average annual rainfall of the British Isles is 39·5 inches, 53 inches fell in 1872, 51 inches in 1877, and 52 inches in 1903, an excess of 32 per cent. The total rainfall over England and Wales during three days, June 13 to 15, is estimated at 5348 million tons.

We have received from the Government Astronomer of Western Australia (Mr. W. E. Cooke) a copy of the meteorological observations made at the Perth Observatory and other places in the colony during 1902. Morning and evening weather forecasts—the latter intended for newspapers—form part of the routine work, and are very successful; in fact, complete failure is of very rare occurrence. In connection with forecasts, Mr. Cooke states that the prediction of rainfall throughout the interior, for several days in advance, was attended with complete success, and that the experiment indicates a forward step in practical meteorology. In addition to monthly and yearly summaries for a number of stations, the report contains coloured maps showing for each month and for the year the mean distribution of the various elements over the whole of the colony.

In a communication to the Société Française de Physique, No. 216, 1904, M. Bouty describes experiments on the dielectric cohesion of argon and mercury vapour. The dielectric cohesion of argon is exceptionally small, its value being only about one-seventh of that of hydrogen. The smallest trace of impurity increases the value, and the author recommends the measurement of the dielectric cohesion as a means of testing the purity of argon, the sensitiveness of the test being comparable with that of the spectral examination.

We have received from the author, Dr. F. Braun, a reprint of an important paper appearing in the *Physikalische Zeitschrift* (No. 8, pp. 194–9) entitled "Methoden zur Vergrösserung der Senderenergie für drahtlose Telegraphie." Dr. Braun discusses the limits of the possible increase of capacity and voltage—and therefore of energy—of the usual sending devices employed in wireless telegraphy, and describes many new arrangements consisting of combinations of capacities and inductances for which considerably greater efficiency is claimed.

Dr. Braun also sends us a copy of an article on "Herstellung doppelt brechender Körper aus isotropen Bestandteilen" (*Physikalische Zeitschrift*, No. 8, pp. 199–203), in which he suggests that a doubly refracting body may consist in a homogeneous mixture of isotropic particles of two kinds the dielectric constants of which are different, the distribution of the particles being regular, but different in three principal directions. In illustration of the suggestion, experiments are described in which the body consisted of fire-bricks with air spaces between them. On passing plane-polarised electric waves through different thicknesses, the waves on issuing exhibited plane, circular, or elliptic polarisation according to the thickness of the body through which they passed. The experiments were conducted on a somewhat gigantic scale.

In No. 1, vol. ix., of *Terrestrial Magnetism and Atmospheric Electricity*, the aims and organisation of the department of international research in terrestrial magnetism of the Carnegie Institution are defined. The director is Dr. L. A. Bauer. Of the first allotment of 20,000 dollars, one half is to be devoted to office expenses, comprising the reduction, discussion, &c., of existing data, the second half being reserved for observational and experimental work. If satisfactory results are obtained during the first year, the same sum of 20,000 dollars is to be granted annually to the department. The aim of the department is to undertake investigations of an international character which are not specifically the subject of inquiry of any one country, such, for instance, as a magnetic survey of ocean areas and unexplored regions, observations of the variation of the earth's magnetism, and magnetic observations in ocean depths and in atmospheric regions.

We have received Nos. 6 and 7 of the series of monographs now being published under the title of "Attualità scientifiche," by Nicola Zanichelli, of Bologna. No. 6 (pp. 68) is a reprint of a lecture, delivered before the Italian Electrotechnical Association by Prof. Augusto Righi, on our present knowledge of radium. No. 7 (pp. 141) is a useful summary by Lavoro Amaduzzi of the investigations which have hitherto been made of the physical properties of selenium, particularly as regards the variation of its electrical properties under the influence of light; the practical application of the element in the photophone and in telephotography is dealt with in detail. As each monograph is written by a specialist, the series is likely to be of use not only to the general scientific reader, but also to those workers who are investigating the problems dealt with. Thus in the number dealing with radium, there is a description of new forms of the gold-leaf electroscope and of the torsion-balance which are suitable for detecting and measuring minute traces of radio-activity, whilst the treatise on selenium is of particular value on account of the complete bibliography of the subject which it contains. We may note that the earlier numbers of the series deal with the discharge of electricity through gases, with "chemical problems of the new century," with morphological and chemical evolution, and with the biological problem of the determination of sex.

IN the *Zeits. fur Instrumentenkunde* for July Messrs. Elster and Geitel describe a new form of apparatus for measuring the radio-activity of soils and of the mud or sediment of thermal springs. The increase in the conductivity of a constant volume of air, which is caused by its exposure, in a metal cylinder, to the action of the radio-active material, is measured by means of a modified form of Exner's electroscope. The especial features introduced into the electroscope are the insulation of the aluminium leaves by means of amber, and the production by means of metallic sodium of a dry atmosphere in the space in which the leaves are suspended. Measurements which were made of the ionising power and of the rate of decay of the emanation of "fango" or mud from the hot springs of Battaglia, would indicate that its activity is due solely to the presence of radium. In a paper contained in the June number of *Terrestrial Magnetism and Atmospheric Electricity* the same authors put forward the view that the conductivity of the atmosphere is largely, if not entirely, due to a radio-active emanation which issues from the earth's crust. In support of their contention, they have observed that the conductivity of air in closed cellars and in deep holes or wells is sometimes fifty times as great as that of normal air. Their view would also explain the fact that at low barometric pressures the conductivity of the atmosphere is much greater than at higher pressures, for a low pressure would favour the escape, from the fissures of the earth's crust, of the radio-active emanation. It is also possible that the electric phenomena which occur over the crater of a volcano are caused by an active emanation accompanying the vapours issuing from the crater.

WE are indebted to Mr. Quaritch, of Piccadilly, for a copy of a catalogue of rare and valuable works, including many on biological and sporting subjects.

THE report of the Maidstone Museum for 1903 records the capture in Maidstone of an apparently freshly-emerged specimen of the silver-striped hawk-moth (*Chaerocampa celerio*). Although the larva has been from time to time observed in the country, English specimens of this moth are generally considered to be immigrants from the Continent. Other specimens are stated to have been taken in England in 1903, but the last great "celerio-year" was 1885.

THE most striking feature of the report of the Field Columbian Museum for 1902–3 is formed by two plates representing groups—the one of the dibatag, or Clarke's gazelle, and the other of the spotted hyæna—mounted in the museum. Of the dibatag no less than six individuals, of different ages and sexes, are exhibited, one of the bucks being mounted in a characteristic attitude, with the neck and tail erect. It is a matter for regret that funds and space are not forthcoming for mounting groups of this nature in our own Natural History Museum. One day it will be too late to do so. We have also received from the Field Museum copies of two papers by Dr. D. G. Elliot on new mammals.

"DINOSAUR-HUNTING" in the Como Bluffs of Wyoming, according to the graphic description given by Prof. H. F. Osborn in the September number of the *Century Magazine* under the title of "Fossil Wonders of the West," must be an exciting sport, and one in which there are few blank days. The Bone Cabin Quarry, which was accidentally discovered in 1897, seems, indeed, to be the richest deposit of dinosaurian remains hitherto known—so numerous being the weathered-out bones that the shepherds actually built their huts from the vertebræ and ribs. "Here," writes the author, "are the largest of the giant dinosaurs closely mingled with the remains of the smaller but powerful carnivorous dinosaurs which preyed upon them, also those of the slow and heavy-moving armoured dinosaurs of the period, as well as of the lightest and most bird-like of the dinosaurs. Finely rounded, complete limbs from eight to ten feet in length are found, especially those of the carnivorous dinosaurs, perfect even to the sharply pointed and recurved tips of their toes." From this wonderful mausoleum Prof. Osborn estimates that remains of no less than 73 individuals were obtained by his party; but, inclusive of the weathered-out bones, it may be conjectured that the total must have reached at least 100 head. The area probably represents an old river-bar, the still waters of which arrested the course of the carcases on their seaward journey. The paper is illustrated by excellent restorations from the facile pencil of Mr. C. R. Knight.

TWO important contributions to our knowledge of the chimæroid fishes of Japan are made by Prof. Dean in the *Journal* of the College of Science of Tokyo University (vol. xix., articles 3 and 4). In the first of these the author treats of the two Japanese species of true chimæra (*Chimaera phantasma* and *C. mitsukurii*) and their egg-cases. Of the former species it is stated that while sometimes the fishermen will catch from twenty to thirty specimens a day in water varying between 50 and 300 fathoms in depth, on other occasions they do not find a single example for days. Although sluggish in their movements when kept in baskets in shallow water (where they soon die), there is reason to believe that in their normal haunts these fishes display considerable activity. Their egg-cases are larger than those of any other species. In the second memoir, Prof. Dean discusses the structure and affinities of the long-snouted chimæra (*Rhinochimaera pacifica*), which has been made the type of a genus by itself, although there is some doubt whether it is really entitled to generic distinction from *Harriotta raleighana*, obtained in deep water about 1894 by the *Albatross* near the Bermudas. The most interesting feature observed in the type specimen of the former was the complete distinctness of the palato-quadrate-bar from the cranium proper, this being thought at first to indicate that the skull was not of the true autostylic type. Other specimens showed, however, that the feature was not constant, although its existence in even one specimen tends to support the view that the autostylic skull of the Dipnoi is a specialised derivative from the hyostylic type characteristic of the fringe-finned ganoids.

THE most recent addition to the literature of cotton cultivation issued by the Imperial Department of Agriculture for the West Indies constitutes No. 31 of the pamphlet series, and is entitled the "A.B.C. of Cotton Planting." The method is adopted of providing the information in the form of question and answer, which combines brevity and precision.

CONTINUING his researches into the parthenogenetic development of embryos of *Thalictrum purpurascens*, Mr. Overton states in the May number of the *Berichte der deutschen botanischen Gesellschaft* that in these cases no reduction takes place in the number of chromosomes. The list of plants for which parthenogenesis has been established includes *Antennaria alpina*, species of Alchemilla, and *Taraxacum officinale*.

IN the first part of the *Bulletin* of the Imperial Society of Naturalists of Moscow, Mr. J. Gerassimow adds another paper to his contributions to the physiology of the cell. In cultures of *Spirogyra crassa* and allied species he obtained abnormal cells, without nuclei, or with excess of nuclear matter, or with two nuclei, by cooling the cultures in which the filaments were in an active stage of division. The result of changing the proportion of nuclear substance to cell contents was to cause irregularity of growth, so that where the nuclear substance was in excess, cell division was retarded, but general growth accelerated.

WE have received a copy of a pamphlet entitled the "Advantages of Ambidexterity," which may be obtained from Messrs. Sampson Low, Marston and Co., Ltd., price 6*d.* The booklet contains a lecture, delivered before the Ambidextral Culture Society by the honorary secretary, Mr. John Jackson, dealing with the "advantages accruing to any and every individual who may acquire the faculty of using both hands with equal facility."

AN unpretentious magazine has just appeared under the title of *Discovery*; and it merits encouragement because its aims are to publish trustworthy information on scientific and other topics. In the first number, Dr. J. Oldfield writes on diet, Dr. Edith Temple Orme on the modern education of women, Mr. A. A. Buss on spectroscopy, and Mr. A. C. D. Crommelin on the total solar eclipse of August 30, 1905. Other subjects of popular interest are dealt with in shorter contributions. The editor is Mr. G. McKenzie Knight, and the London agents Messrs. Bensberg Bros., 7 Electric Parade, Seven Sisters Road, N.

THE Cambridge Scientific Instrument Company has just issued a useful illustrated list under the title "Technical Thermometry." It is a new, revised, and enlarged edition of an earlier catalogue entitled "The Measurement of Temperature by Electrical Means." Copies of the list may be obtained on application to the company. Among the chief contents may be mentioned sections dealing with electrical resistance thermometers, thermoelectric thermometers, continuous temperature recorders, and electrical resistance furnaces. The excellent illustrations and full descriptions will render the list very serviceable to teachers and investigators.

OUR ASTRONOMICAL COLUMN.

THE LINE SPECTRUM OF COPPER.—Some exceedingly interesting results have been obtained by Mr. A. S. King at Bonn during a detailed study of the line spectrum of copper under many various conditions of arc and spark discharges. Mr. King suggests that an accurate knowledge of the conditions which produce spectral changes can only be obtained by the detailed study of each element under every possible condition of temperature, vapour pressure, and electrical excitation, and to this end he has commenced with the line spectrum of copper.

He found that on using a high voltage, but small current, in producing the arc spectrum, the "spark" lines were shown on his photographs, and he attributes this phenomenon to the frequent interruptions of the arc producing electrical conditions similar to those obtaining in the spark discharge. Again, in the spark, he photographed the spectrum of the green luminous vapour outside the direct path of the spark, and found that whilst the air spectrum was almost entirely eliminated, there were very few changes amongst the intensities of the copper lines. As this outer layer would have, presumably, the same electrical conditions as, but a lower temperature than, the spark track, he suggests that the experiment affords strong evidence that the electrical condition, rather than the vapour density or the temperature, is the governing factor in producing the various types of spectra.

Mr. King gives a table of the lines which he has studied, showing the behaviour of each line under the different conditions, and he also describes the experimental methods and the results obtained when the temperature, pressure, &c., were varied (*Astrophysical Journal*, No. 1, vol. xx.).

EPHEMERIS FOR THE RETURN OF ENCKE'S COMET.—A further extract from the ephemeris for the approaching return of Encke's comet, published by MM. Kaminsky and Ocoulitsch in No. 3962 of the *Astronomische Nachrichten*, is given below:—

Ephemeris oh. (M.T. Berlin).

1904	α (app.) h. m. s.	δ (app.) ° ′	log r	log Δ
Sept. 8	1 49 33	+24 59	0·3183	0·1097
,, 12	1 46 38	+25 34	0·3094	0·0828
,, 16	1 43 6	+26 8	0·3002	0·0551
,, 20	1 38 20	+26 41	0·2906	0·0266
,, 24	1 32 21	+27 12	0·2806	9·9974
,, 28	1 25 1	+27 40	0·2702	9·9677
Oct. 2	1 16 12	+28 3	0·2593	9·9377

According to the above, the comet should apparently be situated about half-way between β Arietis and α Triangulum on September 18, and, travelling thence in a W.N.W. direction, it should arrive very near to υ Piscium on October 2.

SUPPOSED RELATION BETWEEN SUN-SPOT MINIMA AND MAXIMA INTENSITIES.—From an analysis of Wolfer's relative numbers, M. Angot believes that he has discovered a connection between the intensity of a sun-spot minimum and the intensity of the succeeding maximum.

According to a table prepared by him, and published in No. 4 (1904) of the *Comptes rendus*, a minimum during which the number of spots is very small is followed by a maximum in which the spots are correspondingly few.

In accordance with this theory, the maximum now approaching should be a feeble one, the relative number for the spots not exceeding 70 or 80, because the relative number for the past minimum was very small, viz. about 3·0.

EPHEMERIS FOR COMET TEMPEL$_2$.—A continuation of the ephemeris for Tempel's second comet during the approaching apparition, taken from the daily ephemeris published by M. Coniel in No. 3962 of the *Astronomische Nachrichten*, is given below:—

Ephemeris 12h. (M.T. Paris).

1904	α app. h. m. s.	δ app. ° ′	log. Δ	$1 : r^2\Delta^2$
Sept. 7	15 7 9	−10 12	0·2361	0·142
,, 11	15 16 36	−11 22	0·2380	0·143
,, 15	15 26 26	−12 30	0·2398	0·145
,, 19	15 36 39	−13 38	0·2416	0·147
,, 23	15 47 15	−14 44	0·2433	0·149
,, 27	15 58 14	−15 49	0·2450	0·151
Oct. 1	16 9 37	−16 53	0·2467	0·152
,, 5	16 21 22	−17 53	0·2484	0·154

The comet is due at perihelion early in November. On September 9 it should apparently be between one and two degrees south of β Libræ, and on October 2 about one degree south of φ Ophiuchi. As this comet is likely to be only a faint object during this apparition, it may be a difficult one for observers in this country.

DIRECTION OF THE SUN'S PROPER MOTION.—In No. 3961 of the *Astronomische Nachrichten* Prof. Kobold discusses the proper motions of 144 stars chiefly taken from the catalogues of Porter and Bradley.

From the discussion he deduces the position of the anti-apex of the Sun's-Way, and finds it to be a point near to α Argus having as its coordinates

$$A = 159°{\cdot}6, \quad D = -54°{\cdot}7.$$

As a general result, he states that the stars, of which the motions are perpendicular to the parallactic motion, are situated in preponderating numbers in a zone which passes through the apex and anti-apex, and runs perpendicular to the plane of the Milky Way, the point towards which they appear to be travelling being situated near to α Argus.

THE BRITISH ASSOCIATION.

SECTION I.

PHYSIOLOGY.

OPENING ADDRESS BY PROF. C. S. SHERRINGTON, M.A., D.Sc., M.D., LL.D., F.R.S., PRESIDENT OF THE SECTION.

Correlation of Reflexes and the Principle of the Common Path.

It has been lightly said that this Association meets to cultivate less muses than amusements. The two are compatible, and here happily the muses not merely nine, but ten; for we surely include among the muses "Physiologia." Here in Cambridge our muse admits frankly that a mistake has been made about Parnassus—it is not a mountain but a flat place, almost fenny, once worried by mosquitoes, and now immune from all worries.

Perhaps the confusion between Parnassus and a mountain was due to the Gog-Magog hills. Those hills our muse has haunted and still haunts. She has votaries there; among them one who instituted her worship in this place, a teacher whose powerful appeal attracted disciples from all sides, one whose enthusiasm was, moreover, never narrowed to a single science alone, but floods all biology. With Cambridge and Physiology the name of Sir Michael Foster rises to the lips as an indissoluble sequence. So it will ever be; and it must give him pleasure, as it gives us, to have for his successor here one of his first pupils, one associated far and wide with that which Physiology treasures as always golden, the discovery of imperishable facts.

When this Section last met, two years ago, its President, Prof. Halliburton, reviewed for us the existing position of chemical physiology. We cannot from the nervous system draw themes of such general attractiveness as the new biochemistry, with its startling reactions, its varied hypotheses, its *toxophores, haptophores, amboceptors*, and other fairy-like agents.

Physiology studies the nervous system from three main points of view. One of these regards its processes of nutrition. Nerve-cells, as all cells, lead individual lives, breathe, dispense their own stores of energy, repair their own substantial waste, are, in short, living units, each with a nutrition more or less centred in itself. The problems of nutrition of the nerve-cell and of the nervous system, though partly special to this specially differentiated form of cell life, are, on the whole, accessible to the same methods as is nutrition in other cells and in the body as a whole.

But beside the essential functions common to all living cells, the cells of the nervous system present certain which are specialised. Among properties of living matter, one by its high development in the nerve-cell may be said to characterise it. I mean the cell's transmission of excitement spatially along itself and thence to other cells. This "conductivity" is the specific physiological property of nerve-cells wherever they exist. Its intimate nature is, therefore, a problem coextensive with the existence of nerve-cells, and enters as a factor into every question concerning the specific reactions of the nervous system.

Thirdly, physiology seeks in the nervous system how by its "conductivity" the separate units of an animal body are welded into a single whole, and from a mere collection of organs there is constructed an individual animal.

This third line of inquiry, though greatly needing more data from the second and the first, must in the meantime go forward of itself. It is at present busied with many questions that seem special—hence its work is generally catalogued as Special Physiology. But it includes general problems. In the time before us I would venture to put before you one of these.

When we regard the nervous system as to this, which I would term its *integrative* function, we can distinguish two main types of system according to the mode of union of the conductors—(i.) the *nerve-net* system, such as met in Medusa and in the walls of viscera, and (ii.) the *synaptic* system, such as the cerebro-spinal system of Arthropods and Vertebrates. In the integrative function of the nervous system the unit mechanism is the *reflex*. The chain of conduction in the reflex is a nervous arc, running from a receptor organ to an effector organ, *e.g.* from a sense-organ to a limb-muscle. We may still, I think, conveniently accept the morphological units termed neurones as units of construction of the reflex arc. It may be that these neurones are in some cases not unicellular but pluricellular. That question need not detain us now. Accepting the neurone as the unit of structure of the reflex chain, the characteristic of the synaptic system is that the chain consists of neurones jointed together in such a way that conduction along the chain seems possible in one direction only. These junctions of the neurones are conveniently termed synapses. The irreversible direction of the conductivity along the neurone chain is probably referable to its synapses. This irreciprocity of conduction especially distinguishes the synaptic nervous system from the nerve-net system.

The first link of each reflex chain is a neurone which starts in a receptor organ, *e.g.* a sense-organ. A receptive field, *e.g.* an area of skin, is always analysable into receptive points, and the initial nerve-path in every reflex arc starts from a receptive point or points. A single receptive point may play reflexly upon quite a number of different effector organs. It may be connected through its reflex path with many muscles and glands in various parts. Yet all its reflex arcs spring from the one single shank, so to say; that is, from the one afferent neurone that conducts from the receptive point at the periphery into the central nervous organ. This neurone dips at its deep end into the great central nervous organ, the cord or brain. There it enters a vast network of conductive paths. In this network it forms manifold connections. So numerous are its potential connections there, that, as shown by the general convulsions induced under strychnia-poisoning, its impulses can discharge practically every muscle and effector organ in the body. Yet in normal circumstances the impulses conducted by it to this central network do not irradiate there in all directions. Though their spread over the conducting network does, as judged by the effects, increase with increase of stimulation of the entrant path, the irradiation remains limited to certain lines. Under weak stimulation of the entrant path these lines are sparse. The conductive network affords, therefore, to any given path entering it some communications that are easier than others. This canalisation of the network in certain directions from each entrant point is sometimes expressed, borrowing electrical terminology, by saying that the conductive network from any given point offers less resistance along certain circuits than along others. This recognises the fact that the conducting paths in the great central organ are arranged in a particular pattern. The pattern of arrangement of the conductive network of the central organ reveals somewhat of the integrative function of the nervous system. It tells us what organs work together in time. The impulses are led to this and that effector organ, gland or muscle, in accordance with the pattern. The success achieved in the unravelling of the conductive patterns of the brain and cord is shown by the diagrams furnished by the works of such investigators as Edinger, Exner, Flechsig, van Gehuchten, v. Lenhossek, v. Monakow, Ramon, and Schäfer. Knowledge of this kind stands high among the neurological advances of our time.

But we must not be blind to its limitations. The achievement may, though more difficult, be likened to tracing the distribution of blood-vessels after Harvey's discovery gave them meaning, but before the vasomotor mechanism was discovered. The blood-vessels of an organ may be turgid at one time, constricted almost to obliteration at another. With the conductive network of the nervous system the temporal changes are even greater, for they extend to absolute withdrawal of nervous influence. Our schemata of the pattern of the great central organ take no account of temporal data. But the pattern of the web of conductors is not really immutable. Functionally its details change from moment to moment. In any active part it is a web that shifts from one pattern to another, from a first to a second, from a second to a third, then back perhaps to the first, and then to a fourth, and so on backwards and forwards. As a tap to a kaleidoscope, so a new stimulus that strikes the central organ causes it to assume a partially new pattern. The pattern in general remains, but locally the patterns are in constant flux of back and forward change. These time-changes offer, I venture to think, a study important for understanding the integrative function of the nervous system.

If we regard the nervous system of any higher organism from the broad point of view, a salient feature in its architecture is the following. At the commencement of every reflex arc is a receptive neurone, extending from the receptive surface to the central nervous organ. That neurone forms the sole avenue which impulses generated at its receptive point can use whithersoever may be their distant destination. That neurone is therefore a path exclusive to the impulses generated at its own receptive points, and other receptive points than its own cannot employ it.

But at the termination of every reflex arc we find a final neurone, the ultimate conductive link to an effector organ, gland or muscle. This last link in the chain, *e.g.* the motor neurone, differs obviously in one important respect from the first link of the chain. It does not subserve exclusively impulses generated at one single receptive source alone, but receives impulses from many receptive sources situate in many and various regions of the body. It is the sole path which all impulses, no matter whence they come, must travel if they would reach the muscle-fibres which it joins. Therefore, while the receptive neurone forms a private path exclusive for impulses of one source only, the final or efferent neurone is, so to say, a public path, *common* to impulses arising at any of many sources in a variety of receptive regions of the body. The same effector organ stands in reflex connection not only with many individual receptive points, but even with many various receptive *fields*. Reflex arcs arising in manifold sense-organs can pour their influence into one and the same muscle. A limb-muscle is the *terminus ad quem* of nervous arcs arising not only in the right eye but in the left, not only in the eyes but in the organs of smell and hearing; not only in these, but in the geotropic labyrinth, in the skin, and in the muscles and joints of the limb itself and of the other limbs as well. Its motor nerve is a path common to all these.

Reflex arcs show therefore the general feature that the initial neurone is a private path exclusive for a single receptive point; and that finally the arcs embouch into a path leading to an effector organ, and that this final path is common to all receptive points wheresoever they may lie in the body, so long as they have any connection at all with the effector organ in question. Before finally converging upon the motor neurone arcs usually converge to some degree by their private paths embouching upon internuncial paths common in various degree to groups of private paths. The terminal path may, to distinguish it from internuncial common paths, be called *the final common path*. The motor nerve to a muscle is a collection of such final common paths.

Certain results flow from this arrangement. One seems the preclusion of qualitative differences between nerve-impulses arising in different afferent nerves. If two conductors have a tract in common, there can hardly be qualitative difference between their modes of conduction.

A second result is that each receptor being dependent for communication with its effector organ upon a path not exclusively its own but common to it with certain other receptors, that nexus necessitates successive and not simultaneous use of the common path by various receptors using it to different effect.

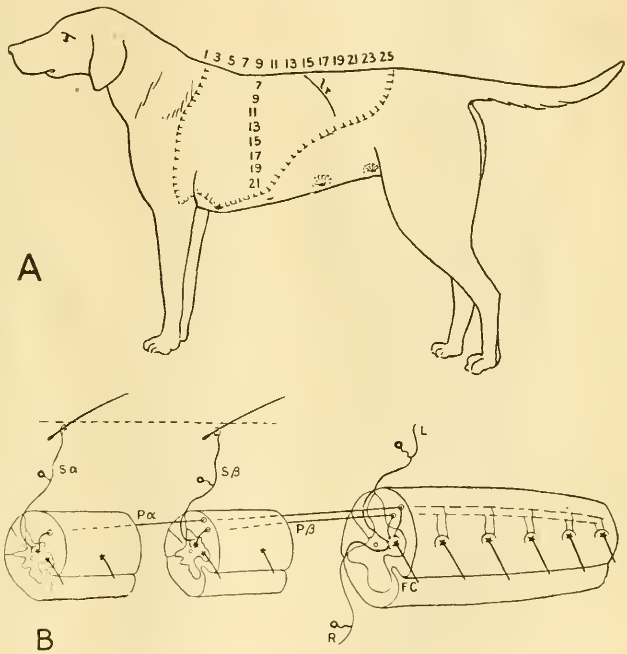

FIG. 1.—The Scratch Reflex. A.—The "receptive field," as revealed after low cervical transection, a saddle-shaped area of dorsal skin, whence the scratch reflex of the left hind limb can be evoked. *lr* marks the position of the last rib. B.—Diagram of the spinal arcs involved. L, receptive or afferent nerve-path from the left foot; R, receptive nerve-path from the opposite foot; Sα, Sβ, receptive nerve-paths from hairs in the dorsal skin of the left side; FC, the final common path, in this case the motor neurone to a flexor muscle of the hip; Pα, Pβ, proprio-spinal neurones.

Let us consider this for a moment. Take the primary retinal reflex, which moves the eye so as to bring the fovea to the situation of the stimulating image. From all the receptors in each lateral retinal half rise reflex arcs with a final common path in the nerve of the opposite *rectus lateralis*. Suppose simultaneous stimulation of two of these retinal points, one nearer to, one farther from, the fovea. If the arcs of both points pour their impulses into the final common path together, the effect must be a resultant of the two discharges. If these sum, the shortening of the muscle will be too great and the fovea swing too far for either point. If the resultant be a compromise between the two individual effects, the fovea will come to lie between the two points of stimulation. In both cases the result obtained would be useless for the purposes of either. Were there to occur at the final common path summation of the impulses received from two unlike receptors, there would result in the effector organ an action useless for the purposes of either.

When two stimuli are applied simultaneously which would evoke reflex actions that employ the same final common path in different ways, in my experience one reflex appears without the other. The result is this reflex or that reflex, but not the two together. Excitation of the afferent root of the eighth or seventh cervical nerve of the monkey evokes reflexly in the same individual animal, sometimes flexion at elbow, sometimes extension. If the excitation be preceded by excitation of the first thoracic root, the result is almost always extension; if preceded by excitation of the

sixth cervical root, it is almost always flexion. Yet although the same root may thus be made to evoke reflex action of the flexors or of the extensors, I have never seen it evoke contrac-

FIG. 2.—Interference between the reflex action of the left hip flexor, FC, caused by the nervous arc from the left foot (L, Fig. 1 B) and the scratch reflex. The stimulation of the dorsal skin (Fig. 1 A) inducing the scratch reflex began at the beginning of the notch in the signal line S, and continued throughout the period of that notch. Later, for the period marked by the notch in the signal line L the stimulation of the foot was made. This latter stimulation interrupts the clonic scratch reflex in the manner shown. The time is registered above in fifths of seconds. The tracing reads from left to right. It is noteworthy that the interruption of the scratch reflex by the foot reflex is not established directly the foot stimulus begins, and that it outlasts for a short time the application of the foot stimulus.

tion in both flexors and extensors in the same reflex response. Of the two reflexes on extensors and flexors respectively, either the one or the other results, but not the two together.

Good opportunity for study of this correlation between reflexes is given in the "scratch reflex." When the spinal cord has been transected in the neck, this reflex in a few months becomes prominent. Stimuli applied within a large saddle-shaped field of skin (Fig. 1 A) excite a scratching movement of the leg. The movement is rhythmic flexion at hip, knee, and ankle. It has a frequency of about four per second. The stimuli provocative of it are mechanical, such as rubbing the skin, or pulling lightly on a hair. The nerve-endings which generate the reflex lie in the surface layer of the skin, about the roots of the hairs. A convenient way of exciting these is by feeble faradisation. A broad diffuse electrode is applied to some indifferent part of the surface elsewhere, and a stigmatic pole is brought to some point in the saddle-shaped area of dorsal skin. This pole is formed by a minute needle with fine wire attached; it is set lightly, so that its point just lies among the hair-bulbs.

Prominent among the muscles active in this reflex are the flexors of the hip. If we record their rhythmic contraction we obtain tracings as in Figs. 2, 3, 4. A series of brief contractions succeed one another at a certain rate, the frequency of which is independent of that of the stimulation. The contractions are presumably brief tetani. The stimulus to the hair-bulbs of the shoulder throws into action a lumbar spinal centre, innervating the hip-flexor much as the bulbar respiratory centre drives the spinal *phrenicus* centre. In the case of the respiratory muscle the frequency of the rhythm is, however, much less.

This reflex is unilateral: stimulation of the left shoulder evokes scratching by the left leg, not by the right. Search in the spinal cord for the path of the reflex demonstrates that a lesion breaking through one lateral half of the cord anywhere between shoulder and leg abolishes the ability of the skin of that shoulder to excite the scratch reflex, but leaves intact the reflex of the opposite shoulder.

In the lateral half of the spinal cord which the reflex path descends, severance of the dorsal column does not interfere with the reflex; nor does severance of the ventral and the dorsal columns together of that side; no more does severance of the grey matter in addition. But severance of the lateral part of the lateral column itself permanently abolishes the conduction of the reflex; and it does so even if all the other parts of the cord remain intact. The path of the reflex therefore descends the lateral part of the lateral column. I enter into these details because they help toward the construction of the reflex arc involved. For in the lateral part of the lateral column one has proved by "*successive degeneration*" that *long* fibres exist directly connecting the spinal segments of the shoulder with the spinal segments containing the motor neurones for the flexor muscles of the hip, and knee, and ankle. The course of these long fibres can be traced and their number

counted. We thus arrive at the following reflex chain for the scratch reflex: (i.) The receptive neurone (Fig. 1 B, sα), from the skin to the spinal grey matter of the corresponding spinal segment in the shoulder. This is the exclusive or private path of the arc. (ii.) The long descending propriospinal neurone (Fig. 1 B, Pα), from the shoulder segment to the grey matter of leg segments. (iii.) The motor neurone (Fig. 1 B, FC), from the spinal segment of the leg to the flexor muscles. This last is the *final common path.* The chain thus consists of three neurones. It enters the grey matter twice, that is, it has two neuronic junctions, two synapses. It is a *disynaptic* arc.

Now if, while stimulation of the skin of the shoulder is evoking the scratch reflex, the skin of the hind foot is stimulated (Fig. 2), the scratching is arrested. Stimulation of the skin of the hind foot by any of various stimuli that have the character of threatening the part with damage causes the leg to be flexed, drawing the foot up. This reflex response to noxious stimuli of the foot is one of great potency. The drawing up of the foot is effected by strong tonic contraction of the flexors of ankle, knee, and hip. In this reaction the reflex arc is (i.) the receptive neurone (Fig. 1 B, L) (nociceptive) from the foot to the spinal segment, (ii.) perhaps a short intraspinal neurone, and (iii.) the motor neurone (Fig. 1 B, FC) to the flexor muscle, *e.g.* of hip. Here, therefore, we have an arc which embouches into the same *final common path* as sα. The motor neurone FC is a path common to it and to the scratch reflex arcs; both arcs employ the same effector organ, a hip flexor. And, as you see, a condition for one reflex is the absence of the other.

The channels for both reflexes finally embouch upon the same common path. The flexor effect specific to each differs strikingly in the two cases. In the scratch reflex the flexor effect is an intermittent contraction of the muscle, in the nociceptive reflex it is steady and maintained. The accompanying tracing (Fig. 2) shows the result of conflict between the two reflexes. The one reflex displaces the other from the common path. There is no compromise. The scratch reflex is set aside by that of the nociceptive arc from the foot. The stimulation which previously sufficed to evoke the scratch reflex is no longer effective, though it is continued all the time. But when the stimulation of the foot is discontinued the scratch reflex returns. In that respect, although there is no enforced inactivity, there is inhibition. There is interference between the two reflexes, and the one is inhibited by the other. Though there is no cessation of activity in the motor neurone, one form of activity that was being impressed upon it is cut out and another takes its place. A stimulation of the foot too weak to cause more than a minimal reflex movement will often suffice to completely interrupt or cut short, or prevent onset of, the scratch reflex.

Suppose, again, during the scratch reflex, stimuli applied to the foot, not of the scratching but of the opposite side (Fig. 1 B, R). Stimulation (nociceptive) of the foot causes flexion of its own leg and extension of the opposite. In numerous instances reflex contraction of one set of muscles is accompanied by reflex relaxation of their antagonists.

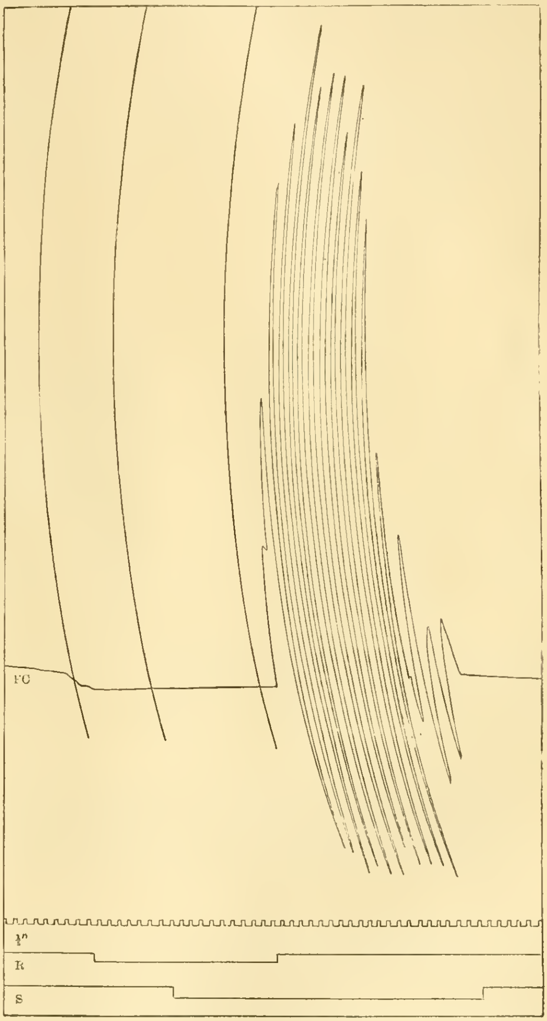

FIG. 3.—Interference of the reflex from the skin of the opposite foot with the scratch reflex, FC, the flexor muscle of the left hip (Fig. 1 B, FC) R, the signal line the notch in which marks the beginning, continuance, and conclusion of a skin stimulation of the right foot (Fig. B, R). S, signal line similarly marking the period of stimulation of the skin of the left shoulder (Fig. 1 B, Sα). The ability of stimulus S to produce the scratch reflex takes effect only on concluding stimulus R; that is, S obtains connection with the *final common path* (the motor neurone of the flexor muscle) only on R's relinquishing it. Stimulus R, while excluding S from FC, causes slight contraction of FC's antagonist, and coincident slight relaxation of FC itself. Time in fifths of seconds. Read from left to right.

The antagonistic muscle is thrown out of action. If, when the left leg is executing the scratch reflex, the right foot is stimulated, the scratching, involving as it does the left

leg's flexors, is cut short concomitantly with or preparatory to the entrance into contraction of their antagonists, the left extensors. Fig. 3 shows a record of this. This inhibition of the flexor scratching movement occurs sometimes when the contraction of the extensors is minimal or hardly perceptible (Fig. 3). As before, the inhibition may temporarily interrupt a reflex or may delay its onset, or simply cut it short, the result depending on the time relations of the applications of the stimuli to the conflicting arcs.

It is obvious from this that the final common path, FC, to the flexor muscle can be controlled by, in addition to the before-mentioned arcs, others that actuate the extensor muscles, for it can be thrown out of action by them. The final path, FC, is therefore common to the reflex arcs, not only from the same-side foot (Fig. 1 B, L) and shoulder skin (Fig. 1 B, $s\alpha$, $s\beta$), but also to arcs from the opposite foot (Fig. 1 B, R), in the sense that it is in the grasp of all of them. In this last case we have a conflict for the mastery of a common path, not, as in the previous instance, between two arcs both of which use the path in a pressor manner although differently, but between two arcs that, though both of them control the path, control it differently, one in a pressor manner heightening its activity, the other in a depressor manner lowering or suppressing its activity.

I said that the scratch reflex is unilateral. If the right shoulder be stimulated, the right hind-leg scratches; if the left shoulder be stimulated, the left hind-leg scratches. If both shoulders be stimulated at the same time, one or the other leg scratches, but not the two together. The one reflex that takes place prevents the occurrence of the other. The reason is, that although the scratch reflex appears unilateral it is not strictly so. Suppose the left shoulder stimulated. The left leg then scratches. If the right leg is then examined it is found to present slight, steady extension with some abduction. This extension of the leg which accompanies the scratching movement of the opposite leg contributes to support the animal on three legs while it scratches with the fourth.

Suppose stimulation at the left shoulder evoking the scratching movement of the left leg, and the right shoulder then appropriately and strongly stimulated. This latter stimulus often inhibits the scratching movement in the opposite leg and starts it in its own. In other words, the stimulus at the right shoulder not only sets the flexor muscles of the leg of its own side into scratching action, but it inhibits the flexor muscles of the opposite leg. It throws into contraction the extensor muscles of that leg. In the previous example there was a similar co-ordination. The motor nerve to the flexor muscle is therefore under the control not only of the arcs of the scratch reflex from the homonymous shoulder, but of those from the crossed shoulder as well. But in regard to their influence upon this final common path, the arcs from the homonymous shoulder and the opposite shoulder are opposed. The influence of the latter depresses or suppresses activity in the common path.

Experiments by Verworn disallow any view that this kind of depression has its field in the motor nerve itself. Many circumstances connect it with the place where the converging neurones come together in the grey matter at commencement of the common path. The field of competition between the rival arcs seems to lie in the grey matter, where they impinge together upon the final or motor neurone. That is equivalent to saying that the essential seat of the phenomenon is the synapse between the motor neurone and the axone-terminals of the penultimate neurones that converge upon it. There some of these arcs drive the final path into one kind of action, others drive it into a different kind of action, and others again preclude it from being activated by the rest.

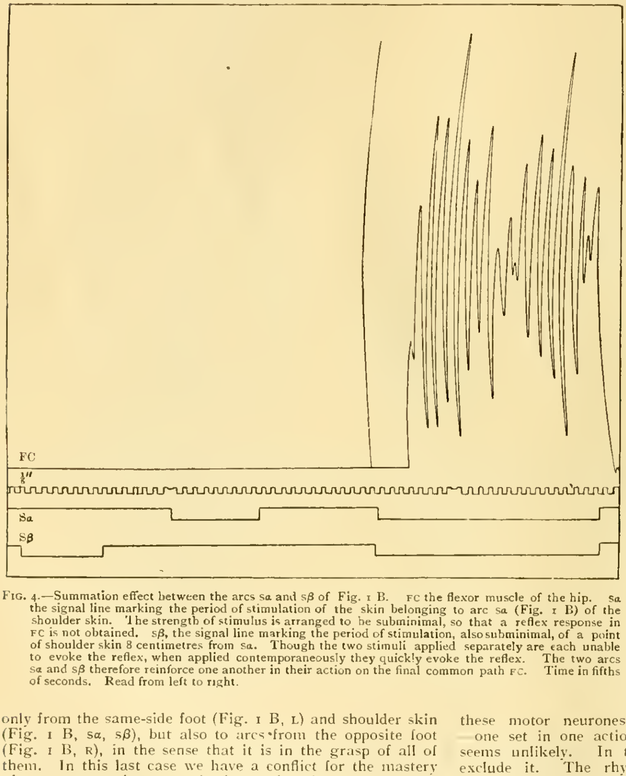

FIG. 4.—Summation effect between the arcs $s\alpha$ and $s\beta$ of Fig. 1 B. FC the flexor muscle of the hip. $s\alpha$ the signal line marking the period of stimulation of the skin belonging to arc $s\alpha$ (Fig. 1 B) of the shoulder skin. The strength of stimulus is arranged to be subminimal, so that a reflex response in FC is not obtained. $s\beta$, the signal line marking the period of stimulation, also subminimal, of a point of shoulder skin 8 centimetres from $s\alpha$. Though the two stimuli applied separately are each unable to evoke the reflex, when applied contemporaneously they quickly evoke the reflex. The two arcs $s\alpha$ and $s\beta$ therefore reinforce one another in their action on the final common path FC. Time in fifths of seconds. Read from left to right.

My diagram (Fig. 1 B) treats the final common path as if it consisted of a single individual neurone. It is, of course, not so. The single neurone of the diagram stands for several thousands. It may be objected that in the various given actions these motor neurones are implicated in particular sets one set in one action, one set in another. That view seems unlikely. In the scratch reflex, I think we can exclude it. The rhythm of that reflex has the same frequence whether it be excited strongly or feebly: thus, whether the extent of the contractions be great or small they recur with practically the same frequence. That a muscle contracts feebly under feeble stimulation of its nerve may be due in some cases to a fraction only of the nerve-fibres and muscle-fibres of the preparation being then active. But in the scratch reflex the whole group of motor neurones seem to act, even when the grade of contraction exhibited is quite weak. Let the reflex be excited by stimulation of the skin-point $s\alpha$ (Fig. 1 B), and let the stimulus be weak, producing only a feeble reflex. Then let another skin-point, $s\beta$ (Fig. 1 B), be stimulated while $s\alpha$ is being stimulated, and let the stimuli at $s\beta$ be timed so as to fall alternately with those applied at $s\alpha$. Then if the two paths impinge on two different sets of units in the compound group of

motor neurones, evidence of two rhythms should appear, for the muscle-fibres can respond to a much quicker rhythm than the four per second. But in result the rhythm remains unquickened and unaltered. Either sα prevents the access of sβ to the motor nerones of FC, or sα's reflex having impressed its own tempo on the neurones of FC, the stimuli from sβ fall within a refractory period of the neuronic apparatus. On either supposition, sα and sβ must play upon the same individual neurones of the final path. A like result is given by all other points I have tried in the receptive field of the scratch reflex. Again, in the inhibitions previously mentioned, when there occurs the tonic contraction or the relaxation of the flexor we find no intermittent contraction of the scratch reflex grafted on them, as would be the case were that intermittent contraction still involving some part of the whole muscle. These various reflexes seem to treat the final common path as a unit. The diagram therefore seems justified in representing the common path, FC, as a unit.

We have no time to multiply further now the categories of reflexes playing upon the final common path FC. I might cite the deep reflex arc which arises in the muscles themselves and is answerable for the mild reflex tonus that even in the spinal animal maintains the tonic posture of the limb. Or, instead of having taken arcs that arise in the skin of the foot, we might have taken others arising above the knee, and traced a reflex influence different from the arcs arising in the foot, but yet playing upon the same final common path; or we might have taken arcs from the skin of the tail, that inhibit the reflex; or from the fore feet, or the ears.

There is, however, one instance of action upon this final common path FC which I would quote. Suppose, while the scratch reflex is being elicited from a point at the shoulder, a second point, say 10 centimetres distant, but also in the dorsal field of skin, is stimulated. The stimulation at this second point favours the reaction from the first point. This is well seen when the stimulus at each point is of subminimal intensity. The two stimuli, though each unable separately to invoke the reflex, do so when applied both together (Fig. 4). This is not due to overlapping spread of the feeble currents about the stigmatic poles of the two circuits used. Mere cocainisation of either of the two skin-points annuls it. Moreover, it occurs when purely mechanical stimuli are used. It is evident that the arcs from the two points, *e.g.* sα and sβ (Fig. 1 B), have such a mutual relation that reaction of one reinforces reaction of the other, as judged by the effect upon the *final common path* FC. Such mutual reinforcement is usual between reflexes of identical species evoked from one and the same receptive field, *e.g.* the nociceptive of the foot.

Not for all the arcs arising in the receptive field of the scratch reflex can, in my experience, this mutual reinforcement be demonstrated. There seems a gradual fall in reinforcing power as the distance between the receptors of the arcs increases. In this connection the following point is noteworthy. The scratch reflex carries the foot broadly toward the place of stimulation. In the spinal dog the reflex does not succeed in bringing the foot actually to the irritated point, yet when the irritation is far forward the foot is carried further forward, and when the irritation is far back the foot is carried further back. A scratch reflex evoked by a stimulus applied far back and high up in the dorsal skin is therefore not wholly like a scratch reflex evoked from far forward and low down. Now, the mutual reinforcement between the scratch reflex arcs in their action on the final common path FC seems greater the greater the likeness between the reflex actions they initiate. The coalition between the reflexes gradually decreases as the interval between their receptive points at the skin surface becomes wider. Whether coalition fades into mere indifference, or passes over into antagonism, my observations as yet do not say. But there are various receptive regions of the body surface that do, in the spinal dog, appear indifferent for the scratch reflex. Were it not that the nervous system is perforce mutilated in the "spinal" animal, the number of these indifferent arcs might be fewer. In presence of the arcs of the great projicient receptors and the brain there can be few receptive points in the body the activities of which are totally indifferent one to another. Correlation of the activities of arcs from receptive points widely apart is the crowning contribution of the brain toward the nervous integration of the individual.

In the case before us, then, the final common path—the motor neurone—to the hip flexor muscle is played upon by various categories of reflex spinal arcs. Of those mentioned, one category (i.), the nociceptive from the leg itself, induces strong, steady contraction in the muscle. A second (ii.), the scalptor or scratching from the dorsal skin, induces rhythmic contraction in the muscle. A third (iii.), from the deep structures of the limb itself, induces the mild enduring contraction known as spinal tonus. A fourth (iv.), *e.g.* the nociceptive from the opposite foot, depresses the activity of the muscle probably by excluding from it the activity of the other arcs which would excite the final path, the motor neurone. And there are many more we could trace from various regions of the body; also, pyramidal and other influences from brain for which our final path is likewise common. The arcs *within* one category may reinforce each other's action on the common path, but those in separate categories are generally correlated in their action on their final common path in such a way as to antagonise one another. They are rivals for possession of their final common path, rivals as retinal points may be rivals for possession of the visual sensorium.

The extent to which in the nervous system this competition for possession of the common path obtains is very great. The multiplicity of the conflict seems extreme. The afferent fibres—that is, private paths—entering the central organ are much more numerous than are the final common paths. We owe to Donaldson and his pupils enumerations which show that the afferent fibres entering the human spinal cord three times outnumber the efferent which leave it. Add the cranial nerves and the so-called optic nerves, and we may take the afferent fibres to be five times the greater. The receptor system bears therefore to the efferent paths a relation like the wide ingress of a funnel to its narrow egress. The simile is bettered by supposing that within the general systemic funnel the conducting paths of each receptor may be represented as a funnel inverted, so that its wider end is more or less co-extensive with the whole plane of emergence of the final common paths. All these private paths converge in the nervous system to the great central organ, the spinal cord and brain, whence on the other hand all the final common paths irradiate. This central organ is, to return to our earlier metaphor, a vast network the lines of which follow a certain pattern. But, as we see from the instances cited—more could be given abundantly, had we time—the pattern is unstable, the details of connection shift from moment to moment. We might compare the central organ with a telephone exchange, where from moment to moment the connections between starting and end points are changed to suit passing requirements. In order to realise the exchange at work, one has to add to its purely spatial plan the temporal datum that within certain limits the connections of the lines shift to and fro. The connections of any entrant path not only offer different degrees of resistance, but their resistances, both absolutely and relatively, vary from occasion to occasion. It is not merely that general conditions of nutrition, of blood-supply, &c., affect these resistances. The functional conductive activity of the nervous organ itself produces from moment to moment the temporary opening of some connections and the temporary closing of others. A good example is the "reciprocal innervation" of antagonistic muscles—when one muscle of the antagonistic couple is thrown into action the other is thrown out of action. This is only a widely spread special case of a general principle. The general principle is the mutual interaction of arcs which embouch upon one and the same common path. Unlike arcs have successive use, but not simultaneous use of the common path. Like arcs mutually reinforce each other in their action on the common path. Expressed teleologically, the common path, although economically subservient for various purposes, is yet used only for one purpose at a time.

Thus the reaction initiated by one receptor while in progress excludes in various directions the reactions of other receptors. In this way the motor paths at any moment accord in a united pattern for harmonious synergy, co-operating for one effect. In the case of simple antagonistic muscles, and in the instances of simple spinal reflex arcs, the shifts of pattern of the conductive network from occasion

to occasion are but of small extent. The co-ordination covers one limb or a pair of limbs. But the same principle extended to the reactions of the great arcs arising in the projicient receptor organs of the head, *e.g.* the eye, that deal with wide tracts of musculature as a whole, involves much further-reaching shift of the conductive pattern. The singleness of action from moment to moment thus assured is a keystone in the construction of the individual whose unity it is the specific office of the nervous system to perfect. Releasing forces acting on the brain from moment to moment shut out from activity whole regions of the nervous system, as they conversely call vast other regions into play. The interference of unlike arcs and the reinforcement of like arcs seem to lie at the very root of the great psychical process of "attention." I will not trench on psychological aspects of the problem.

I have urged that the struggle between dissimilar arcs for mastery over their final common path takes place in the *synaptic field* at origin of the final neurones. Mutual reinforcement by similar arcs seems also referable to the same synaptic field. As to the nature of the physiological processes involved, little, it appears to me, can be said. The final common path seems an instrument more or less passive in the hands of the various arcs that use it. Thus in the scratch reflex one arc can impress one rhythm on it, another another. And in "fatigue" FC reveals, though it does not share, the failure of force of the tired arc playing on it. In regard to the reciprocal innervation of antagonistic muscles W. MacDougall has offered a suggestion of great interest, for which he obtains support from various sensual reactions. He suggests that the neurones of an antagonistic pair are so coupled that when one becomes active it drains energy from its fellow. This takes cognisance of the significant fact that central inhibition seems always accompanied by heightened activity at some related spot. Yet at certain times both the antagonists can show high contemporaneous activity (strychnia, some forms of "willed" action). I think, rather, that in some way the terminal of that arc which for the moment dominates the final common path, disconnects that path from all terminals dissimilar from itself.

Whatever be the nature of the physiological process in the conflict between the competing reflexes, the issue of that conflict—namely, the determination of which competing arc shall for the time being reign over the final common path —is largely conditioned by three factors. One of these is the relative intensity of the stimulation of the rival reflexes. An arc strongly stimulated is *caeteris paribus* more likely to capture the common path than one which is excited feebly. In the spinal dog, retraction equally induced in both legs mutually excludes the crossed extension of either side, but if unequally induced allows the crossed extension of the stronger reflex to exclude the weaker reflex altogether. The common path is probably never out of the grasp of some one or other reflex. Thus, in the spinal dog even, with its limb apparently at rest, this is true. The final common path of the extensor of the knee lies, then, in the hands of a tonic reflex arising in the muscle itself. Given a strong skin stimulus, and it passes under the mastery of the reflex arising in the stimulated skin; but when that is over, the tonus arc immediately repossesses it, and for a short time, as shown by the knee-jerk, more strongly than before.

A second main determinant for the issue of the conflict between the rival reflexes is the functional species of those reflexes. Arcs belonging to species of receptors which, considered as sense-organs, provoke strongly affective sensation —*e.g.* pain, sexual feeling &c.—win the final common path with remarkable facility. Such reflexes override and set aside with peculiar potency reflexes belonging to touch organs, muscular sense-organs, &c. As the sensations evoked by these arcs, *e.g.* pains, exclude and dominate concurrent sensations in consciousness, so do the reflexes of these arcs prevail in the competition for possession of the common paths. They seem capable of pre-eminent intensity of action.

A third main factor deciding the conflict between the competing reflexes is "fatigue." An arc under long continuous stimulation of its receptor tends, even when it holds the common path, to retain its hold less well. Other arcs can then more readily dispossess it. A stimulus to a fresh arc has, in virtue of its mere freshness, a better chance of capturing the common path. The common path does not tire. In the scratch reflex under stimulation of sα when the motor discharge becomes slow and irregular from fatigue, it is still perfect for sβ, or L, &c. (Fig. 1 B). This waning of a reflex under long-maintained excitation is one of the many phenomena that pass in physiology under the name "fatigue." Its place of incidence lies at the synapse. It seems a process elaborated and preserved in the selective evolution of the neural machinery. It prevents long continuous possession of a common path by any one reflex of considerable intensity. It favours the receptors taking turn about. It helps to ensure serial variety of reaction. The organism, to be successful in a million-sided environment, must in its reactions be many-sided. Were it not for such so-called "fatigue," an organism might, in regard to its receptivity, develop an eye, or an ear, or a mouth, or a hand or leg, but it would hardly develop the marvellous congeries of all those various sense-organs which it actually does.

But while talking of fatigue in general I forget the fatigue in particular of listeners. The principle I have tried to outline to you has many and wide applications; it seems fruitful for problems of Pathology and Psychology, as well as for those of Physiology. But I keep you too long. Let me sum up. The reflex arcs (of the synaptic system) converge in their course so as to impinge upon links possessed by whole varied groups in common—*common paths*. This arrangement culminates in the convergence of many separately arising arcs upon the efferent-root neurone. This neurone thus forms a final common path for many different reflex arcs and acts. It is responsive in various rhythm and intensity, and is relatively unfatigable. Of the different arcs which use it in common, each can do so exclusively in due succession, but *different* arcs cannot use it simultaneously. There is, therefore, interference between the actions of the arcs possessing the common path, some reflexes excluding others and producing inhibitory phenomena, some reflexes reinforcing others and producing phenomena of "bahnung." Intensity of stimulation, species of reflex, fatigue, and freshness, all these are physiological factors influencing this interaction of the arcs—and under pathological conditions there are many others, *e.g.* "shock," toxins, &c. Hence follows successive interchange of the arcs that dominate one and the same final common path. We commonly hear a muscle—or other effector organ—spoken of as innervated by a certain nerve; it would be more correct as well as more luminous to speak of it as innervated by certain receptors; thus, the hip flexor, now by this piece of skin, now by that, by its own foot, by the opposite fore-foot, by the labyrinth, by its own muscle-spindles, by the eye, by the "motor" cortex, &c. This temporal variability, wanting to the nerve-net system of medusoid and lower visceral life, in the *synaptic* system provides the organism with a mechanism for higher integration. It fits that system to synthesise from a mere collection of tissues and organs an individual animal. The animal mechanism is thus given solidarity by this principle which for each effector organ allows and regulates interchange of the arcs playing upon it, a principle which I would briefly term that of "the interaction of reflexes about their common path."

SECTION K.

BOTANY.

OPENING ADDRESS BY FRANCIS DARWIN, F.R.S., FELLOW OF CHRIST'S COLLEGE, PRESIDENT OF THE SECTION.

On the Perception of the Force of Gravity by Plants.

WHEN I had the honour of addressing this Association at Cardiff as President of the mother-section from which ours has sprung by fission, I spoke of the mechanism of the curvatures commonly known as tropisms. To-day I propose to summarise the evidence—still far from complete—which may help us to form a conception of the mechanism of the stimulus which calls forth one of these movements—namely, geotropism. I have said that the evidence is incomplete, and perhaps I owe you an apology for devoting the time of this Section to an unsolved problem. But the making of theories is the romance of research; and I may say, in the words of Diana of the Crossways, who indeed spoke of romance, "The young who avoid that region escape the title of fool at the cost of a celestial crown." I am prepared for the risk in the hope that in not avoiding

the region of hypothesis I shall at least be able to interest my hearers.

The modern idea of the behaviour of plants to their environment has been the growth of the last twenty-five years, though, as Pfeffer has shown, it was clearly stated in 1824 by Dutrochet, who conceived the movements of plants to be "spontaneous"—*i.e.*, to be executed at the suggestion of changes in the environment, not as the direct and necessary result of such changes. I have been in the habit of expressing the same thought in other words, using the idea of a guide or signal, by the interpretation of which plants are able to make their way successfully through the difficulties of their surroundings. In the existence of the force of gravity we have one of the most striking features of the environment, and in the sensitiveness to gravity which exists in plants we have one of the most widespread cases of a plant reading a signal and directing its growth in relation to its perception. I use the word perception not of course to imply consciousness, but as a convenient form of expression for a form of irritability. It is as though the plant discovered from its sensitiveness to gravity the line of the earth's radius, and then chose a line of growth bearing a certain relation to the vertical line so discovered, either parallel to it or across it at various angles. This, the reaction or reply to the stimulus, is, in my judgment, an adaptive act forced on the species by the struggle for life. This point of view, which, as I regret to think, is not very fashionable, need not trouble us. We are not concerned with why the plant grows up into the air or down into the ground; we are only concerned with the question of how the plant perceives the existence of gravitation. Or, in other words, taking the reaction for granted, what is the nature of the stimulus? If a plant is beaten down by wind or by other causes into a horizontal position, what stimulative change is wrought in the body of the plant by this new posture?

It is conceivable in the case of a stem supported by one end and projecting freely in the air that the unaccustomed state of strain might act as a signal. The tissues on one side (the upper) are stretched, and they are compressed below: this might guide the plant; it might, in fact, have evolved the habit of rapid growth in the compressed side. This is only given as an illustration, for we know that the stimulus does not arise in this way, since such a plant, supported throughout its length, and, therefore, suffering no strain, is geotropically stimulated. The illustration is so far valuable, as it postulates a stimulus produced by weight, and we know from Knight's centrifugal experiment that weight is the governing factor in the conditions. Since we cannot believe that the stimulus arises from the strain as affecting the geotropic organ as a whole, we must seek for weight-effects in the individual cells of which the plant is built. We must, in fact, seek for weight-effects on the ectoplasm[1] of those cells which are sensitive to the stimulus of gravity.

If we imagine a plant consisting of a single apogeotropic cell we shall see that the hydrostatic pressure of the cell-contents might serve as a signal.

As long as the cell is vertical the hydrostatic pressure of the cell-sap upon the ectoplasm at C (Fig. 1) is equal to that at D. But the pressure on the basal wall, B, differs from that at A (the apical wall) by the weight of the column AB. If the plant be forced into the horizontal, the pressure at A and B becomes the same, while the pressure at C no longer equals that at D, but differs by the weight of the column CD. Here undoubtedly is a possible means by which the plant could perceive that it was no longer vertical, and would have the means of distinguishing up from down. So that if it were an apogeotropic plant it would need to develop the instinct of relatively accelerated growth on the side D, on which the pressure is greatest.

What is here roughly sketched is the groundwork of the theory of *graviperception*[2] suggested by Pfeffer[3] and supported by Czapek,[4] which I shall speak of as the radial pressure theory, and to which I shall return later.

[1] See Noll's ingenious reasoning by which he makes it clear that the stationary ectoplasm, not the flowing endoplasm, is the seat of stimulation. Noll (88).

[2] I propose this term in place of *geoaesthesia*, which does not lend itself to the formation of adjectives, or the hybrid word *geoperception*. By not using the form "geo" we avoid any necessary connection with geotropism, and may thus use terms compounded of *gravi* for phenomena other than those of curvature.

[3] Pfeffer (81). [4] Czapek (98), (01).

It is obvious that there is another consideration to be taken into account, namely, that cells do not contain cell-sap only, but various bodies—nucleus, chloroplasts, crystals, &c.—and that these bodies, differing in specific gravity from the cell-sap, will exert pressure on the physically lower or physically higher cell-walls according as they are heavier or lighter than the cell-sap. Here we have the possibility of a sense-organ for verticality. As long as the stem is vertical and the apex upwards the heavy bodies rest on the basal wall, and the plant is not stimulated to curvature; but if placed horizontally, so that the heavy bodies rest on the lateral cell-walls, which are now horizontal, the plant *is* stimulated to curve. This is known as the *statolith* theory.

It seems to me quite certain that the stimulus must originate either in the weight of solid particles or in the weight of the fluid in the cells, or by both these means together. And for this reason. Take the statolith theory first. There undoubtedly are heavy bodies in cells; for instance, certain loose, movable starch-grains. Now, either these starch-grains are specialised to serve the purpose of graviperception or they are not. If they are so specialised, *codit quaestio*; if they are not, there still remains this interesting point of view: the starch-grains fall to the lower end of the cells in which they occur; therefore, shortly before every geotropic curvature which has taken place since movable starch-grains came into existence, there has been a striking change in the position of these heavy cell-contents. Now, if we think of the evolution of geotropism as an adaptive manner of growth we must conceive plants growing vertically upwards and succeeding in life, others not so behaving, and consequently failing.

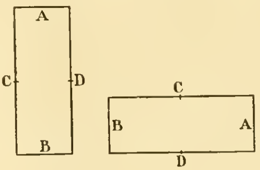

FIG. 1.

There will be a severe struggle tending to pick out those plants which associated certain curvatures with certain preceding changes, and therefore it seems to me that, if movable starch-grains were originally in no way specialised as part of the machinery of graviperception, they would necessarily become an integral part of that machinery, since the act of geotropism would become adherent to or associated with the falling of the starch-grains.

This argument must in fairness be applied to any other physical conditions which constantly precede geotropic curvature; it is therefore not an argument in favour of the statolith theory alone, but equally for the pressure theory, and cannot help us to decide between the two points of view.

Are there any general considerations which can help us to decide for or against the statolith theory? I think there are—namely, (1) analogy with the graviperceptive organs of animals; (2) the specialisation and distribution of the falling bodies in plants.

(1) Berthold[1] (to whom the credit is due[2] of having first suggested that Dehnecke's falling starch-grains might function as originators of geotropic reaction) is perhaps somewhat bold in saying that "the primary effect of gravity" as regards stimulation must depend on the passive sinking of the heavier parts. Noll, too,[3] says that Knight's experiment depends on weight, and not the weight of complete parts of the plant-body; but of weight within the irritable structure. I cannot see that these downright statements are justified on direct evidence, and I accordingly lay some stress on the support of zoological evidence. It

[1] "Protoplasmamechanik," 1886, p. 73. I was directed to this passage by Pfeffer's discussion ("Pflanzenphysiologie," ed. 2, ii., p 641).

[2] Berthold's remarks seem not to have received much notice, and it was not till the publication of Noll's "Heterogene Induction," 1892, that a form of the statolith theory was at all widely recognised as a possible explanation.

[3] "Heterogene Induction," p. 41.

has been conclusively proved by Kreidl's[1] beautiful experiment that in the Crustacean Palæmon the sense of verticality depends on the pressure of heavy bodies on the inside of cavities now known as statocysts, and formerly believed to be organs of hearing. The point of the experiment is that when the normal particles are replaced by fragments of iron the Palæmon reacts towards the attraction of a magnet precisely as it formerly reached towards gravity.

It is unfortunate that Noll's arguments in favour of the existence of a similar mechanism in plants were not at once followed by the demonstration of those easily visible falling bodies, which, in imitation more flattering than accurate, are called *statoliths*, after the bodies in the statocysts of animals. Personally I was convinced by Kreidl, as quoted by Noll, that here was the key to graviperception in plants. But it was not until the simultaneous appearance of Haberlandt's[2] and Němec's[3] papers that my belief became active, and this, I think, was the case with others. The whole incident is an instance of what my father says somewhere about the difficulty of analysing the act of belief. I find it impossible to help believing in the statolith theory, though I own to not being able to give a good account of the faith that is in me. It is a fair question whether the analogy drawn from animals gives any support to the theory for plants. The study of sense-organs in plants dates, I think, in its modern development, at least, from my father's work on root-tips, and on the light-perceiving apices of certain seedlings. And the work on the subject is all part of the wave of investigation into adaptations which followed the publication of the "Origin of Species." It is very appropriate that one of the two authors to whom we owe the practical working out of the statolith theory should also be one of the greatest living authorities on adaptation in plants. Haberlandt's work on sense-organs,[4] especially on the apparatus for the reception of contact stimuli, is applicable to our present case, since he has shown that the organs for intensifying the effect of contact are similar in the two kingdoms. No one supposes that the whisker of a cat and the sensitive papilla of a plant are phylogenetically connected. It is a case of what Ray Lankester called homoplastic resemblance. Necessity is the mother of invention, but invention is not infinitely varied, and the same need has led to similar apparatus in beings which have little more in common than that both are living organisms.

But, whether we are or are not affected in our belief by the general argument from analogy, we cannot neglect the important fact that Kreidl proves the possibility of gravisensitiveness depending on the possession of statoliths. We must add to this a very important consideration—namely, that we know from Nemec's work[5] that an alteration in the position of the statoliths does stimulate the *statocyte*.[6] Such, at least, is, to my mind, the only conclusion to be drawn from the remarkable accumulation of protoplasm which occurs, for instance, on the basal wall of a normally vertical cell when that wall is cleared of statoliths by temporary horizontality. The fact that a visible disturbance in the plasmic contents of the statocyte follows the disturbance of the starch-grains seems to me a valuable contribution to the evidence.

There is one other set of facts of sufficiently general interest to find a place in this section. I mean Haberlandt's result,[7] also independently arrived at by myself, that when a plant is placed horizontally and rapidly shaken up and down in a vertical plane the gravistimulus is increased. This is readily comprehensible on the statolith theory, since we can imagine the starch-grains would give a greater stimulus if made to vibrate on one of the lateral walls, or if forced into the protoplasm, as Haberlandt supposes. I do not see that the difference in the pressure of the cell-sap on the upper and lower walls (*i.e.*, the lateral walls morphologically considered) would be increased. It would, I imagine, be rendered uneven; but the average difference would remain the same. But in the case of the starch-grains an obvious new feature is introduced by exchanging a stationary condition for one of movement. And though I speak with hesitation on such a point, I am inclined to see in Haberlandt's and my own experiments a means of distinguishing between the pressure and statolith theories. Noll,[1] however, considers that the shaking method is not essentially different from that of Knight's experiment, and adds that the result might have been foreseen.

Distribution.

As far as I know, the development of *statoplasts*[2] has not been made out. Are they at first like ordinary immovable amyloplasts; and, if so, by what precise process do they become movable? Where the two forms of starch are seen in close juxtaposition the difference between them is striking, and it is hardly possible to doubt that these differently situated bodies have different functions. In a seedling *Phalaris canariensis* the apical part has only falling starch-grains, while lower down both forms occur. It suggests a corresponding distribution of graviperception; and, as a fact, the seedling is gravisensitive throughout, but is especially so at the apex. If this is not the meaning of the statoplasts we must find some other. For instance, are the loose starch-grains connected in an unknown way with heliotropic sensitiveness, which often has the same distribution as that of graviperception? Or is the looseness of starch connected in some way with food storage? Is it to allow of starch being closely packed in part of the cell, leaving the rest of the space free?

Again, the most striking general fact about the distribution of falling starch is its presence in the endodermis.[3] If we believe that the endodermis is essentially a tissue of gravisensitive cells we can understand the striking fact that it contains loose starch only as long as the stem is capable of growth curvature.[4] Otherwise the theories of the function of the endoderm, which have never been very satisfactory, have the additional burthen of explaining this last-named fact.

According to Haberlandt (00), some monocotyledons the leaves of which contain no starch have falling grains in the endodermis. Němec (01, p. 24) quotes from Sachs the case of *Allium cepa*, where statoplasts occur in the root-cap, the endoderm, and punctum of the seedling, and not elsewhere. Then we have occurrence of starch in the pulvinus of grasses and not in the rest of the haulm. Viscum is not geotropic, and has no statoplasts. In the holdfast roots of Hedera and Marcgravia there is no starch, and in Hoya, Pothos, and Ficus the starch is not movable, and these roots are not geotropic.[5]

Jost (02) brought forward, as a serious objection to the statolith theory, the fact that tertiary roots possess statoliths, but are not sensitive to gravitation. This objection has been overcome by the discovery[6] that when the primary root is cut off and a secondary assumes its place and manner of growth, the tertiaries springing from it are diageotropic, and thus have at least an occasional use for their statoplasts.

I have shown[7] that the cotyledon of Setaria and Sorghum is the seat of gravi-perception, and it is there that the statoplasts are found.[8] Wiesner (02) was unable to find statoliths in the perianth-segments of *Clivia nobilis*, which are geotropic, nor in those of *Clivia miniata*, which are not geotropic. Here would seem to be a serious objection to the statolith theory, but Němec (04, p. 58), on repeating Wiesner's observations, finds, on the contrary, a confirmation of his own views. For movable starch-grains occur in the perianth of *C. nobilis*, but not in those of *C. miniata*. In the case of roots the distribution of the statoplasts is especially worthy of note. Physiologists have gradually come to believe that my father[9] was right in his view that

[1] Noll (03, p. 131).
[2] I would suggest the word *statoplast* in place of the cumbersome expression *movable starch-grains*.
[3] See Haberlandt (03) for a description of certain special cases of statocyte-tissue, apparently replacing the endodermis.
[4] According to Haberlandt (03, p. 451), it is easy to be deceived in asserting that the endoderm contains no starch. Thus Fischer failed to find it in outgrown stems of some plants which possess it when young. Tondera (03) asserts that in certain Cucurbits the falling starch is only present in the older parts no longer capable of geotropism. But Miss Pertz, who has examined most of the species investigated by Tondera, finds statoplasts in the young parts where he failed to find these. Tondera makes some interesting remarks on the distribution of starch in the Cucurbits harmonising with Heine's storehouse theory. It is obviously difficult in the case of the endoderm to distinguish between starch serving as a reserve and starch serving as part of the mechanism of perception. I see no reason why the second function should not be evolved from the first.
[5] Haberlandt (03, p. 461). [6] Darwin and Pertz (04). [7] F. Darwin (99).
[8] According to Němec they occur to some extent in the hypocotyl of Panicum. [9] C. Darwin ("Power of Movement").

the organ of graviperception is in the tip of the root; and it is there—generally in the root-cap and there only, that statoplasts are found. But these facts do not entirely harmonise with the statolith theory, as I shall show later on in the section devoted to experimental evidence. Here I will only add that the group of statocytes in the root are strongly suggestive of some special function, and those who deny that they form an organ of graviperception must find some other use for them; and this will be no easy task. I must not omit to mention the ingenious experiments of Piccard (04), which prove (if they prove anything) that the root-tip is not the seat of the graviperception, but that this quality is found in even greater perfection in the growing region of the root. But until the whole of the other experimental evidence is proved to be illusory, I must suspend judgment on Piccard's results and treat the question provisionally from our previous standpoint.

The existence of statoliths in regions which have ceased to be capable of ordinary geotropic curvature is at first sight a difficulty. Thus Miss Pertz has found in the pith of the watercress (*Nasturtium officinale*) the most perfect statoplasts, and this in winter, when the capacity for geotropic curvature was probably absent. Again, she has found movable starch in the xylem elements and in the cortex of a number of trees. In this case we must remember that, according to Meischke (99), Jost (01), and Baranetzky (01), woody branches of several years' growth are capable of geotropic curvature. If so, graviperceptive organs must exist. We must remember, too, that in the regeneration of cuttings, Vöchting (78) has shown that gravitation has an influence in certain cases; such cuttings must therefore have organs of graviperception. Or, if this is not granted as necessary, it seems to me conceivable that falling starch-grains, though made use of, and in a certain sense specialised, for graviperception, should nevertheless exist and serve other purposes in the economy of the plant. But this question needs further detailed work.

Lastly, as part of the general question of distribution, it must be clearly pointed out that in a large number of plants, such as Algæ and Fungi, no statoliths are known to exist, though their complete absence has not been proved.[1] Here we must either believe in Noll's minute and hitherto unseen statoliths or in a different mechanism, such as hydrostatic pressure. There is no more impossibility in this state of things than in the presence of statoliths in Palæmon and their absence in higher animals. And I am glad to note that both Pfeffer and Czapek are not disinclined to believe in the possibility of various forms of graviperception.

Experimental Evidence.

A flaw runs through a great part of the experimental evidence, which may be illustrated by an experience of my own. I found[2] that seedlings of Setaria and Sorghum could be nearly deprived of statoplasts by means of a high temperature, and, further, that such destarched plants were markedly less geotropic than normal specimens. Here seemed a proof of the theory; unfortunately, however, it turned out that the plants in question were also rendered less heliotropic. These facts make it impossible to allow Němec's gypsum experiment to be convincing. He caused a loss of starch by enclosing roots in plaster of Paris, and found that they had in great part lost their geotropic power. But he did not discover whether this loss depended on disappearance of part of the sense-organ or on general loss of curving power, though he has since (02) made the interesting observation that roots so treated are capable of hydrotropism. Again, Nemec found in resting seeds of *Vicia Faba* that the statoliths are undeveloped, and that they appear synchronously with the power of geotroping. Would not a similar thing be true of the apheliotropism of Sinapis roots—*i.e.*, might it not be found that they were not heliotropic until the starch appeared?

The same objection must be brought against Haberlandt's otherwise convincing observation[3] that Linum growing out of doors in late autumn or winter is both devoid of statoplasts and incapable of geotropism, and that the power of curvature returns on bringing the plants indoors, when the starch reappears. The full value of these experiments cannot be made clear without going into more detail than is here admissible. They are particularly interesting because, as Haberlandt remarks, so far as they prove the truth of the statolith theory, they also disprove the pressure theory. This may also be said of other experiments mentioned in the present section.

[1] See Němec (*Beihefte Bot. Central.*, B. xvii. 1904, p. 59), where he describes the cases and the occurrence of statoliths in the mosses and liverworts. Giesenhagen (01) has described heavy bodies at the tips of the rhizoids of *Chara* which fall to the physically lower side.

[2] F. Darwin (03).

[3] Haberlandt (03). It seems, however, that the starchless plants had some heliotropic capacity.

We must, I think, object on similar grounds to Nemec's observations, suggestive though they are, on the absence of geotropism in certain individual leaves and roots which, through unknown causes, had no statoliths.[1]

The same must be said of the above-mentioned experiments of Haberlandt, in which geotropism is increased by rapid shaking in a vertical plane. I attempted[2] to avoid this fault in the similar experiments with a tuning-fork made independently, which showed that the effect of vibration in increasing reaction is far greater in the case of geotropism than in heliotropism.

Haberlandt (00) made the interesting observation that plants deprived of their endodermis by means of an operation lose the capacity of geotropism. Here, again, we ought to know how the operation affects sensitiveness other than geotropic; and, as Haberlandt grants, it may perhaps be said that the operation is too serious to allow of the foundation on it of a very convincing argument.

The question how far the statolith theory is applicable to the root is a difficult one. It involves the old and apparently insoluble difficulty of distinguishing between the removal of the tip of the root, considered as a perceptive organ, and the effect of the shock of the operation. The question is, moreover, complicated by contradictory evidence. According to Czapek, cutting off a small part of the root-tip, an operation which does not remove the whole of the statoliths, interferes with geotropism in the same way as does actual amputation.[3]

Němec, on the other hand, finds evidence for the operation depending on the removal of the sense-organ; for according to him the power of geotroping does not return with the appearance of *general* symptoms of recovery, such as cell division and the growth of a callus, but only with the actual reappearance of statocytes.

Němec's most recent experiments[4] are confirmatory of this result. He finds that Lupin roots, from which $\frac{1}{2}$ mm., 1 mm., and $1\frac{1}{2}$ mm. respectively are cut off, behave differently. The $\frac{1}{2}$ mm. lot were clearly geotropic in seven hours, while no curvature occurred in the others. After a further interval of thirteen hours the 1 mm. lot had curved. Microscopic examination showed that statoplasts had appeared in these roots, but not in the $1\frac{1}{2}$ mm. lot, which showed no geotropism. It is particularly interesting that according to Němec the statoplasts appeared in a new growth which was visible as a slight convexity of the cut surface.[5]

An experiment by Nemec with the roots of *V. Faba* must also be mentioned. One millimetre was cut from the tips of each of a number of roots, and they were all placed horizontally. They were examined after fifteen hours, when considerable variety in the result of the operation was evident; some of the roots had bent geotropically, while others were still horizontal. On cutting sections it was found that the geotropic roots had statoplasts, the horizontal ones none. It may of course be said that the result depends on the effect of shock lasting longer in some individual roots, since, as Czapek has well said, the only proof of the disappearance of shock effect is the act of curving. But since the operation was approximately the same in all the roots, it is hard to believe in such a malicious coincidence as that the shock was smaller in all those roots which produced statoplasts. But it may be said that shock prevented both geotropism and statoplast-formation in certain roots.

[1] Němec (01).

[2] F. Darwin (03).

[3] Czapek (02, p. 118).

[4] Němec (04, pp. 46, 53).

[5] This agrees, as Němec says, with Wachtel's (99) results, who found geotropism returning before the whole tip was regenerated.

Czapek (02) quotes the experiment of Brunchorst, who found that a circular cut round the tip, not deep enough to free the terminal part, has the same effect as amputation. On the other hand, Němec[1] states that geotropism persists, if the root-tip is cut half through by two opposite incisions in different planes, so that the whole of the tissues are divided, and yet the tip is not amputated. Thus four out of five bean-roots treated in this way showed distinct geotropism in $5\frac{1}{4}$ hours. This seems to me a striking result, as showing that the shock of the operation is not exclusively the decisive element. Nemec has, moreover, shown that if geotropic curvature has begun on a normal root, a wound interferes with the amount of after-effect, and that the precise nature of the wound is not decisive, and this, as far as it goes, confirms the assumption that two half-cuts would produce as much shock as actual amputation.

Czapek[2] finds that splitting a bean-root longitudinally has the same effect as decapitation. This would mean that decapitation produces its results by shock only, since in a split root there is no removal of the tip. I think I was the first to make use of the splitting of roots in this connection. I wished to show[3] the incorrectness of Wiesner's view—viz., that amputation prevents geotropism by checking growth. In my experiments the split roots were greatly checked in growth, but curved geotropically, behaving in this respect quite differently from amputated specimens.

Another striking bit of evidence on Czapek's side of the question[4] is the fact that Lupin roots from which "$\frac{1}{2}$ mm. of the tip has been removed, and which, therefore, contain no statoliths," show the remarkable homogentisin reaction which he has convincingly proved to be a symptom of graviperception. Czapek adds that the same is true of roots from which 1 mm. has been removed. It seems to me that Němec's reply to this[5] is of value. He finds that the root-cap in Lupin is variable in length, but always longer than $\frac{1}{2}$ mm.; therefore, in the roots from which $\frac{1}{2}$ mm. only was removed there should have been some statocyte tissue remaining. Even after the removal of 1 mm. the root can, according to Nemec, rapidly form statocytes, since the section is in the neighbourhood of the calyptrogen.[6]

Nemec suggests it to be conceivable that differences of pressure in Czapek's sense may give rise to the homogentisin reaction, while the true act of graviperception is confined to the statoplasts. This is no doubt possible, but I confess that, if the homogentisin reaction can occur in root-tips which have no statoliths I should consider it a strong argument in favour of the view that pressure-difference in Czapek's sense supplies the machinery of perception in roots. Czapek also claims that his experiments with bent-glass tubes (Czapek, 95) prove the graviperceptive region of the root not to be confined to the region of statoplasts, since if the root-cap alone is in the vertical branch of the tube, geotropic curvature is not excluded. Němec (04) has attempted a rejoinder to this objection; with what success readers must judge for themselves.

It will be seen that, in my opinion, the balance of evidence is not fatal to the statolith theory. Czapek, who treats the question in a broad and liberal spirit, is by no means inclined to deny that statoliths have a share in graviperception; all he claims to prove is that the statoplasts do not supply the whole of the mechanism. It is not easy for an upholder of the theory to allow this much in the present stage of the controversy. The best way of testing the theory is by comparing the distribution of geotropism with that of statoliths; and if we are to allow, in all cases which are opposed to the statolith theory, that the stimulus depends on pressure differences in Czapek's sense, we deprive ourselves of the best means of proving the truth or falsehood of our theory. Those who uphold the theory must have the courage of their opinions and finally trust to the facts of distribution. But further knowledge is necessary before such a judgment can be made.

[1] Němec (01, p. 19). [2] Czapek, (98, p. 202) and (02, p. 118). [3] F. Darwin (82). [4] Czapek (02, p. 468). [5] Němec (04, p. 53).
[6] He adds that the calyptrogen may in this way have an indirect importance, and Firtsch's belief that this tissue was the essential seat of graviperception may be accounted for.

Centrifugal Force.

Jost[1] objects that plants on a centrifugal machine do not behave as the theory would lead us to expect. Thus he found that certain roots and seedlings showed geotropic curvature, although the statoplasts were scattered through the cell, not spread out on the cell-walls furthest from the axis of rotation. Miss Pertz[2] and I have repeated some of Jost's experiments, and have come to an opposite conclusion. We find that Setaria does not curve with a centrifugal force of less than 0.02 g., and this is about the limit for visible displacement of the starch-grains. As the centrifugal force increases up to 0.04 g. we get slight amounts of curvature and slight amounts of starch displacement. The two phenomena cannot be accurately compared, but so much is clear: that the result of Knight's experiment is not destructive of the statolith theory, but, on the contrary, is roughly in harmony with it.

The result of an intermittent stimulus may seem to some a difficulty. Jost[3] produced geotropic curvature by placing seedlings in the horizontal and vertical positions for alternate periods of $3\frac{1}{2}$ minutes. With alternate periods of 50″ horizontal and 2′ 30″ vertical he sometimes failed to get a geotropic curve, and exposures if less than 50″ always failed. It is commonly said that 15–25 minutes are needed for the starch to fall on to horizontal cell-walls, and it may seem, therefore, that in these experiments neither $3\frac{1}{2}$ minutes nor, *a fortiori*, 50″ could produce a change of position in the statoliths, and that therefore the experiment is destructive to the theory. But this would be a wrong conclusion, for, according to my experience, the falling time of starch is often less than 15 minutes; and even if this were not so there would be no difficulty in understanding the above experiments, for, as Jost allows (*loc. cit.*), and as Němec (02) has also pointed out, the statoplasts may stimulate the cell without the occurrence of any visible displacement; for if the statoplasts do not fall over and spread out on the horizontal walls there must be a column or heap of starch-grains, the height of which equals the width of the cell, resting on the lateral wall of the cell instead of, as in the normal position, a shallower layer pressing on the basal wall. Here we have plain conditions of differentiation between the vertical and horizontal positions.

The same considerations apply to the whole question of what is known as the geotropic presentation time[4]—*i.e.*, the minimal period of horizontality needed to induce a geotropic curvature. It has been said that the presentation time corresponds with the time needed for the statoliths to fall on to the horizontal walls of the sensitive cells. It seems to me that we hardly have knowledge enough to be certain of this coincidence, and since, as above pointed out, the statoliths may begin to stimulate before they are visibly displaced, the question is not one of much interest or deserving of special inquiry.

Theoretical.

Elfving's[5] well-known experiment with grass haulms shows that (in this instance) the action of the klinostat depends, not on the prevention of all graviperception, but on the equal distribution of stimulus.[6] But other plants react differently—that is to say, they do not exhibit increased rectilinear growth on the klinostat. This can best be accounted for, as Noll[7] suggests, by the supposition that the equally distributed stimulus tends to produce a simultaneous increase and decrease of growth-rate on opposite sides of the rotating plant.[8] We, therefore, get in an indirect way evidence in favour of what has not been directly proved—namely, that in geotropic curvature the diminution of growth

[1] Jost (02).
[2] Darwin and Pertz (04). By an oversight we omitted to give a reference to Němec's (02, p. 347) interesting reply to Jost's criticism
[3] Jost (02), p. 175. See also Czapek (98), p. 206; and Noll (00), p. 462.
[4] Czapek (98), p. 183.
[5] Elfving (84) proved that the pulvini of grass haulms increase in length when kept in slow rotation on a klinostat.
[6] My experiments on the germination of Cucurbita demonstrate the same point (Darwin and Acton, 94) Czapek (02, p. 469) shows that the homogentisin reaction occurs on the klinostat.
[7] Noll (92, p. 35).
[8] We have shown (Darwin and Pertz, 04) that in *Setaria* the statoliths undergo changes of position on the klinostat, indicating a succession of stimuli. See Heine (85), who briefly describes similar changes.

on the concave side is not the result of compression produced by increased growth on the convex side, but rather an independent reaction. It is necessary, therefore, to inquire what theoretical conclusions may be fairly made as to the stimulation correlated with such a mechanism of curvature. Noll[1] uses the term "Reizfeld," or "stimulation-area," to express the regions in which graviperception occurs. The distribution of these areas is expressed in diagrams which serve as shorthand methods of recording the geotropic reactions of various organs. All such ways of clarifying and expressing our ideas of the laws of perception are useful. I must confess that I do not find Noll's terminology easy to use, and I prefer to express the same ideas in terms of the distribution of the pressure of statoliths on the different parts of the ectoplasm of the gravisensitive cells.

Imagine an apogeotropic shoot placed in the horizontal position as shown in longitudinal radial section in Fig. 2, where C and C′ are the cortical tissues and the seat of motile power; E and E′ the endodermis, the supposed region of graviperception; M, the central tissues, which do not concern us.

The fact that the statoliths now rest on the horizontal (tangential) walls differentiates the horizontal from the vertical position of stable equilibrium. But what circumstance is there that can be conceived to originate curvature in one direction more than another? It can only be that in the endodermis E on the physically upper side the statoliths rest on the inner tangential wall, whereas in E′ they

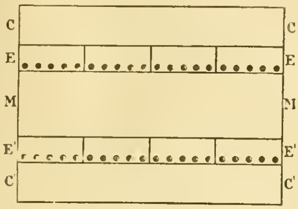

FIG. 2.

rest on the outer wall. This view agrees with Noll's hypothesis of the arrangement of stimulation-areas. There is no difficulty in believing that the inner and outer tangential walls have different individualities: Vöchting's work[2] on transplantation seems to indicate that this is the case. And if this analogy with formative polarity is not allowable, we must still insist that the presumption is in favour of E and E′ in Fig. 2 being in different conditions, since we have certainly no right to assume that the outer and inner walls are identical in what we have called their individuality.

It is not here necessary to go into the question whether the radial walls of the endodermis are or are not sensitive, since the problem of geotropism in its broad outlines is not concerned with it.[3]

The Position of Maximum Stimulation.

This problem involves the question whether an orthotropic organ in the vertical position is or is not freed from stimulus. We will first take the question as to the existence of a stimulus in the normal (*i.e.*, not the inverted) position. One of Pfeffer's[4] arguments for the existence of a stimulus is as follows. A root having been allowed to curve from the horizontal to the vertical position is placed on a klinostat, and after a time the curve disappears. It is therefore assumed that there existed a geotropic stimulus keeping the root curved until the stimulus in question was rendered inoperative by the klinostat, when the rectipetality of the root could have free play. But it is not a necessary conclusion that while the root is strictly vertical any stimulus is acting. If from some internal cause the root leaves the vertical, the ordinary geotropic curvature depending on the

[1] Noll (92, p. 19). [2] Vöchting (92, p. 151).
[3] See the discussion in Haberlandt (03, p. 467).
[4] Pfeffer (93, p. 19). I am only concerned with this special point, not with Pfeffer's general argument.

stimulation of the tangential walls will come into action and bring the root back to the vertical. To translate into the language of the statolith theory, it is not necessary to assume that the lower walls of the graviperceptive cells are sensitive to the pressure of the statoliths—the sensitiveness of the tangential walls will suffice. The experiment above mentioned does not therefore seem to prove that an orthotropic organ in stable equilibrium is stimulated. But it is quite conceivable that a stimulus might be originated by the *loss* of pressure on the lower wall, for this would be a well-marked change in the internal condition of the cell, and therefore might become associated with a reflex. Thus, when an organ is placed horizontal the stimulus from the pressure of statoliths on the lateral walls (now horizontal) may be combined with, or in some way influenced by, the loss of pressure on the terminal wall of the cell which was formerly horizontal. But if the absence of pressure on a cell-wall acts in this way are we not bound to consider the pressure (when present) as a stimulus? I think we are, and therefore, though I do not think that the particular experiment referred to supplies the necessary evidence, I hold the lower wall of an orthotropic cell to be sensitive to the stimulus of statoliths, though such stimulus cannot be of a *directive* nature.

Since an organ when accurately inverted[1] and prevented from circumnutating receives no impulse to curve, it is assumed that the normally upper cell-wall (which is now below) is not stimulated. According to the statolith theory it is inconceivable that the organ should curve, since uniform pressure on the horizontal terminal wall cannot determine the *direction* in which such curve shall begin.

But though no directive stimulus seems to be a possible result of uniform pressure on the end-walls, it does not follow that such pressure has no effect. It seems to me that such a striking change as pressure on a wall which in normal circumstances does not receive pressure may very well modify the result of the normal stimulation of the lateral walls of the cell.

Czapek[2] has shown that with both stems and roots the gravistimulus is greater when the organ is removed from the normal vertical position by 135° than when it deviates from the normal by 45°. In the case of an apogeotropic shoot the position of the starch in the endoderm is given in Fig. 3. The pressure of the starch on the lateral walls is the same in the two cases. In i., however, the starch rests partly on the basal wall (B), while in ii. it rests, to the same degree, on the apical wall (A). On the usual assumption that the basal and apical walls are insensitive, there is nothing to differentiate i. from ii. I cannot help suspecting that the pressure on the apical wall does in some way affect the sensitiveness of the tangential walls. If the pressure on the wall (A) was in itself the decisive element we should expect the stimulus to increase as the angle increased —from 135° to nearly 180°—which is not the case. From my point of view we can dimly understand why 135° should be the position of maximum stimulation. It would be the result of a compromise, being a position in which the combined pressure on both lateral and apical walls was as high as possible[3]—a mean, in fact, between full pressure on the lateral walls (as in the horizontal position) and full pressure on the apical walls (as in the vertical position).

If some such theory is not adopted we must imagine with Haberlandt that the difference between positions i. and ii. depends on the weight of the statoliths in i. being on the *basal half* of the lateral wall, and on the apical half in ii. It seems to me that the difference of sensitiveness in the two regions would have to be very great, considering that in the horizontal position, in which the gravistimulus is less than in position ii., the full pressure of a considerable fraction of the total starch acts on the supposed extra-sensitive region of the cell-wall.

But when all has been said there remains a difficulty with which I do not know how to deal. It is clear that, according to either theory, the critical position should be the hori-

[1] In the whole of this discussion the organs are supposed to be supported by the morphological base.
[2] Czapek (95, 1). As doubt has been expressed as to the actual facts, it is worth while mentioning that Miss Pertz (99) has confirmed his results for the haulms of grasses.
[3] The fact that at angles above 135° the stimulus remains greater than when the organ is horizontal seems to point to the conclusion that the share of the end wall in graviperception is relatively great.

zontal, and that as the organ is moved further and further from the normal (in successive experiments) the geotropic reaction ought to increase decidedly as the horizontal is passed; and this is not the case.

Diageotropism.

The diagram, Fig. 2, will serve to represent a diageotropic organ in stable equilibrium. In spite of the fact that it is at rest in the horizontal position, we must assume that the tangential (horizontal) walls of the endodermis are sensitive to the pressure of the statoplasts. For when the organ is placed obliquely it has the power of returning, by curvature, to the horizontal; and this requires that the plant shall distinguish up from down. If its apex is above the horizon it must curve downwards, *i.e.*, towards that side on which the statoplasts rest on the *external* walls of the endoderm cells, and *vice versa* if the apex is below the horizon. But what signal tells the plant that it is not horizontal? This can only be effected by the statoplasts pressing on the basal or apical walls, as in Fig. 3.

The difficulty is increased by the fact that when a diageotropic organ is fixed vertically, the apex being up or down,[1] no curvature follows. This, according to the usual idea, would mean that the terminal walls are not sensitive. But the walls must be sensitive in some way, or the plant would not react to the gravistimulus, as it undoubtedly does. The only conclusion I can come to is that the position of the statoliths shown in Fig. 3, in which they rest partly on the terminal wall and partly on the lateral (tangential) wall,

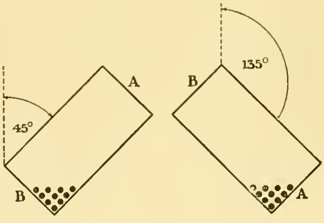

FIG. 3.

must be capable of giving the combined stimulus,[2] as above suggested.

Personally I do not attach great importance to the details of how the statoliths act on the different walls of the cells, although as part of the history of the inquiry I feel bound to discuss it. The broad fact that the statoliths rest on different parts of the cell-walls when the geotropic organ is placed at different angles with the vertical seems to me sufficient. The precise manner in which various reactions are associated with the position of the statoliths may be confessed to be for the present beyond our knowledge or powers of imagination, and such confession need not weaken the position of our theory.

Finally, I desire to say a word on a subject having but a remote connection with my theme. There is at the present time a tendency to pay an increasing attention to what is known as rectipetality or autotropism—viz., the inherent capacity of rectilinear growth. In my Cardiff Address[3] to Section D I showed that rectipetality is really part of the phenomena of circumnutation. We must believe that rectipetality does not merely come into play in those comparatively crude experimental instances in which a geotropic curvature is flattened out by means of growth on the klinostat. We must believe that it also corrects curvatures which arise from the slight irregularity of normal everyday growth. This will imply that normal growth is built of a series of internal corrections; in other words, of circumnutation. The point I wish now to emphasise is that the stimuli, be they of geotropic or any other nature, should be conceived as acting not on a stationary but on a moving plant—acting, in fact, on the spontaneous correcting power, whether we call it rectipetality, autotropism, or circumnutation. It is impossible to say how this consideration might modify our speculations as to the manner of action of the gravistimulus. It is quite conceivable that it might not alter our theoretic views at all, but without more knowledge we cannot be certain. My only point at present is that if we are led into contradictions or confusion by attempts to analyse what goes on in the gravisensitive region according to the statolith theory, such a result must not be held to be fatal to the theory until we know more of the problem.

In conclusion—and to clear our minds of the doubtful speculations in which I have entangled myself—I should like to reiterate my belief in the general, though not the universal, applicability of the statolith theory. I find it impossible to doubt that, in the case of the higher plants, sensitiveness to the pressure of heavy bodies will be found to be by far the most important, if not the exclusive, means by which gravity is perceived. We have seen that the stimulus must depend on weight; and since neither the theory of radial pressure nor Noll's supposition of stimulation by small unknown bodies lends itself to experimental inquiry we are driven, as practical people, to test the views of Haberlandt and Němec.

I base my belief partly on what I have already said, namely, that geotropism, being an adaptive reflex action, must during its development have been correlated, by that mysterious bond which unites stimulus to reaction, with some change, by which in the natural course of events it is uniformly preceded. Now the most obvious change which precedes geotropism is the disturbance of the falling starch-grains. This fact, together with what we know of the distribution of statoplasts, would almost force conviction on me. But this is not the whole of the evidence. We know from Nemec's researches that the protoplasm, in the cells assumed to be sense-organs, is sensitive to the pressure of the statoplasts; and we know from zoological evidence that heavy bodies resting on a sensitive surface can function as a sense-organ for gravitation. Finally, the experimental evidence, though not absolutely convincing, has not revealed any absolute bar to our belief in the statolith theory, and has brought to light a number of facts harmonising with it in a remarkable manner. It seems to me that the theory of Nemec and Haberlandt may fairly hold the field until a better theory of graviperception and a better theory of the function of falling starch-grains are established.

THE SIXTH INTERNATIONAL CONGRESS OF ZOOLOGY.

THE smoothness with which the complicated arrangements for the reception and housing of so many guests were carried out, and the kindness and hospitality of the welcome extended to them, formed a good augury for the success of the sixth International Congress of Zoology, which opened at Berne on Monday, August 15. On the previous day the members, gathered from many parts of the world, were received by the reception committee at the railway station, and invited afterwards by the Mayor of the city to a "symposium" in the "Kornhauskeller." The gaiety of the assembly, which did not break up until a late hour, formed an agreeable prelude to the work of the congress, which was throughout interspersed with pleasant entertainments.

At the general meeting the next morning Prof. Studer, the president, chose as the subject of his address the Swiss fauna, to the study of which he has devoted so much of his life. Prof. Perrier, of Paris, as president of the permanent committee, thereupon expressed his feelings of gratitude to the Swiss Government and to the authorities of the canton of Berne for the hospitality which had been extended to the members of the congress. The following gentlemen, Profs. Studer, Minot, Grassi, and Perrier, were afterwards elected presidents for the general meetings, and Profs. Emery, Fujii, Spengel, Osborn, v. Graff, Pelseneer, Lönnberg, Blanchard, Chun, v. Wijhe, Lang, and Drs. Horvath, Stejneger, Stiles, and Miller as vice-presidents. The meeting also agreed to divide into seven sections, viz.:—General Zoology, president, Prof. Salensky; vice-president, Mr. Schlumberger; secretary, Dr. Gurwitsch. Vertebrata (systematic), president, Dr. Jentink; vice-president, Dr. Scharff; secretary, Dr. André. Vertebrata (anatomy, &c.), president, Prof. Monticelli; vice-president, Dr. Bashford Dean; secretary, Dr. Penard. Invertebrata (excluding Arthropoda), president, Prof. Ehlers; vice-president, Prof. Koehler; secretary, Dr. Fuhrmann. Arthropoda, president, Prof. Heymons; vice-president, Dr. Janet; secretary, Dr. Steck. Applied Zoology, president, Prof. Hoek; vice-president, Prof. Plate; secretary, Dr. Duerst. Zoogeography, president, Prof. Hérouard; vice-president, Prof. Blasius; secretary, Dr. Roux.

Two propositions had been received by the president, Prof. Studer, one from the Prince of Monaco, to hold the next congress at Monaco, and another from the zoologists of the United States of America. After due consideration of these proposals, it was decided by the permanent committee and by the delegates of the scientific societies to recommend that the latter invitation be accepted, which was unanimously adopted at the general meeting. It was therefore agreed that the next congress, in 1907, should be held at Boston, and that Prof. Agassiz be asked to preside. Prof. Minot expressed the hope that it might be possible to place at the disposal of the European zoologists a large steamer, which would call for them at Hamburg, Cherbourg, and Southampton.

Subsequently, Prof. Blanchard gave an interesting address on the production of disease in man by animal parasites, and also pointed out in how many ways zoological discoveries had aided not only the elucidation and diagnosis of disease, but also its cure; after which Prof. Lang made some remarks on the life of the Swiss naturalist, Alexander Morizi, born in 1806 at Chur, who, some years before the appearance of Darwin's "Origin of Species," had published a paper in which he promulgated the theory of evolution and supported the view that man had evolved from the higher animals.

At one of the later general meetings, Profs. Salensky, Osborn, Chun, Hoek, and Sarasin delivered addresses. Prof. Salensky referred to the results of the most recent investigations of the life-history and anatomy of the mammoth, and exhibited photographs of a specimen *in situ* (already noticed in NATURE), as well as preparations of the skin, muscles, hairs, &c. It seems now to be a well established fact that the mammoth was a northern species feeding especially on conifers, but also on cyperaceous, gramineaceous, and leguminous plants. The recently discovered stages in the evolution of the horse and contemporary mammals in North America formed the subject of Prof. Osborn's lecture, while Prof. Chun dealt with the vertical distribution of the marine plankton.

Altogether more than four hundred zoologists, many of whom brought one or more members of their family, took part in the congress. The general meetings were held in the large hall of the Swiss House of Parliament, and the sections met in the lecture rooms of the splendid university buildings, of which the country is justly proud.

I.—GENERAL ZOOLOGY.

It has been assumed that the South American Stegomyia was the means of transferring a blood parasite to man, which gave rise to yellow fever; Prof. Goeldi, of Para, however, gave reasons for his belief that this disease is not due to any blood parasite, but to an organic toxin which he discovered in the saliva of Stegomyia.

The zoological aspect of De Vries's mutation theory was discussed by Prof. Plate, who recognised that the theory signified an important advance of knowledge in so far as it showed that sudden changes could arise in the organism which were highly transmissible, but he urged that a sharp morphological boundary could not be drawn between variations and mutations. The former must be considered as changes with a slight capacity of inheritance, the latter as such with a high capacity.

As the result of anatomical investigations in butterflies, Mr. Petersen, of Reval, attempted to show that all species can be distinguished morphologically by their reproductive organs, and that it is through physiological isolation that varieties form the starting point for new species.

Prof. Maas reviewed the experiments he had carried out in depriving young sponges of carbonate of lime before their metamorphosis.

Prof. Vejdovski demonstrated the presence of a nucleus in *Bacterium Gammari*, already described (*cf. Centralblatt f. Bakteriologie*, 1901 and 1904), while Prof. Looss, of Cairo, indicated how the larvæ of Ancylostomum and Strongyloides migrate through the hair-follicles of the human hand into lymph- or blood-vessels, and from there reach the intestine by way of the heart, lungs, and air passages.

II.—VERTEBRATA (*Systematic*).

Several papers of particular interest were discussed in this section. Among these may be mentioned that of Prof. Scott, of Princeton, on the Miocene mammals of Patagonia. He referred to the fact that the fossil rodents all belong to the Histricomorpha, of which South America is still the headquarters. The Edentata are represented by the three orders Gravigrada, Dasypoda, and Glyptodontia. Several orders of ungulates, he remarked, displayed striking similarities to northern orders, but these similarities must be looked upon as convergent developments, and not due to a common descent.

Mr. Bieler, of Lausanne, described the skull of an extremely small bear obtained in the Alps some years ago, which he identified as belonging to *Ursus formicarius*.

An artificially produced hybrid between *Triton cristatus* and *T. marmoratus* was exhibited by Dr. Wolterstorff, who remarked on its identity with *Triton Blasii*.

Mr. Borodine, of St. Petersburg, described the herrings of the Caspian, in which sea he was able to distinguish no less than five species, three of which were essentially marine forms.

Recent studies and discoveries in the evolution of the horse, with lantern demonstrations, formed the subject of an interesting lecture by Prof. Osborn, who mentioned that more than a hundred more or less complete skeletons of horses and horse-like animals had been found fossil in North America. He thought he had established the fact that horses were polyphyletic, there being four or five contemporary series in the Miocene, but that the direct origin of the genus Equus in North America was not established with certainty.

Prof. von Méhely's paper dealt with the skull and dentition of the species of Spalax, a small East European rodent. As the result of his careful investigations he was able not only to demonstrate that the twelve species described hitherto could be reduced to three, but that the origin of the latter was clearly traceable from an extinct form by gradual mutations, due chiefly to selection.

Prof. Tornier dwelt on the subject of the origin and significance of the coloration of the skin in reptiles, and attempted to demonstrate that those parts which were folded during the animals' movements were less well nourished than the remaining parts, and were therefore lighter in colour.

III.—VERTEBRATA (*Anatomy and Embryology*).

Dr. Kerbert referred to the fact that the giant salamanders of Japan in the aquarium at Amsterdam had produced young, and described the eggs of the species; while Dr. Bashford Dean, of New York, pointed out the peculiarities in the development of *Chimaera Collici*.

The specimens of Ceratodus brought back from Australia by the Semon Expedition enabled Prof. Burckhardt, of Basle, to undertake some anatomical investigation of its central nervous system, of which the author exhibited illustrations and models, and he also showed some reconstructions of fossil vertebrates not hitherto figured.

Prof. van Wijhe, of Groningen, gave a demonstration on the development of the skull in elasmobranchs, while Prof. Lönnberg, of Stockholm, exhibited a fœtal *Elephas cyclotis*, and made some remarks on the homologies of the avian bill.

Dr. Helbing, of Basle, communicated the results of his investigations on the anatomy of Læmargus, and Mr. Bles spoke on the hatching of Anuran tadpoles and the function of Kupfer's "Stirnknospe." He also exhibited Prof. Kerr's slides of the early development of the motor nerve trunks in *Lepidosiren paradoxa*.

IV.—INVERTEBRATA (*exclusive of Arthropoda*).

Prof. Meyer, of Kasan, described the primitive ambulacral system in Echinoderms, and the diaphragm-sacs which serve to swell the head tentacles in terrebelloid annelids, and discussed the theoretical bearings resulting from a comparison of these somewhat similar structures.

Prof. Salensky gave an account of the prototroch, and also referred to the formation of cœlomesoblast of the larva of Echiurus, while the morphology of the cardial organs of Appendicularia formed the subject of another of his papers.

A description of the mode of nutrition of the embryos of Purpura was then given by Prof. Pelseneer. It appears that the majority of the ova undergo an irregular segmentation and form a vitelline mass, on which a few embryos fix themselves and absorb it completely.

Profs. Caullery and Mesnil exhibited preparations of two cœlomic annelid parasites. The first of these, *Pelmatosphaera polycirri*, forming numerous spheres, is allied to the Orthonectida, and lives in the general body-cavity of the host. The next, *Sphaeractinomyxon Stolei*, is the first marine representative of the Actinomyxidæ, and inhabits marine Oligochæts.

Prof. Fuhrmann, of Neuchâtel, described the three known species of Cestodes in which the sexes are in distinct individuals, and which are characterised by very marked dimorphism.

It was urged by Prof. Monticelli, of Naples, that the Temnocephala, for which he proposes the name of Dactyloda, should be looked upon as constituting a group distinct from the Platelminthes.

The most exciting exhibition in this section, and, indeed, one of the most fascinating features of the congress, was a kinematograph demonstration of the development of one of the Botryllidæ. These were kept in a flat-sided glass jar to which a constant stream of fresh sea-water was supplied. Taking a series of photographs at certain regular intervals by means of an ingeniously constructed registering camera, Prof. Pizon, of Nantes, succeeded in producing before the audience a continuous and rapid picture of the gradual evolution of the colonies of the Tunicate. Prof. Marey had shown us some years ago how the quick movements of animals such as the horse and the dog could be reduced on the screen to slow motions, while Prof. Pizon now demonstrated how this can be accomplished in a converse manner.

V.—ARTHROPODA.

Most of the papers in this section dealt with ants. Dr. Forel brought forward some new biological observations, in the course of which he mentioned that there were now about 4000 species known, and 900 varieties; while Prof. Emery discussed the origin of ants' nests; Dr. v. Buttel-Reepen the insect colonies in general; Mr. Piéron the problem of recognition among ants; and Prof. Goeldi, of Para, the mushroom gardens constructed by *Atta cephalotes*.

A few other papers dealt with Lepidoptera, such as that of the Countess v. Linden on the influence of the withdrawal of oxygen during the pupal stage on the shape of butterflies, and that of Mr. Pictet on variations produced in butterflies by changing the food of their caterpillars and by humidity.

Two communications deserve a special reference, viz. Prof. Blanc's discovery of a Caprellid in the Lake of Geneva, and Prof. Heymons's paper on the development of the Solifuga. Prof. Blanc exhibited a female specimen of an undescribed Podalirius, a marine genus of crustacean, and mentioned that other invertebrates allied to marine forms were known to inhabit the lake. The development of the Solifuga agrees, according to Prof. Heymons, in all important respects with that of the Arachnida, but it offers no clue to any closer relationship with insects, as some authors seem to think.

V.—APPLIED ZOOLOGY.

Dr. Jentink's discourse on the ideal natural history museum was delivered in this section. The director of the

Leyden Museum advocates the complete separation of the study and exhibition series, and insists on the great importance of the absolute protection of the specimens from fire, dust, and light.

Prof. Plate described a new microscope suitable for exhibition in museums; Prof. Forel a new method of collecting specimens inhabiting the deep water in lakes; while Prof. Fujii, of Tokyo, referred to some micro-technical apparatus of his own invention.

Finally, a demonstration was given on the installations of the "concilium bibliographicum," by Dr. Field.

VII.—ZOOGEOGRAPHY.

Mr. Schmidt, of St. Petersburg, explained the distribution of the fishes in the northern Pacific, and mentioned that the northern fauna of Japan should be considered as belonging to the Arctic region, and that the fishes of southern Japan and the west coast of North America are very distinct from those of the northern parts.

Prof. Simroth gave his views on the origin of the Alps, based chiefly on the distribution of the Mollusca. Dr. Pellegrin, of Paris, described the fish-fauna found in Lake Tchad and the Chari River, which he declares to be very similar to that of the Nile.

Prof. Forel gave his experiences on the occurrence of *Larus ridibundus* on the Lake of Geneva. It appears that thousands of these gulls are present on the shores of the lake during winter, and that they migrate northward in March, to return again in October with their young. A few remain all the year round. The principal lines of migration of birds across Switzerland were then described by Prof. Fatio, of Geneva.

The congress ended with a couple of days of most pleasant social intercourse. The members were afforded an opportunity of seeing the beauties of the Bernese Oberland during an excursion along the Lake of Thun, and an afternoon spent at Interlaken, where a final meeting was held in the "Kursaal." Saturday was devoted to a trip to Geneva, where, after a lunch and a visit to the museums, the venerable Mr. de Saussure entertained the guests at his country seat near the city, and a Venetian *fête* with fireworks brought the congress to a close.

ROTATION OF SATURN'S RINGS.

ON 1903 November 6, 5h. 25m., I observed a large diffused white spot a little north-east of the extremity of the western ansa. It was placed on the bright rim of the interior ring, just bordering Cassini's division, and appeared to extend faintly over the outer ring.

November 7 was cloudy, but on November 8 there was a clear sky and pretty good definition, but no certain differences of tint could be remarked in the individual rings.

On November 9, 5h. 10m., the planet was very faint, and the two ansæ seemed equally bright. At 5h. 50m., however, the western ansa was decidedly the more luminous, and the aspect appeared similar to that on November 6.

November 10, 11, 12, and 13 were cloudy; November 14 was stormy with fine intervals, but definition was very unsteady, and no white spot could be discerned on the rings.

On November 15 there was a clear, frosty sky. At 5h. 50m., under good definition, the ring seemed notably brighter on western than on eastern ansa.

On November 16 definition was very bad, and no details could be satisfactorily made out. November 17 was cloudy.

On November 18, 5h. to 5h. 40m., there was a good deal of fog, and the planet's image appeared very faint. The western ansa seemed decidedly brighter than the other, but the luminosity appeared diffused and not caused by a definite spot.

No satisfactory observations were secured after the latter date. The weather was extremely unsettled, and definition generally very bad, so that though the planet was examined, whenever visible, until December 11, no further inequalities in the luminosity of the rings were noted.

The bright area seen on November 6 and several other evenings appeared recurrent in same position at intervals of 3 days, whence I infer that the rotation period of the ring is about 14h. 24m. This determination is, however, extremely rough, and only useful as affording evidence of the approximate value.

After I had arrived at this result, I consulted various authors to find what previous estimates had been made as to the rotation of the rings.

Laplace theoretically computed that the ring ought to rotate in 10h. 33m. 36s. (Chambers's "Descriptive Astronomy," third edition, p. 143). In Laplace's "System du Monde," however, it is stated that Saturn rotates in 0·428 day and the ring in 0·437 day, the equivalents being =10h. 16m. 17·2s. and 10h. 29m. 16·8s.

Sir W. Herschel, from a spot or luminous point seen on the interior ring in July, 1789, ascertained that the ring revolved round the ball in 10h. 32m. 15·4s. (*Phil. Trans.*, 1790, vol. lxxx. p. 479).

Secchi obtained many measures of Saturn's system in 1854–6, and apparently detected an ellipticity in the rings, for the discordances were considerable, and harmonised at intervals of 3 and 9 days. He concluded that a period corresponding to that which a satellite would have if situated on the outer ring, viz.

14h. 23m. 18s.,

would satisfy them (*Monthly Notices*, vol. xvi. p. 52). The correspondence between Secchi's period and my own roughly ascertained value, being quite independent, is rather singular.

Now that Saturn is very favourably visible, it is to be hoped that observers will frequently examine the rings for differences in tint or tone which may afford material for the rotation period to be re-determined.

W. F. DENNING.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE title of professor has been conferred on Dr. Karl Schreber, of Greifswald, for physics, and on Dr. Robert Pschorr, of Berlin, for chemistry.

MR. ALEXANDER LAUDER, senior demonstrator in chemistry in the University College of North Wales, Bangor, has been appointed lecturer in agricultural chemistry in the Edinburgh and East of Scotland College of Agriculture.

IN connection with the technical college which will shortly be proceeded with at Stoke-on-Trent, it is proposed to have a school of pottery, which shall not only train pupils, but also act as a central advisory and analytical department for manufacturers. There will also be a mining department. The estimated cost of the building, some 25,000*l.*, has been practically assured, the North Staffordshire Institute of Mining and Mechanical Engineers contributing 4000*l.*, the Staffordshire County Council 4000*l.*, the training authority 6000*l.*, while close on 10,000*l.* has been promised as voluntary contributions.

DR. ANTON LAMPE and Dr. Hans Benndorf, of Vienna, and Dr. F. Streintz, of Graz, have been appointed extraordinary professors of physics. Herr Reinhold Lutz has been appointed professor of mechanical engineering at the Aachen Technical College, Dr. George Schlesinger professor of the theory of mechanical implements in the Berlin Technical College. Dr. Karl Rohn, now professor of geometrical drawing in Dresden, has been appointed professor of mathematics in the University of Leipzig as from April 1, 1905. Dr. Ludwig Prandtl, now professor at Hanover, has been appointed to the chair of technical physics and agricultural mechanics at the University of Göttingen.

THE calendar for the session 1904–5 of the Merchant Venturers' Technical College, Bristol, indicates several improvements which have been made recently at this institution. Among these may be mentioned the new experimental steam engine, with its boiler and measuring appliances, and the experimental light and power station now in use by the students. The courses for engineering students have been re-arranged, and provision has been made for a fourth year's course in civil, mechanical, and electrical engineering. The staff of the engineering departments has been strengthened by the appointment of an additional lecturer.

SIR HENRY CRAIK, K.C.B., in his report for the year 1904 on secondary education in Scotland, says that the examiners are of opinion that the teaching of theory is still the weak point in the instruction in science given in the schools, though there has been some improvement since last session. This weakness is specially conspicuous in the subjects of magnetism, electricity, and hydrostatics. It would appear that most teachers rely too exclusively on the experiments done by the pupils in the laboratory, and do not supplement them sufficiently by full discussion and cross questioning, and by demonstration experiments. It is to be feared that the subjects mentioned are too often attempted by boys who are not sufficiently equipped with a previous knowledge of mathematics and dynamics, who would have been much more profitably employed in going through a course in heat or chemistry. It is satisfactory to find evidence of a tendency to simplify the courses followed in the schools.

THE Higher Education Subcommittee of the Lancashire Education Committee has issued a series of circulars detailing the provision made in the county for instruction in various branches of agriculture. In the first of the pamphlets full particulars are given of a scheme of agricultural education to be carried out at the County Council Farm, Hutton, the Harris Institute, Preston, and in various parts of the county during the session of 1904–5. The course in agriculture at the Harris Institute, Preston, extends over four years, and is intended to prepare youths for the practical work of a farmer's life by instructing them in the principles which underlie farming operations, and demonstrating—in the lecture room and on the farm—modern and scientific methods of agriculture. The instruction is free to approved students, and, in addition, the County Council allows a sum not exceeding ten shillings per week, either for board, lodging, or for travelling expenses, to each student in full attendance, not being a holder of an agricultural scholarship, who fulfils certain conditions laid down. The Higher Education Subcommittee has also made arrangements to consider applications from local committees, agricultural societies, and farmers' associations, for courses of lectures by members of the agricultural staff at the Harris Institute, Preston.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 29.—M. Mascart in the chair.—On the fall of Perseids in 1904: Henry **Perrotin.** The most favourable evenings for observations were August 9 to 14. Owing to the exceptional purity of the atmosphere at the summit of Mont Mounier (2740 metres) a large number of meteors were noted. As regards their points of appearance, disappearance, velocity, and brightness, the results clearly indicate the advantages possessed by stations at high altitudes for methodical observations of meteors.—On the approximate solution of certain congruences: Frédéric **Riesz.**—On the formulæ of tonometry and cryoscopy: E. **Ariès.** In a preceding communication it has been shown that the expression for the potential of each of the two substances in a dilute solution can be deduced from the law of van 't Hoff. In the present paper these results are extended to include the formulæ connecting the alteration of vapour pressure and of freezing point, deduced experimentally by Raoult.—On a case of globular lightning at Autun on July 16: M. **Roche.**—On the theory of macles: G. **Friedel.**—The passage from the root to the stem in *Primula Auricula*: H. **Ricome.**—Researches on the assimilation of some ternary substances by the higher plants: P. **Mazé** and A. **Perrier.** From the experiments described, it is shown that green plants, like fungi and micro-organisms, are capable of assimilating sugars, the only distinction between the two cases being that the former can create these substances at the expense of atmospheric carbon dioxide, whilst in the latter, the nitrous and nitric ferments are the only ones known to be able to take carbon from carbonic acid.—On the preservation of flour by cold: M. **Balland.**

NEW SOUTH WALES.

Linnean Society, July 27.—Dr. T. Storie Dixson, president, in the chair.—Notes on Australian Coccidæ ex Coll. W. W. Froggatt, with descriptions of new species, No. i.: E. Ernest **Green.** A species of Chionaspis found upon the undersurface of the leaves of *Eucalyptus tereticornis*, Sm., and the nut-grass Coccid, a species of Antonina, are described as new. The latter may be classed with the few beneficial species of Coccids, as it is credited with destroying the host-plant (*Cyperus rotundus*, Linn.), a most objectionable weed, over a large area of the Hunter River flats, N.S.W.—Three new generic names for Mollusca: Captain F. W. **Hutton,** F.R.S. The author finds, through the publication of the "Index Zoologicus," that the following generic names, published by him for land Mollusca, have been forestalled:—Pyrrha, by Cabanis in Aves, 1849; Carthæa, by Walker in Lepidoptera, 1858; and Rhenea, by Saalmüller in Lepidoptera, 1884. He therefore proposes the following names to replace them:—Thermia for Pyrrha, Serpho for Carthæa, and Delos for Rhenea.—On a new species of Heteronympha, and a new variety of *Tisiphone abeona*, Don.: G. A. **Waterhouse.**—On four new species of Eucalyptus: J. H. **Maiden.**

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part iii. for 1904, contains the following memoirs communicated to the Society:—

May 14.—Ph. **Furtwängler**: On the construction of the *Klassenkörper* for any algebraic *Zahlkörper*. Lothar **Heffter**: On the definition of the definite integral in two dimensions, independently of previous integration. G. **Prasad**: On the notion of lines of curvature.

June 11.—J. **Stark**: Experiments on the genesis of the band- and the line-spectrum.

June 25.—David **Hilbert**: Principles of a general theory of linear integral equations.

NEW AND OLD VIEWS ON GLACIATION.

Die Gletscher. By Dr. Hans Hess, königl. gymnasial-Professor in Ansbach. Pp. xii+426. (Brunswick: F. Vieweg und Sohn, 1904.) Price 15 marks.

THE author of this closely written treatise reminds us that it is nineteen years since Heim issued his classical "Handbuch der Gletscherkunde," and that the numerous additions to our knowledge since 1885 may well be brought together in a convenient form. Dr. Hess has an intimate personal knowledge of European glaciers, on which he has made patient and numerical observations; and in the difficult matter of the theory of glacier-motion he has had the cooperation of Prof. Finsterwalder, of Munich. The work of Finsterwalder, indeed, is in many ways an inspiration throughout the book, but the references to Chamberlin, Brückner, Drygalski, Penck, Reid, and many others show what an immense amount of material has been added to our knowledge in very recent years.

In summarising the conclusions of these authors, the work of Dr. Hess becomes somewhat encyclopædic, and it will be felt, according to the idiosyncrasies of the reader, that certain subjects are unduly dwelt on, while others are summarily compressed. Those who live in countries that were at one time buried under confluent sheets of ice will wish to see an extended history of Polar and Alaskan glaciers, and a further discussion of the widely spread moraine-material which appeared on their melting and retreat. The mention (p. 388) of Kames and Eskers as "durch die Schmelzwasser geformte Hügel in den Schotterbänken" will hardly satisfy dwellers in Britain or Scandinavia, not to say the Prussian plain; nor does it represent the views recently accepted by Prof. Jas. Geikie, from whose work it is professedly a translation. We ought, however, to be willing to refer to memoirs on special districts when pursuing inquiries such as these, and we may well be grateful to Dr. Hess for the new details brought to our notice from the regions in which he himself has studied.

The book opens with a review of previous observation, in which priority is accorded to John Playfair for realising the meaning of erratic blocks so far back as 1802. The physical characters of ice are then discussed, and full stress is laid on the recognition of ice as a viscous body, yielding to pressures and adapting itself to its surroundings. Glacier-ice (p. 20) suffers some reduction in plasticity owing to the admixture of sand and dust. The discovery by McConnel and Kidd, and by Emden, of the plasticity of the individual ice-crystal led Emden (p. 316) to remark that a glacier consisting of a single crystal at the temperature of its melting point would move precisely as a granular glacier. Regelation, as an explanation of glacier-motion, though still holding its own in physical text-books, has been set by geologists in the second place in recent years. In the regeneration of fractured glaciers, however, as Hess points out, this phenomenon plays a most important part.

We could wish that the tenth section, on the theory of glacier-movement, had followed closely on the first, and had thus offered an explanation of much that is obscure in the earlier chapters of the book. The development of Finsterwalder's "Strömlinien" is greatly needed during the discussion of moraines, and readers of so special a treatise are naturally familiar enough with general physical geography and the form of glaciers to understand the exposition of Finsterwalder's views at an early stage. This exposition, from p. 325 onward, shows how every point in the surface of the firn-basin is connected by a "Strömlinie" with a corresponding point on the surface of the glacier lower down. The ice-particle enters the firn at one end of the line, by deposition from the atmosphere, and disappears from the glacier, by melting or evaporation, at the other end of the line. In between, it has had a course within the ice-mass, longer or shorter, according to the form of the rock-floor and of the bounding walls. The lower boundary of the firn marks the line of division between the area where the flow-lines enter the glacier and that in which they emerge upon its surface. While a "Strömlinie" never lies entirely on the glacier-surface, a "Bewegungslinie" is (pp. 138 and 327) the course of a stone dropped upon and remaining on the surface. Shortly, "Strömlinien" emerge at all points along "Bewegungslinien," but do not coincide with them.

Dr. Hess regards the stratified structure of glacier-ice as essentially arising, by natural conditions and irregularities of deposition, in the area of the firn; the appearance becomes intensified by streaming out and extension lower down (p. 173), but has nothing to do with internal pressures. Experimental evidence of this conclusion is provided. An interesting case of unconformity in the bedding of ice-layers is quoted and illustrated from Finsterwalder on p. 177.

The title of the seventh section, "Eis und Fels," reminds us that massive ice is as much one of the rocks of the earth's crust as desert-sand or a reef of coral. Marine limestones are, for instance, formed of material withdrawn from invisible solution in the sea; on one side they may receive almost molecular additions, on the other side they may disappear again by solution. An ice-mass is similarly added to or removed at different points, but it is none the less a rock. Its plastic behaviour, however, among other rocks has led us to think of it as a thing apart, just as we sometimes forget that mercury has a crystallographic form. The chapter in question will attract attention on account of its treatment of moraines, and the belief of the author in the rapidity of the erosion that takes place upon the glacier-floor. From personal observations, which are now being carried further, he estimates this erosion, in specially active cases, as indicating a reduction of the floor-level by 3 cm. per annum. Allowing for the additional influence of water-erosion, which he considers to be far less than that of the moraine-laden ice, he uses the figure of 3 cm., somewhat adventurously, in calculating (p. 376) the age of some of the larger valleys of the Alps.

A fine picture (p. 35) is given to show how the fissile structure of rocks affects their mode of weathering by the ice. The author holds that large blocks are re-

moved from the walls and floor of glaciers wherever the planes of division lie at favourable angles. In this way, medial moraines have a very real existence below the surface of the glacier as well as upon it, since a rocky island yields ice-scratched material over its surfaces of contact with the ice that sweeps round it on either side. "Such medial moraines (p. 194) possess only ground-moraine material"; the word "only," however, seems negatived by the following sentence:—"their constituent débris is not limited to the surface, but reaches right down to the base. In consequence, the débris seen at the surface is not constant in quantity as in the pure medial moraines, but increases in proportion as the end of the glacier is neared, in accordance with the progress of ablation."

Internal moraines may similarly arise from projections in the firn-area; the fragments are carried forward as a wall within the ice. A little diagram on p. 203 makes Finsterwalder's scheme of moraine-structure clear, though it perhaps exaggerates the filmy character of the ordinary ground-moraine.

It has seemed to many geologists that the increasing stress laid on the plasticity of ice, and the ease with which it adapts itself to obstacles, make it all the more necessary to look to frost and storm, and to the erosive action of sub-glacial streams, as the agents by which glaciated hollows are cut out. The passages (p. 361 *et seq.*) on cirques—no such Gallic word is really admitted to this treatise—and the forms of Alpine valleys will show how much room there is for differences of opinion on this point. We fancy that the views put forward by Dr. Hess as to the simple "peneplain" character of the pre-Glacial Alpine slopes will receive considerable criticism from those who have described the successive movements along the mountain-axis in Miocene and Pliocene times. The grouping of the pre-Glacial river deposits of France and Switzerland, as they are traced back into the hills, should give us some idea of the depth of the valleys before the ice spread down into them. The work of rivers at the present day in rapidly destroying the Glacial troughs, and in carving out ravines on ice-worn walls, leads many of us to regard glaciers mainly as moulders and preservers of the basins which they temporarily fill. Dr. Hess, however, extends his support of the excavation-theory to the Scandinavian fjords (p. 388), and it is well to realise that these views, once widely prevalent, have not lost their hold upon men who can measure and observe.

Modern English writers may find their contentions somewhat slightly dealt with, and their names occasionally mis-spelt. Through a certain Teutonicism, moreover, the glacial terms familiar to three-quarters of the globe are omitted from the text and from the index. Scarcely any German work mentions *roches moutonnées*, made classical by De Saussure; but it is hard to see *nieves penitentes* admitted as a newcomer.

In conclusion, Dr. Hess has produced a book that must find a place in every scientific library, both as the work of an original observer and as a record of the active progress of geological research.

GRENVILLE A. J. COLE.

MATHEMATICS FOR SCHOOLS.

Practical Geometry for Beginners. By V. Le Neve Foster and F. W. Dobbs. Pp. ix+96. (London: Macmillan and Co., Ltd., 1904.) Price 2*s.* 6*d.*

Elementary Algebra. Part i. By W. M. Baker, M.A., and A. A. Bourne, M.A. Pp. viii+275+lii. (London: George Bell and Sons, 1904.) Price 3*s.*

A New Trigonometry for Schools. Part i. By W. G. Borchardt, M.A., B.Sc., and the Rev. A. D. Perrott, M.A. Pp. vii+237+xxxv. (London: George Bell and Sons, 1904.) Price 2*s.* 6*d.*

The Elements of Plane Trigonometry. By R. Lachlan, Sc.D., and W. C. Fletcher, M.A. Pp. v+164. (London: Edward Arnold.) Price 2*s.*

Preliminary Practical Mathematics. By S. G. Starling, B.Sc., A.R.C.Sc., and F. C. Clarke, B.Sc., A.R.C.Sc. Pp. viii+168. (London: Edward Arnold.) Price 1*s.* 6*d.*

Constructive Geometry. By John G. Kerr, LL.D. Pp. 122. (London: Blackie and Son, Ltd., 1904.) Price 1*s.* 6*d.*

New School Arithmetic. Part i. By Charles Pendlebury, M.A., F.R.A.S., assisted by F. E. Robinson, M.A. Pp. xv+206+xxi. (London: George Bell and Sons, 1904.) Price 2*s.* 6*d.*

THE Practical Geometry by Messrs. Le Neve Foster and Dobbs consists of a collection of more than seven hundred examples, grouped in sets, each set illustrating some fundamental geometrical principle, the whole covering the subject-matter of Euclid, Book i. There is little or no descriptive matter, but the examples themselves are carefully selected and arranged, so as to lead the pupil by easy steps from experimental quantitative work, in which geometrical truths are discovered, to generalisations based on the knowledge thus obtained. In part i. the examples are entirely practical. In part ii. the work is partly deductive, and this section is intended to supplement the study of pure geometry, and especially to be used in conjunction with Mr. Allcock's "Theoretical Geometry for Beginners." These two parts are followed by a large number of miscellaneous examples and by twenty-six illustrations of geometrical patterns, in which the student finds scope for the application of the knowledge he has obtained. The book will be found very useful in supplementing any elementary text-book which is confined to the abstract reasoning of pure geometry.

A feature of the Algebra by Messrs. Baker and Bourne is the profuse supply of easy and well graduated examples provided at short intervals, enabling even the very backward student who works through them to acquire by almost insensible stages facility in the manipulation of algebraical symbols, and a sound knowledge of algebraical processes. Revision papers are given from time to time, by which he can test his progress. Considerable use is made of squared paper in the graphing of algebraical functions, the solution of equations, and in other ways, thus greatly adding to the interest of the work, and giving a better insight into the nature of the subject. This book is the first instalment of a larger work, to be completed in a second volume. It carries the subject up to the

solution and theory of quadratic equations. The style is attractive, and well suited to beginners. The answers themselves occupy more than fifty pages, and the volume can, if desired, be obtained without these at a reduction in cost.

The movement of reform in the teaching of elementary mathematics has affected trigonometry, and an outcome is seen in the new text-book by Messrs. Borchardt and Perrott, in which the authors have aimed at presenting the subject in a manner suited to the new conditions. Four-figure mathematical tables are provided for general use. Graphs are introduced from time to time. The first endeavour of the authors is to give the student a good working knowledge of the elements of trigonometry, with facility in practical computation. The opening chapters are thus confined to acute angles. Easy problems are solved on heights and distances, but more attention might well have been given to the solution of right-angled triangles under all sorts of conditions, as this is fundamental. In establishing the general formula for angles of any magnitude, the authors have not perceived that a satisfactory account can only be given by introducing the conception of a vector, with the projections of rotation vectors and vector polygons. Consequently, the heart of the matter is missed, and the foundation for future development is not completely laid. The usual formulæ for triangles, and for compound, multiple, and sub-multiple angles are established, the work consisting largely of a mass of trigonometrical transformations. It is not evident why practical applications should be confined to problems in surveying. There are other rich sources to draw from. Thus, an investigation of simple harmonic motion could be made to throw a flood of light on the significance of trigonometrical formulæ, awakening a living interest in dead symbols. This is the first half of the complete text-book. The part which is to follow will contain chapters on De Moivre's theorem, the exponential theorem, trigonometrical series, &c. The book is a fair attempt to teach elementary trigonometry in a more rational manner, but falls far short of the ideal text-book on the subject.

The remarks just made apply generally to the volume by Messrs. Lachlan and Fletcher, except that the whole of the subject-matter, including De Moivre's theorem, &c., is compressed into one small volume, and in order to be suitable for beginners would require considerably to be amplified and supplemented by the teacher.

The "Preliminary Practical Mathematics" by Messrs. Starling and Clarke is the result of experience gained with technical students, who find, when entering the laboratory or workshop, that their mathematical knowledge is not suited to the requirements, and who have not time to enter on an extended mathematical course to supply the deficiency. If the subject were properly taught to boys at school, a book like the present would not be required.

The ground covered in Mr. Kerr's "Constructive Geometry" is substantially that of the first three books of Euclid's Elements, but the treatment of the subject is in accordance with modern ideas, and is very suitable indeed for beginners. Starting with a few concrete objects and using simple drawing appliances for quantitative experimental work, the pupil "is helped to build up ideas about lines, points, triangles, circles, &c., in precisely the same way as that followed in dealing with the elements of physics and chemistry." Deductive reasoning is increasingly employed as the pupil advances, and we think the author is justified in hoping that "there will be as net result an extensive fund of available knowledge on which more advanced work can rest securely, and also such habits of inquiry and thought as will give a stimulus to further study."

The "New School Arithmetic" by Messrs. Pendlebury and Robinson is based on the sixteenth edition of the Arithmetic by the former, the first edition of which was published eighteen years ago. During this time commercial conditions have changed, scientific requirements have advanced, and a reform in the teaching of elementary mathematics has been inaugurated. The authors have aimed at producing a text-book which shall be fully abreast of the times. Thus metric weights and measures are given and used along with British, and these, being introduced at an early stage, afford excellent concrete examples in illustration of vulgar and decimal fractions. The new style of multiplication is used exclusively, and thus at the proper time approximate methods become natural and easy. Squared paper and other graphical illustrations are used with good effect, and algebraical symbols are introduced on appropriate occasions. The present volume deals with money, weights and measures, and examples thereon, with vulgar and decimal fractions, and with the decimalisation of money. The examples are very numerous and well graduated. The style is simple and clear, and altogether this excellent text-book deserves a wide circulation.

OUR BOOKSHELF.

Die Vorgeschichte des Menschen. By G. Schwalbe. Pp. 52+1 plate. (Brunswick: Vieweg und Sohn, 1904.)

THE author of this work is already well known by his writings on *Pithecanthropus erectus*, the Neanderthal skull, and that of Egisheim. The basis of the pamphlet now before us is a lecture delivered by the author at the meeting of the Society of German Naturalists and Physicians, held at Cassel in 1903, but two valuable appendices have been added to the original lecture. The line of argument runs in the main on palæontological and anatomical evidence, though the existence of man in pre-Glacial times is regarded as an established fact. The writer claims for the Neanderthal man a specific distinction from the "homo sapiens" of Linnæus, and would term him "homo primigenius." He traces the relations of this early representative of the human race not only with the *Pithecanthropus erectus*, but with the Dryopithecus and some of the more anthropoid forms of living apes, and in the illustrative plate gives diagrams of the forms of the different skulls. The agreement of the human remains from Spy, in Belgium, with those from the Neanderthal is accepted, and those from the Krapina cave, in Croatia, though varying in the brachycephalic direction, are regarded as belonging to the "homo primigenius." Mr. Schwalbe seems even inclined to accept evidence of the existence of man in Tertiary times. Whether his conclusions can in all cases be adopted without hesitation or not, his arguments are worthy of careful consideration, and the

appendices, which include an extensive catalogue of the literature on the subject of primæval man, will be found to contain a large amount of useful information.

J. E.

Metallurgia dell' Oro. By Ing. Emilio Cortese. Pp. xv+262; 35 incisioni. (Milano: Ulrico Hoepli, 1904.) Price 3 lire.

Metalli Preziosi. By Ing. A. Zinone. Pp. xi+315. (Milano: Ulrico Hoepli, 1904.) Price 3 lire.

NOTHING exactly resembling the Hoepli manuals is published in the English language, though in French the "Encyclopédie scientifique des Aide-Memoire" constitutes a close parallel. The Hoepli series now amounts to 800 little volumes dealing with science, literature, and the fine arts. The method of publishing is useful, and contrasts favourably with the inconvenient system adopted in the old-fashioned encyclopædias with large volumes containing heterogeneous congeries of subjects. The latest additions to the series are neatly bound, well printed with good sized type, and can be carried in the pocket. The book on the metallurgy of gold contains brief accounts of the washing and sluicing of auriferous gravels, and of the crushing and amalgamation of gold ores. There are also chapters on the Plattner and Mears processes of chlorination, on cyaniding, and on the refining and parting of gold bullion. The descriptions are fairly clear and accurate, but some of them deal with antiquated processes. The Newbery-Vautin process, the Crauford mill, and Greenwood's electrolytic process are all described, but on the other hand no mention is made of the use of the lead-zinc couple in the precipitation of gold from cyanide solutions, or of Taverner's lead-smelting process. In the other book, the metals dealt with are silver, gold, and platinum. The properties of these metals and their alloys, and the methods of assaying and treating their ores are briefly described, and the remaining eighty-five pages of the book are devoted to the uses of gold and silver in the arts. Both volumes are supplied with a complete table of contents, but suffer from the absence of indexes.

The Telephone Service: its Past, its Present, and its Future. By H. L. Webb. Pp. 118. (London: Whittaker and Co., 1904.) Price 1s. net.

AN interesting description of the general working of the modern city telephone system is given in the pages of this book. No attempt is made to describe the power plant of the modern telephone exchange, or the details of other parts of the machinery by which an efficient telephone service is maintained, but the general principles of this means of communication are clearly explained, and suggested developments of telephone policy in Great Britain are discussed. Every subscriber who reads the book will be given an intelligent and tolerant view of the telephone service.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Magnetic Disturbances and Navigation.

CAN the compasses of modern ships be influenced by magnetic disturbances to such a degree as to imperil navigation? The disaster which on the morning of June 28 befell the Danish s.s. *Norge*, and by which about 600 lives were lost, ought, in the opinion of the present writer, to bring this question to the front. The course of the ship should take her about 25 miles south of Rockall. The last observations, by which position, deviation, and the absence of current were ascertained, were made only twelve hours before the ship struck, and showed nothing extraordinary. It seems impossible to explain the discrepancy between the real position and that of the reckoning on the morning of June 28 without assuming a sudden and considerable alteration of the deviation on the compass.

This view is supported by communications, called forth by the disaster, from two captains, who have, or at any rate think they have, directly observed such alterations. The communications run as follows:—

(1) "A few years ago I (Captain Hveysel, s.s. *L. H. Carl*) was on a voyage from the United States of America to Denmark, following the great circle from Newfoundland to Pentland Firth. About 200 miles west of Rockall I had the position at noon accurately determined by observations of the sun, but as the sky was clear in the dusk, I determined anew the latitude, as well as the longitude, by stellar observations, and found to my astonishment that the ship had gone forward in a direction about 1 point more southerly than calculated according to the reckoning. By observation of the pole star it was in fact ascertained that both the compasses of the ship had acquired a hitherto unknown easterly deviation of 10° to 11°. The weather was fine, but a faint northern light was observed, which I supposed to be the cause of the magnetic disturbance. The course was shaped in accordance with the new deviation, but I continued to take the bearings of the pole star, and towards midnight the compasses were observed to return to their normal deviation, while the aurora disappeared."

(2) "I, Captain F. W. Horner, master of the s.s. *Elixir* of West Hartlepool, while on a voyage from Port Inglis, Florida, to Linhamn, Sweden, between noon June 24 and noon June 25, in the vicinity of the Island of Rockall, found by observation of the sun that the deviation on the compasses had changed 9°, whereby my ship had gone 25 miles out of her course to the north. I was steering to pass 20 miles north of Rockall, and found by observation at noon June 25 that I had passed 45 miles north of it. After passing through the Pentland Firth the compasses again returned to normal."

This last observation has a special interest as relating to the immediate vicinity of Rockall, and to about the same time as the shipwreck of the s.s. *Norge*. Can any of your readers furnish facts of a similar nature?

So far as I have been able to ascertain, disturbances of the declination needle of like duration and intensity are completely unknown, but, to my mind at least, compasses, mounted in steel ships and compensated by powerful magnets, cannot be directly comparable to the needles of a magnetic observatory. Is it possible to explain such temporary deviations of ships' compasses, as appear to have been observed in the cases related above, from the known variations of the earth's magnetism?

AUGUST KROGH.

The Physiological Laboratory, Copenhagen University.

The Great Red Spot on Jupiter.

OWING to very ill-health, I have not been able to make observations of Jupiter during the last few weeks, but have been interested in receiving the results of some other observers. It appears that the great red spot is rapidly accelerating its motion, so that its longitude is decreasing, and with a continuation of this behaviour the spot will ultimately correspond with the position of the zero meridian of system ii. of Crommelin's ephemerides. The present longitude of the marking is about 25°, which is the same as it was in the summer of 1898, so that the mean period of rotation during the last six years has been identical with the rate of system ii., viz. 9h. 55m. 40·63s.

The variations in the velocity of the spot during the past few years have exhibited a curious oscillation, and it will be important to watch the future developments of the object. It would be interesting to see in NATURE during ensuing months some reports from observers as to whether this singularly durable marking maintains its present rapid westerly drift.

W. F. DENNING.

Bristol, September 12.

THE OLDER CIVILISATION OF GREECE: A PREHISTORIC SEA-POWER.[1]

READERS of the articles on the "Older Civilisation of Greece" which have from time to time appeared in the columns of NATURE will remember that the archæological labours of Mr. Arthur J. Evans, F.R.S., Prof. Ludovico Halbherr, Mr. D. G. Hogarth, and Mr. R. C. Bosanquet (not to mention their assistants, of whom Dr. Duncan Mackenzie and Prof. Luigi Pernier are the most distinguished) in the island of Crete have succeeded in disinterring for modern science the remains of an ancient civilisation as highly developed as the contemporary cultures of Egypt and Babylonia, and possibly as old; in any case a thousand years older than the civilisation of Greece which we have learnt to know at our schools and academies—the Greek civilisation of the schoolmasters and the sculptors. Of this prehistoric civilisation (for prehistoric it still remains, since we cannot yet read its written records) the first remains were found by the famous Schliemann at Mycenæ and Tiryns, hence the use of the term "Mycenæan" to describe it. The excavations in Crete have of late years very considerably modified our conceptions of its character; we see now that the chief seat of its development was not the continent of Greece, but the great island of Crete, and that the two most important remains of its Cretan phase were the great stone palaces of Knossos and Phaistos, which have been excavated by Dr. Evans and Prof. Halbherr respectively.

Now it is evident that the whole Mycenæan civilisation did not pass away without leaving some trace of its greatness and power upon the minds of the semi-barbarous tribes from the north who overthrew it, and afterwards built up the renascent "classical" culture of Greece upon its ruins, just as the English built up the modern renascent Roman civilisation of England on the ruins of the Romano-British culture which they destroyed. Just as traditions of the greatness of the Romans remained in the minds of the English, so, but to a much greater extent, traditions of their "Pelasgian" forerunners remained in the minds of the later Greeks and combined with their own "Aryan" tales to form the legendary history of early Greece. A considerable proportion of the Greek legends—the Wars of Troy and of the Seven against Thebes, the stories of the Atridæ and of the Minyæ, &c.—are undoubtedly altered reminiscences of the prehistoric period of high civilisation to which the remains discovered at Mycenæ, at Orchomenos, at Knossos, and at Phaistos belong. Among these legends, which certainly contain a substratum of historical truth, those of the Thalassocracy of the Cretans under the sway of the great and wise Minos are the most important. It is certain that the palace discovered by Mr. Evans at Knossos is the veritable Labyrinth of the Minotaur; one may believe in the Labyrinth without being accused of also believing in the Minotaur, and if one believes in the Labyrinth one also believes in the magnificence and power of its builders, whether their names be Minos and Dædalus or not. Probably their names were not really in the least like Minos or Dædalus, but it is evident that these appellations signify, the one the powerful prehistoric dynasty of Knossos, the other the skilled craftsmen who made for them the beautiful works of art which we can admire in the Museum of Candia, and which are photographically reproduced in the pages of the "Annual of the British School at Athens."

The most characteristic feature of the Knossian or "Minoan" power in legend is the fact that it was a sea-power. This is always insisted upon. Cretans raid the Attic coast, found colonies in Sicily and at Miletus, and so on. A power of the calibre of that which is revealed to us by the Cretan excavations can never have confined its operations to the isle of Crete alone. And the evidence of over-sea connections, with Egypt and with the continent of Greece, is so strong that there can be little doubt that the legends are right, and that Minoan Crete held a thalassocracy, was a great sea-power. Sea-power means the foundation of colonies, and apparently Minoan Crete was no exception to this rule. It may be that the coast settlement of Paláikastro, beyond Sitía at the extreme eastern end of the island, was a Minoan colony established on the non-Minoan, possibly hostile, shore of the Eteokretans, though it is only fair to say that Mr. Bosanquet is not in favour of the theory of the predominantly non-Minoan character of the Sitía country in Minoan days. At Phylakopi, in the island of Melos, the nearest of the Cyclades to Crete, has been

Fig. 1.—Shrine of snake-goddess with marble cross as central cult object. Conjectural arrangement. (From "The Annual of the British School at Athens.")

[1] "The Annual of the British School at Athens," No. ix., 1903-4. Pp. x+422, and Plates. (London: Macmillan and Co., Ltd.) Price 17s. net. "Excavations at Phylakopi in Melos." Hellenic Society Supplementary Paper, No. 4. Pp. xv+280, and Plates. (London: Macmillan and Co., Ltd.) Price 30s. net.

discovered a strongly walled settlement of indubitably "Minoan" character, superimposed upon the ruins of earlier, no doubt native, towns; that this was a Cretan over-sea colony there can be little doubt.

The excavations which have revealed to us these striking confirmations of the Greek legend of the Minoan thalassocracy have been carried out by the British School at Athens during the last eight years under the control of its successive directors, Mr. Cecil Smith, the present keeper of Greek and Roman antiquities in the British Museum, Mr. D. G. Hogarth, and Mr. R. C. Bosanquet. The energy of the British School at Phylakopi and Paláikastro, combined with the remarkable results achieved by Dr. Arthur Evans at Knossos, has largely helped to win for England that foremost position in practical Greek archæology which she holds at present. For not even our friendly rivals in Germany can for a moment dispute the fact that England and Italy are *facile principes* in Greek archæology at the present day. Germany is only tardily following in our footsteps with the excavations at Orchomenos, and has not even yet secured for herself a site for exploration in Crete, while France seems hopelessly wedded to classical traditions, and has no thought for the extraordinary prehistoric civilisation, twin-sister it would almost seem to that of Egypt, which is revealing itself in Crete.

FIG. 2.—Two of the ancient crania exhumed at Hagios Nikolaos. (From "The Annual of the British School at Athens.")

The chief publication of the year dealing with these English discoveries is, as usual, the "Annual of the British School at Athens." The volume for 1904 contains Dr. A. J. Evans's annual report on Knossos, and Mr. Bosanquet's report on Paláikastro. Dr. Evans tells us how his work in the Labyrinth still goes on, and seems to be no nearer completion. Discoveries of the highest historical importance still continue to be made. An extraordinary light has been thrown upon the religion of Pelasgian Greece by the discovery of the images of a snake-goddess by Miss Boyd (American excavations) at Gourniá, half-way between Knossos and Paláikastro, and by Dr. Evans at Knossos, in the latter case in conjunction with a *cross* as central cult-object. What is to be made of this? Any day's work, any turn of the spade, may turn up something extraordinary. And these same snake-goddesses of Knossos are made of a fine varicoloured glazed faïence, like that of Egypt. That the Minoans derived this idea from Egypt is certain. Other objects of the same glaze were found, shells especially; the colour of the glaze of many of these shells is that of the rare Egyptian glazed faïence of the dynasties of the Old Empire, between B.C. 4000 and B.C. 2000. This typical colour is a light blue, radically different from the shining dark blue of the twelfth dynasty or the beautiful colours of the blue glazed pottery of the eighteenth. It is not, however, very different from the light blue of the twenty-sixth dynasty. The reason is not far to seek; the twenty-sixth dynasty artists archaised here as in greater matters; they imitated the colour of the earliest faïence. The date of the Minoan palace of Knossos is between the epoch of the twelfth dynasty and that of the eighteenth; the date of the old light blue faïence is earlier, between B.C. 4000 and the twelfth dynasty. It was this faïence that the Minoan potters imitated. The conclusion as to the date at which Greek civilisation first began to borrow ideas from that of Egypt may seem extraordinary; but Mr. Evans's diggings at Knossos have already produced so many extraordinary things that we are prepared for more.

We do not expect the same remarkable discoveries from Mr. Bosanquet's diggings at Paláikastro. It is a poorer site, and it is not the Labyrinth of Minos. Enough has, however, been found more than to maintain the interest of former years of excavation, and there is little doubt that here was a Minoan settlement like that of Phylakopi. Two new features at Paláikastro are the remains of primitive burials from the cave of Hagios Nikólaos and the remarkable ossuaries at the sites of Roussolakkos and Patema, and the great hoard of votive terracottas found by Messrs. Myres and Currelly on the hill of

FIG. 3.—External face of great wall, showing revetment on the right and bastion in the distance. (From "Excavations at Phylakopi in Melos.")

Petsofà or Tsofàs, south of Paláikastro. The skeletons are usually in the contracted position characteristic of the Neolithic race of the Mediterranean; they show small stature (average 1.625 m.) and dolichocephalic head-form. Mr. Duckworth, who describes them, says "it seems that the early Cretans anticipated in head-

form and stature the proportions assigned to the 'Mediterranean race' [of Sergi], and thus can be described as the earliest known representatives of that race" (p. 354). It is, however, confusing to speak of the Paláikastro people as "anticipating" the Mediterraneans in any way; the Paláikastro skulls, though no doubt a few hundred years older than "those discovered at Zakro [on the coast south of Paláikastro] and described by Boyd Dawkins, and those from Erganos [a Mycenæan site in a valley running up from the Pediada plain into the Lasíthi mountain-system near the Aphendis Sarakinos] described by Sergi" (p. 353), are of Bronze age date, while the Neolithic Mediterraneans belong to Sergi's race as much as the Mycenæans; the Paláikastro people *were* "Mediterraneans" (as Mr. Duckworth says on p. 349)—they did not anticipate them.

The Petsofà find of votive terracottas is paralleled by the very similar pocket of votive female figures and models of female breasts, &c., phalli, and figures of cows, of red pottery and blue glazed faïence, found by Prof. Naville and myself during the past season in the eighteenth dynasty dust-heap of Queen Hatshepsu's temple at Deir-el-Bahari, in Egypt; a number of these votive figures were exhibited at the annual show of the Egypt Exploration Fund at University College, Gower Street, in July.

The pottery from Paláikastro is discussed by Mr. R. M. Dawkins, who publishes a very fine "filler-vase" (p. 311) of the well known Mycenæan type. For a parallel Mr. Dawkins refers to a representation of a vase in the tomb of Rekhmara, at Thebes in Egypt, published by Mr. W. M. Müller in his "Asien und Europa," p. 340, and by me in "The Oldest Civilization of Greece," frontispiece. This representation of the vase in question, for which not Mr. Müller, but the great Champollion is responsible, is, however, inaccurate. Mr. Dawkins would have found a better parallel from the tomb of Rekhmara in last year's "Annual of the British School," p. 171. Mr. Dawkins also contributes a most interesting account of a visit to the rather remote island of Karpathos, between Crete and Rhodes, which should be of interest to geographers and anthropologists. To anybody who has seen them from the Eteokretan heights above Sitía, or from the shores of Grandes Bay by which Paláikastro lies, the islands of Kasos and Karpathos offer a most alluring invitation; but it is not everybody who can spare the time to accept it. Mr. Dawkins has been able to do so, and is lucky.

The excavations at Phylakopi, in Melos, were conducted by the School before those at Paláikastro, in Crete, were begun. They are not yet completed, the work at Paláikastro having been taken up with the idea of returning to Phylakopi at some future date. It is to be hoped that this aspiration will be fulfilled, for Phylakopi is among the most interesting of "Mycenæan" sites. The excavations were carried out from 1896 to 1899, Mr. Cecil Smith being in command during the first two years, Mr. Hogarth in the third, and Mr. Mackenzie, now Mr. Evans's assistant at Knossos, in the fourth. Mr. Mackenzie was present during the whole four seasons, thus supplying the "element of continuity" in the excavations. Each of these gentlemen has contributed his quotum to the combined work which has been issued for the school by the Society for the Promotion of Hellenic Studies under the direction of an editorial committee, composed of Mr. Bosanquet, Mr. E. A. Gardner, and Mr. G. F. Hill, of the British Museum. Messrs. Arthur Evans, Bosanquet, G. C. Edgar, F. D. Atkinson, and F. B. Welch have also contributed to the volume.

The result is a remarkably valuable and well got-up book, with an extremely good series of illustrations. Among articles which are all of equal value and interest it is invidious to direct special attention to any in particular, but while Mr. Bosanquet's on the wall-paintings and Mr. Edgar's on the pottery are of special interest to "Mycenæologists," those of Mr. Bosanquet on the early Ægean trade in obsidian, which seems to have radiated from Melos, and of Mr. Mackenzie on the general historical relations of the successive settlements, especially in connection with the Minoan culture, which Mr. Mackenzie has had such unequalled opportunities of observing in the course of his work with Mr. Evans at Knossos, will be of more general interest, and should be carefully noted by all students of early culture-development. The famous fresco of the flying-fish, the most remarkable example of Mycenæan art found at Phylakopi, is published in colour on Plate iii.; as a delineation of the animal it is remarkably accurate, and as a design most admirable.

Fig. 4.—The site from north-east. Beach of boulders in the foreground. (From "Excavations at Phylakopi in Melos.")

Enough has been said to show that this year's record of the annual progress of the discovery of the older civilisation of Greece has in no way fallen behind its predecessors in interest. H. R. Hall.

NOTES.

On Saturday last, September 10, the *Discovery* arrived at Portsmouth with the members of the British Antarctic Expedition. On Sunday Captain Scott received a telegram from the King offering His Majesty's congratulations on the success and safe return of the explorers. The King has directed that a new medal for service in the Polar regions shall be struck and granted to the officers and crew of the *Discovery* in recognition of the successful accomplishment of their enterprise. Commander Scott has been promoted to the rank of captain in the Royal Navy; and the nation's thanks are due to him, the officers, scientific staff, and crew of the *Discovery* for the successful way in which they have maintained the credit of our country in the records of geographical discovery. The first news of the expedition after the departure of the *Discovery* from New Zealand in

December, 1901, was brought by the relief ship *Morning*, which arrived at Lyttelton in March, 1903. From the information then received, described in NATURE of April 2, 1903 (vol. lxvii. p. 516), it was evident that the expedition had already achieved great success, both in the way of exploration and of scientific observation. Further details of the first year's work of the expedition, especially with regard to the great southern ice barrier and the nature of the lands discovered, are contained in Captain Scott's official report communicated to the presidents of the Royal and the Royal Geographical Societies, summarised in these columns on July 30, 1903 (vol. lxviii. p. 307). Upon the return of the *Discovery* to Lyttelton at the beginning of last April, accompanied by the relief ships *Morning* and *Terra Nova*, it became known that many specimens of great scientific interest had been collected, including fossil remains of dicotyledonous plants from an altitude of 8000 feet. The material thus accumulated, as well as the continuous magnetic records and other observations in terrestrial physics, will be of the greatest value to science, and the study of it will engage the attention of naturalists and physicists for some time to come. The specimens brought home include the emperor penguin and other rare Arctic birds and their eggs, geological and other specimens, a large number of photographs of Antarctic scenes, some of which were taken by moonlight; and a set of coloured drawings of parhelions observed when the sun rose.

THE report of the council of the Society of Chemical Industry was presented to the annual general meeting opened in New York on Thursday, September 8. From this report we learn that the number of members on the register on July 31 was 4134, as compared with 3050 at the previous annual meeting. The council urges that Government, through a department, should be in closer touch with commerce and industries. In Germany the functions of the Ministry of Commerce comprise the control of "all matters affecting handicrafts," and to it, as a consultative body, is attached the technical committee for industry, which studies the scientific progress of industries, and keeps the minister in touch with them. America has recently established a department of commerce and labour, and France has had a Minister of Commerce for some years. The council two years ago appointed a committee to cooperate with members of Parliament and others who are in favour of this reform. The council has given its support to a petition asking the Treasury that the National Physical Laboratory may be placed in a position to do its important international work by means of a grant for capital expenditure and an increased annual subvention. Among the more important researches carried out by the laboratory during the past year may be mentioned those on pure iron-carbon alloys, certain nickel-steel alloys, mercury standards of resistance, a comparison of thermometers up to 1100° C., and measurements of the specific heat of superheated steam up to a pressure of 200 lb. to the square inch. The society's medal, founded in 1896, and awarded by the council once in every two years for conspicuous service rendered to applied chemistry by research, discovery, invention, or improvements in processes, has this year been awarded to Prof. Ira Remsen, president of the Johns Hopkins University of Baltimore.

A LARGE party of members of the Liége Association of Engineers, the leading technical society in Belgium, visited London on September 12 and 13. On September 12 they proceeded to Teddington and visited the National Physical Laboratory, where they were received by Sir Edward Carbutt on behalf of the executive committee. On September 13 they were entertained at dinner at the Hotel Cecil by the Iron and Steel Institute. Mr. E. Windsor Richards, who was president when the institute visited Liége in 1894, occupied the chair, and an eloquent speech of welcome was delivered by Sir James Kitson, past-president of the Iron and Steel Institute, and ably responded to by Mr. Jules Magery, the president of the Belgian society.

THE second International Philosophical Congress was held at the University of Geneva under the presidency of M. Ernest Naville on September 4–8, and was attended by 500 members, representative of every school of philosophic thought in Europe. We learn from the *Times* that the following papers were read:—Prof. Boutroux, of l'Institut Paris, on the *rôle* of the history of philosophy in the study of philosophy; Profs. Stein (of the University of Bern) and Gourd (of the University of Geneva), the definition of philosophy; Prof. Windelband (of Heidelberg), the present task of logic and philosophical inquiry in relation to natural science and culture; Profs. Vifredo Pareto (of Lausanne) and De Greef (of Brussels), the individual and society; and Profs. Reinke (of Kiel) and Giard (of Paris), neovitalism and finality in biology. At the sectional meetings the subjects under discussion were the history of philosophy, general philosophy and psychology, applied philosophy, logic and philosophy of the sciences, and history of the sciences.

IN connection with the reception given by the United States Naval Observatory to the eighth International Geographic Congress at Washington on Thursday, September 8, a special set of time signals was sent over the Western Union Telegraph Company's system from Washington to England for transmission over the lines of the Government, the Eastern Telegraph Company, and the Great Northern and Western Telegraph Companies to observatories in various parts of the world. The object of the signals was to mark the actual passing of midnight at Washington, and accompanying the signals was the following message:—"The eighth International Geographic Congress now in session in Washington sends with this midnight signal its greeting to the nations of the world through the courtesy of the various telegraph and cable companies." The *Times* states that the observatories at the following places sent complimentary responses in most cases immediately on receipt of the foregoing messages and signals:—Greenwich, Pulkowa (Russia), Helsingfors, Madrid, Lisbon, Rome, Madras, Mauritius, Cape Town, Melbourne, Adelaide, Sydney, Wellington, N.Z., Rio de Janeiro, and Cocos. It was hoped that the signals would have a favourable influence on the movement to secure the universal adoption of standard time, based on the meridian of Greenwich.

Science announces that the Department of Agriculture at Washington is making definite arrangements concerning the work which will be carried on with the Guatemalan ants found by Mr. O. F. Cook in Guatemala to kill the cotton boll weevil. Mr. Cook has authority under the chief of the Bureau of Entomology to carry to completion the study of the life-history of the Guatemalan ant, and of such other species of ants as may be involved, in order properly to understand the life-history of this species. He will also direct and superintend the further introduction of the *kelep* ant from Guatemala if the same is deemed necessary, and will supervise and carry out the work connected with the colonisation of the ant in the southern United States.

AN exceptional rainfall in Cuba is reported in the *Times* of September 10 as having occurred on June 13. Mr. W. A. Wilson, of the Public Works Office at Santiago,

writes that the storm lasted for three hours, and was accompanied with almost continuous thunder and lightning, and he estimates that at least 12 inches of rain fell during that time. Bridges and houses were washed away, and about a hundred lives were lost in that locality. The storm extended over a considerable area, probably 200 to 300 square miles, and the Guaninicum and Platanillo Rivers each rose 33 feet. Mr. Wilson gauged the fall for an hour and a half, during which time nearly 7 inches were measured. Santiago is a station of the U.S. Weather Bureau; we shall therefore hope to receive a fuller account of the storm. In looking through their last published report (1902–3), we do not find any figures equalling the above, but in Symons's "British Rainfall for 100?" 3·50 inches are recorded in one hour. The most noteworthy facts appear to be the duration of the great intensity of the fall and the large area over which the storm occurred.

The Meteorological Council has recently issued part I. of "Climatological Observations at Colonial and Foreign Stations." In the preface Dr. W. N. Shaw states that the council has contemplated for some time the issue of summaries of the observations which they receive from the Foreign Office, the Colonial Office, or directly from the observers in various British colonies and dependencies, but that it has been unable hitherto to carry out the preparation of the observations for the press. Mr. E. G. Ravenstein, who was chairman of a committee appointed by the British Association at the Cardiff meeting in 1891 for the collection and discussion of observations from tropical Africa, has, however, been good enough to put together the observations for a large number of stations, and to superintend the preparation of the summaries. These have now been issued by the Meteorological Council for the years 1900–2, with summaries for previous years, and form a very valuable contribution to the meteorology of that part of the world. The observations refer chiefly to stations in the Egyptian Sudan, British East and Central Africa, and Rhodesia. The volume is accompanied by useful sketch maps showing the positions of the various stations.

Dr. F. M. Exner contributed a useful paper to the Vienna Academy of Sciences (*Sitzb.*, Heft x., 1903) on a relation between the distribution of air pressure and amount of cloud, based on an examination of the mean values of twenty years' observations. The question to be solved was with what distribution of pressure, with a west wind of given strength, has Vienna a certain amount of cloud or rainfall. The result of the investigation showed that when the air flowed from an area of steep barometric gradients to one of slight gradients, it was accompanied by bad weather, and *vice versâ*. The reason is that in the first case more air flows towards the locality than flows away from it horizontally, so that a portion of it finds its way to the upper strata, while in the second case the opposite occurs. The same rule would apply not only to a west wind, but would hold good for wind from any quarter. The paper is illustrated by a series of charts.

Messrs. S. Hirzel, of Leipzig, announce a new publication bearing the title *Jahrbuch der Radioaktivität und Elektronik,* to be edited by Dr. J. Stark, of Göttingen. Each volume will be issued in four quarterly parts.

The mathematical and scientific section of the Imperial Academy of Sciences, Vienna, announces a prize of 2000 krone to be awarded for the best thesis embodying "an improvement in our knowledge of the hysteresis of dielectrics." The competition will close on December 31, 1906.

No. 16 of the *Physikalische Zeitschrift* contains several papers dealing with radio-activity. F. Paschen shows that when the kathode rays produced by radium are caused to impinge from above upon a photographic plate placed film downwards on a small sheet of platinum, an intense blackening is produced in the negative which corresponds in outline with the metal. That this effect is due to a secondary radiation, and is not caused merely by reflection of the kathode rays from the platinum, appears to be proved by the fact that when these rays are directly transmitted through a sufficiently thin plate of the metal, the darkening beneath the metallic film is much more intense than elsewhere. It is the γ rays which seem to be mainly responsible for the secondary radiation. Mr. H. A. Bumstead has carefully investigated the nature of the radio-activity induced in a negatively charged wire by exposure to the atmosphere. He concludes that the atmosphere contains principally the emanation of radium, but that the thorium emanation is also present to an extent varying largely with conditions such as the temperature and stillness of the air. On the other hand, Dr. E. F. Burton considers that the radio-active emanation which is evolved on heating raw petroleum is due solely to radium, and that a small quantity of radium itself is present in the oil. Miss C. Böhm-Wendt describes measurements which show that the amount of ionisation produced by polonium in different gases is independent of the nature of the gas. In this respect, therefore, polonium resembles radium.

It has long been a controversial question whether by the action of heat alone the line spectrum of gases can be produced. In the July number of the *Atti dei Lincei* R. Nasini and F. Anderlini endeavour to give a definite answer to the problem. On subjecting the vapour of iodine to a high temperature in a carbon tube heated in an electric furnace, they found that at slightly above 1000° an emission spectrum is produced which is the inverse of the usual absorption spectrum of iodine vapour. Similarly nitrogen at temperatures above 3000° gives an emission spectrum in which the principal lines characteristic of the element are visible. Under the conditions used it is probable that electrical influences were excluded, and that the spectra obtained were due solely to the high temperature employed. In the same number of the *Atti* L. Vanzetti has studied the electrolysis of glutaric acid in order to decide whether the dibasic aliphatic acids are capable of being converted in this way into polymethylene hydrocarbons, and whether the synthesis of a closed ring can thus be effected. The acid gave, however, only ordinary propylene, not a trace of trimethylene being formed.

We have received copies of two interim reports issued by the Engineering Standards Committee. One of the publications contains British standard tables of copper conductors and thicknesses of dielectric; the other includes the British standard specification for tubular tramway poles. The tables and specification are to be regarded as final, and they will be embodied in the final report of the Engineering Standards Committee, which will combine all specifications. The tables dealing with copper conductors give the British standard sizes of stranded conductors for electric supply, and separate tables are concerned respectively with large, intermediate, and small sizes. Other tables provide British standard radial thicknesses for jute or paper dielectric, lead and armour, for underground cables, and British standard radial thicknesses for rubber dielectric, for lead sheathing and armouring. The specification for tramway poles gives full particulars as to construction, length, length of section, outside diameters, minimum thickness, &c., and also as to

what tests should be applied to the poles. As the preface to the specification says, a standard specification having now been arrived at as the result of the joint labours of the committee and the makers, it is hoped that, in future, the standards recommended by the committee will be universally adopted by all engineers engaged in designing and installing electrical tramways throughout the British Empire.

THE contents of the June number of the *American Naturalist* are chiefly biographical and botanical, Dr. R. T. Jackson contributing an account (with a portrait) of the life and work of the late C. E. Beecher, while Dr. B. M. Davis continues his studies on the plant-cell, and Mr. F. C. Lucas illustrates diagrammatically the range of variation displayed by the blossoms of the common cone-flower (*Rudbeckia hirta*).

THE entomological division of the Biological Laboratory of Manila has issued an illustrated *Bulletin* of fifty-eight pages, by Mr. C. S. Banks, the Government entomologist, on insects affecting the cacao, intended specially for the benefit of cultivators of that valuable crop in the Philippines. Every part of the cacao plant, from the root to the fruit, has its particular enemies, black ants and cicadas attacking the roots, while beetle-grubs bore into the trunk, and various Coccidæ and aphides damage the fruit. Fortunately the ravages of certain of these scourges are somewhat checked by other insects which prey upon the species damaging the cacao. Much further work is required before the whole history of cacao-hunting insects can be known, and the best means of checking their ravages devised.

WE have received from the publishers, Messrs. Asher and Co., Bedford Street, W.C., a specimen of a series of fifty coloured biological diagrams, reproduced from the German issue of Messrs. Schröder and Kulls, but with the explanatory legends in English. The plates are 34 by 42 inches in size, are printed in from six to eight colours, and are sold at 3s. each. The one with which we have been favoured illustrates the structure and life-history of the cockchafer, with comparative studies of other beetles. It is admirably adapted for school purposes. Judging from reduced photographic reproductions of other diagrams, we think those devoted to invertebrates are superior to those illustrative of mammals, so far as drawing is concerned; but this is a common feature in German zoological art.

IN the September issue of the *Quarterly Journal of Microscopical Science* Prof. E. R. Lankester re-publishes his valuable and profusely illustrated article on the structure and classification of the Arachnida from the tenth edition of the "Encyclopædia Britannica." One of the points emphasised in this communication is the affinity of the king-crab (Limulus) and the trilobites to the Arachnida rather than to the Crustacea; and in summarising the evidence for the arachnid nature of the former, the author alludes to the interesting discovery by Mr. Pocock of a rudiment of the seventh segment of the scorpion-limb in Limulus, thus bringing the two genera very closely into line. Another interesting feature to which special attention is directed is the mode of evolution of the "lung-book" of the scorpion from the "gill-book" of the king-crab, which appears to be a unique phenomenon. Among the other contents of the number in question may be mentioned two papers by Prof. W. B. Benham on new worms from New Zealand, and one by Dr. H. J. Hansen on new parasitic copepod crustaceans.

PARTS iii. and iv. of vol. xlv. of *Smithsonian Miscellaneous Contributions* contain an important paper by Mr. M. W. Lyon on the hares, rabbits, and picas, illustrated by a number of figures of their comparative osteology and dentition. Needless to say, the old Linnean genus Lepus is much subdivided, and, unfortunately, the generic and subgeneric divisions adopted by the author by no means coincide with those proposed a few years ago by Dr. Forsyth Major in the *Transactions* of the Linnean Society—a notable divergence being the generic separation of the South African thick-tailed hare from the rabbit. Owing to the complexity of the classification adopted, some of the species of Leporidæ cannot at present be definitely placed, and are therefore, strictly speaking, without subgeneric names. This will, however, be remedied in the course of time, and there is no doubt whatever that the present memoir—whether or no its proposed scheme of classification be adopted in its entirety—is an important contribution towards the right understanding of an exceedingly difficult group of mammals.

A SERIES of Jurassic ammonites from Echizen and Nagato in Japan has been described and figured by Prof. Matajiro Yokoyama (*Journ.* Coll. Sci. Tokyo, vol. xix., art. 20). The strata in the province of Echizen comprise a series of shales and sandstones, mostly of fresh-water origin, but divisible into a Lower or Ammonite bed, a Middle or Plant bed, and an Upper or Cyrena bed. The Ammonites include several new species of Perisphinctes, all more or less allied to foreign Lower Oxfordian forms, and one species of Oppelia, which exhibits a distant relationship to *Oppelia nobilis* of the Tithonian. The strata which have yielded Ammonites in Nagato consist of clay-slates, so that the fossils are much compressed. Species of Hildoceras, one of which is near to *Am. Levisoni* (of Wright); of Harpoceras, near to *A. lythensis* and *A. exaratus*; of Cœloceras, near to *A. fibulatus*; and of Dactylioceras, near to *A. annulatus*, indicate that the Nagato slates belong to the Lias, and probably to the upper part of it.

SOME useful hints on the practical development of a farm wood-lot are given in a *Bulletin* of the Hatch Experiment Station of the Massachusetts Agricultural College, issued last May. The products required in this particular case were fire-wood, fencing posts, and lumber for making fruit boxes, besides which some poles and more valuable timber were obtained. The writer, Mr. F. A. Waugh, recommends larch for posts and chestnut and hickory for lumber. The illustrations added are numerous and well chosen.

THE formation of root-hairs in the vascular cryptogams and flowering plants has been studied by Mr. R. G. Leavitt, and his account, which is published in the *Proceedings* of the Boston Society of Naturalists (April), contains several points of interest. In the case of lycopods, horsetails, and a few ferns, the trichoblasts are determinate, but in all dicotyledons, except the Nymphæaceæ and most of the true ferns, root-hairs may arise from any external cell. Of monocotyledons, the Liliifloræ and Spadicifloræ generally conform to the latter type, but in the Helobieæ, Glumifloræ, and Enantioblastæ the root-hairs develop from definite cells.

THE annual report of the Botanical Department of Trinidad for the year ending March 31 has been received. The superintendent, Mr. J. H. Hart, states that he has succeeded in raising seedling sugar canes in Trinidad which compare with the best varieties obtained in Barbados, Antigua, and elsewhere. It appears that owing to the practice of cutting the plants annually in May, the seed production and the sucrose content are reduced, so that the experiment will be tried of allowing plants for seed to remain over for a longer period. The plantations of

Balata, *Mimusops globosa*, and of the imported timber trees, Honduras mahogany and African mahogany, *Kasya senegalensis*, are growing freely

FOR the forthcoming new edition of the "Imperial Gazetteer of India," Sir J. D. Hooker has written a chapter on the flora of India, which is prefaced by an introductory summary. With the authority of the Secretary of State for India, this chapter has been issued in an advanced form, and the summary is reprinted in the *Journal of Botany* (August). In the same number an account will be found of certain changes which will be proposed at the forthcoming congress of botanists to be held at Vienna in June, 1905, in connection with the rules which govern botanical nomenclature. The three lists of suggestions here given take the form of alterations in, or additions to, the Paris code, and have been drafted respectively by British botanists of the British Museum, American botanists of the Gray Herbarium, and a group of Italian botanists.

THE latest addition to the Manueli Hoepli is a handbook dealing with artisan dwellings, by the engineer Effren Magrini, of Turin. In the same series Dr. Guido Sandrinelli has issued a new and completely revised edition of the manual of the late Pietro Gallizia on strength of materials and applied elasticity. It deals with calculations of strains and stresses in beams and other structures, and allied problems of use to the practical engineer.

No. 5 of the *Bulletin* of the Belgium Academy of Sciences contains an account by A. de Hemptinne of a remarkable electrolytic synthesis of stearic acid from oleic acid. This acid, when subjected in an atmosphere of hydrogen to the discharge of a Tesla transformer, combines with the gas to form principally stearic acid. In No. 6 of the *Bulletin* is a description of the preparation and properties of a number of fluorine-substituted amines. These substances are remarkable because of their extraordinary stability as compared with the corresponding chloro- and bromo-derivatives, which, as a rule, decompose rapidly at the ordinary temperature.

To the *Smithsonian Miscellaneous Collections* (vol. xlv., parts iii. and iv.) Prof. F. A. Lucas contributes an account of a nearly perfect skeleton of a pavement-toothed iguanodon (Trachodon or Claosaurus). The edentulous predentary and premandibular bones of the iguanodont dinosaurs are considered by the author to have been sheathed in horn, and thus to have formed a beak adapted for nipping off the branches or herbage on which these reptiles fed. Among other contributors to the same part are also Messrs. Jordan and Snyder, who describe several new deep-water fishes from Japan. These include a shark of the genus Pristiurus, as well as one of Pseudotriacis, and likewise a new genus, Trismegistus, allied to Liparis. *Trismegistus owstoni*, as the third of these new species is called, is certainly a very remarkable fish, somewhat like a sole in shape, although, of course, bilaterally symmetrical, with the skin dotted with prickles supported on broad bases, so as to recall inverted drawing-pins.

IN the August number of the *American Journal of Science* Mr. Bertram B. Boltwood records observations which indicate that the quantities of radium present in several uranium minerals, which have been examined, are directly proportional to the quantities of uranium contained in the minerals. This is perhaps to be regarded as experimental evidence in favour of the suggestion that radium is formed by the breaking down of the uranium atom.

IN the August issue of the *Annales de Chimie et de Physique* is a contribution by Messrs. Moissan and Rigaut on the use of metallic calcium in the preparation of argon. It is shown that the last traces of nitrogen, which are not so easily removed by a heated mixture of lime and metallic magnesium, are readily absorbed by passage of the gas over a small quantity of metallic calcium. An apparatus is described in which argon can be continuously produced at the rate of a litre every twelve hours.

SOME interesting experiments relating to the electrolytic reduction of carbonic acid are described by Messrs. Coehn and Jahn in the *Berichte der deutschen chemischen Gesellschaft* (vol. xxxvii. p. 2836). The reduction cannot be effected in acid solutions or in solutions containing the normal carbonates, but takes place readily in bicarbonate solutions. From this the authors conclude that the reducing action is limited to the bicarbonate ion, and that the carbonate ion and the undissociated carbonic acid molecule are not reducible. The reduction only takes place at those electrodes at which hydrogen is discharged at a considerable over-voltage, and the product of reduction is formic acid.

WE have received a copy of the report and recommendations presented to the Pharmacopœia Committee of the General Medical Council by Prof. Wyndham R. Dunstan and Mr. H. H. Robinson with reference to the tests for the detection of arsenic in the drugs of the British Pharmacopœia. It is found that the test proposed by Mayençon and Bergeret in 1874, if performed under certain conditions, is best adapted to the purpose. This test depends on the production by arseniuretted hydrogen of a stain on paper soaked in mercuric chloride. The method possesses the advantage of requiring only such a degree of purity in the acid and zinc as is to be found in purchaseable materials, and thus avoids the special purifications involved in the Marsh-Berzelius test. The stain decided on as the standard of comparison is that given by 0·012 milligram of arsenic.

OUR ASTRONOMICAL COLUMN.

RE-DISCOVERY OF ENCKE'S COMET.—A telegram from the Kiel Centralstelle announces the re-discovery of Encke's comet at the Koenigstuhl on September 11. The position of the comet at 13h. 16·9m. (local M.T.) was

R.A. = 1h. 46m. 16s., dec. = +25° 24'.

These positions seem to be very slightly lower than the apparent positions given in the ephemeris reproduced in these columns on September 8. As this is the second comet of this year, it will be designated 1904 *b*.

DR. COMMON'S 60-INCH REFLECTOR.—In *Circular* No. 83 of the Harvard College Observatory, Prof. E. C. Pickering announces that, thanks to the generosity of an anonymous donor, who, unconditionally, gave twenty thousand dollars to the observatory, and to the intermediary services of Prof. Turner, the observatory has been able to purchase the well known 60-inch mirror which was made by the late Dr. Common.

Arrangements are being made to transport the mirror to Cambridge (Mass.) as soon as possible, and, when mounted, it will be used to complete the photometric survey of the heavens which has been so thoroughly—so far as means would permit—prosecuted at Harvard. With an instrument of this aperture it will be possible to measure the light of the very faintest stars known.

Prof. Pickering states that Mr. T. A. Common, from whom the mirror was purchased, let them have it on such favourable terms that he may fairly be regarded as having contributed a large portion of the cost.

VARIABLE STARS IN THE LARGE MAGELLANIC CLOUD.—Although the Magellanic clouds have been looked upon as centres of extraordinary physical conditions, the congregation of variable stars within their limits has hitherto remained unnoticed.

In *Circular* No. 79 of the Harvard College Observatory, however, it was announced that an examination of the Harvard photographs showed that the small cloud contained numerous variables. Consequently, an examination of the photographs of the large cloud was made, and resulted in the discovery of 152 new variable stars within its boundaries. A catalogue of these, giving their positions (for 1900·0), their magnitudes, and the magnitude-range of their light-variations, is published in No. 82 of the Harvard College Observatory *Circulars*.

All these variables have short periods, and seem to be arranged in definite groups, the most remarkable of which begins near N.G.C. 1850, and extends towards a point about one degree south of N.G.C. 2070. This group contains more than half the stars observed, and the included stars are remarkable for their faintness and for the small range of their variations.

THE SUN'S ANTI-APEX.—Mr. J. E. Gore sends the following remarks upon Prof. Kobold's study of the sun's proper motion, mentioned in last week's NATURE (p. 459):—"Prof. Kobold gives the position $A=159°·6$, $D=-54°·7$, or R.A. 10h. 38·4m., $\delta=-54°·7$, and says the point is near α Argus. (His words are, 'Der berechnete Punkt liegt am Himmel ganz in der Nähe von α Argus, der gegenüberliegende Punkt in der Nähe von δ Cephei,' *Astronomische Nachrichten*, 3961.)

"This is, however, not correct, for the position of α Argus (Canopus) is R.A. 6h. 21·8m., $\delta=-52°\ 39'$ (1900). His statement that the 'opposite point' (the apex) lies near δ Cephei is, however, correct. The point found by Prof. Kobold for the anti-apex lies a little north of the famous variable star η Argus. This point lies in the Milky Way, as stated by Prof. Kobold. The fact that most of the determinations of the position of the solar apex lie in or near the Milky Way seems to suggest that the sun may be moving in an orbit 'nearly coinciding with the plane of the Milky Way.' This was pointed out by Mr. G. C. Bompas in the *Observatory*, January, 1896."

OBSERVATIONS OF THE SOLAR SURFACE, JANUARY–MARCH.—M. Guillaume, director of the Lyons Observatory, communicated a *résumé* of his observations of the solar surface during the first three months of the present year to the Paris Academy of Sciences on August 1.

The total spotted area was less than half the amount for the previous trimestre, the observed values being 2572 and 5130 millionths respectively. This was not due, however, to the absence of spots, for the phenomena have decidedly entered upon a period of increasing activity; the solar disc has not been free of spots since September 21.

In the preceding cycle the present condition of activity obtained 1·6 years after the minimum of 1889; in the present cycle 2·0 years have elapsed since that of 1901.

During the period under discussion 77 groups of faculæ with a total area of 86·0 thousandths were recorded, instead of 64 groups and 66·0 thousandths as recorded in the previous trimestre. The faculæ were also less symmetrically arranged in regard to latitude, there being 35 groups in the southern hemisphere and 42 in the northern in place of 33 and 31 respectively (*Comptes rendus*, No. 5).

INSTRUCTIONS TO VARIABLE STAR OBSERVERS.—At a meeting of the Société astronomique de France held in 1900 it was decided to form a section for the observation of visual variable stars, and for the organisation of the section a committee was formed.

This committee now publishes, in the September *Bulletin* of the society, the first chapter of a set of very detailed instructions to variable star observers.

This first instalment contains a list of stars which are especially suitable for observations of the nature proposed, minute instructions as to the methods of observing and of recording and reducing the results, and many other hints which will be found extremely useful by anyone engaged in making visual observations of variable stars.

OBSERVATIONS OF FUNDAMENTAL STARS.—In the catalogue of 2798 zodiacal stars published by Sir David Gill in 1899, 210 of the objects named were designated "fundamental stars," but the places of only about two-thirds of these were given in Newcomb's fundamental star catalogue for 1900.

To facilitate the work of other observers, Mr. R. H. Tucker, of Lick Observatory, has just published the observed places of the remaining third in No. 3965 of the *Astronomische Nachrichten*. He gives the designation, the magnitude, the observed positions (reduced to 1900), the precessional values, and, in some cases, the proper motion in each coordinate of all the stars which are given in the zodiacal catalogue but are not mentioned in Newcomb's catalogue.

THE BRITISH ASSOCIATION.

SECTION K.

SUBSECTION, AGRICULTURE.

OPENING ADDRESS BY WILLIAM SOMERVILLE, M.A., D.SC., D.ŒC., CHAIRMAN OF THE SUBSECTION.

THE audience that I have to-day the honour of addressing may be assumed to consist of a considerable proportion of the members of the British Association, and some others, who are primarily interested in, and have themselves made appreciable contributions to, the progress of Agricultural Science. I may, therefore, take the opportunity of congratulating you on this fresh evidence of progress in the subject that you have at heart, and of offering to the British Association our thanks for the encouragement and stimulus which are associated with the formation of an agricultural subsection. Perhaps I rightly interpret your feelings when I say that for the present we are satisfied with the position attained by our subject, but that we trust to see this and other meetings demonstrating that Agricultural Science is not unworthy of further advancement.

In view of the large amount of work that lies before us during the next few days, I do not propose to intervene for long between you and the contributions to original research which we have been promised. The scope of my remarks will be limited no less by time than by the fact that it would be presumptuous in me to attempt to traverse the whole field of Agricultural Science, including, as it may be held to do, the no small compartments of Horticulture and Forestry. What I propose to do, therefore, is to confine myself to touching upon a few of the subjects that have recently been receiving attention at the hands of scientific investigators, especially abroad. I have purposely avoided discussing English work, partly because it may be assumed that we are all familiar with it, and partly because, where friends are concerned, selection is difficult.

Although Agriculture has only now been elevated to a position of semi-independence in the programme of this Association, it has, in the aggregate, received much attention at the meetings inaugurated with that at York in 1831. It is interesting to turn up the early volumes of the Reports, and to ascertain what was running in the minds of our predecessors, and what the problems that they thought it vital to solve. In the account of the first meeting in this town in 1833 we find a Report by Lindley on the Philosophy of Botany, two of the items in which are of interest to students of Rural Economy. Apparently at that time much attention was being given to the mode of the formation of wood. Two theories appear to have divided botanists—the one that wood was organised in the leaves, and sent down the stem in the form of embryonic but organised fibres, to be deposited on the surface of wood already formed. The other theory was that wood was secreted *in situ* by the bark and older wood. It is to the former of these theories that Lindley gives his adherence. Although this problem has ceased to interest, the same cannot be said of another subject discussed in the same Report, namely, the so-called "fæcal excretions" of plants. In the words of Lindley, "A new apple orchard cannot be made to succeed on the site of an old apple orchard unless some years intervene between the destruction of the one and the planting of the other; in

gardens no amount of manure will enable one kind of fruit-tree to flourish on a spot from which another tree of the same species has been recently removed, and all farmers practically evince, by the rotation of their crops, their experience of the existence of the law." He attributes to Macaire the demonstration of the fact that all plants part with a fæcal matter by their roots. These excretions he held to be poisonous, maintaining that, although plants generate poisonous secretions, they cannot absorb them by their roots without death, concluding that "the necessity of the rotation of crops is more dependent upon the soil being poisoned than upon its being exhausted." He indicated the lines along which investigation might with advantage proceed, one of the questions put forward being "the degree in which such excretions are poisonous to the plants that yield them, or to others."

In 1833 botanists and agriculturists had not the advantage of the knowledge that is at our disposal through the continuous growth for a long series of years of certain crops at Rothamsted, but consideration of the fact that some crops (as, for example, pure forests of beech, silver fir, Scots pine and other trees, as also permanent pasture) may be grown for hundreds of years on the same ground without any evidence of poisoning might have led to the conclusion that the law, as it was called, was not of general application. It is, of course, true that rotations are an advantage, and it is a matter of experience that certain crops—*e.g.* clover and turnips—cannot be grown continuously on the same land, but the cause is not now associated with excretions. The reason for the failure of clover, or the cause of land becoming "clover-sick," as it is called, is still a debated point; but I may hazard the conjecture that it is due to the fact that organisms or enzymes inimical to the vital activity of the minute living bodies, that exist in symbiotic relationship with the clover plants, increase with great rapidity when the living bodies that they affect are present in abundance. Red clover is the species that is usually associated with the term clover-sickness, but it would appear that a precisely similar phenomenon is exhibited in the growth even of wild white clover. It is a matter of common observation that on certain classes of land white clover is stimulated to such vigorous growth by the use of phosphatic manures that for one year at least it monopolises the area to the almost total exclusion of other plants. But such rank luxuriance is not of long duration. In a year or two the clover disappears to a very large extent, and cannot at once be restored by any process with which we are acquainted. The land has, in fact, become sick to white clover. But given a period of rest, during which the inimical agents will disappear, and it again becomes possible to stimulate white clover to vigorous growth. We have, it seems to me, an analogous state of things in the case of certain insects. On the Continent the caterpillar of the Nun Moth (*Liparis monacha*, L.) periodically proves extremely destructive to certain conifers, and it is found that in the first year the insects are moderately abundant, in the second they are excessively abundant, while in the third the visitation begins to decline, and usually terminates quite suddenly. The causes of this cessation have been thoroughly worked out, and are found in the great increase of parasitic insects, and insecticidal fungi, including bacteria. I believe it will be found that the almost sudden cessation of our periodic visitations of the diamond-back moth is due to a similar cause.

The failure of turnips is apparently largely, if not entirely, due to the increase of insects and parasitic fungi.

The subject of harmful excretions has recently obtained renewed attention through the work being done at the Woburn Fruit Station. No point has received more striking demonstration there than the harmful influence that growing grass exerts on fruit-trees. It has been shown that this prejudicial influence is not due to the withdrawal of moisture, to the curtailment of supplies of plant food, to interference with aëration, or to modifications of temperature. In Mr. Pickering's opinion,[1] "the exclusion of all these possible explanations drives us to believe that the cause of the action of grass is due to some directly poisonous action which it exerts on the trees, possibly through the intervention of bacteria, or possibly taking place more directly." It is satisfactory to know that the subject, which is of considerable scientific and practical importance, is likely to be vigorously followed up.

[1] The Effects of Grass on Apple Trees." *ournal R.A.S.E.* Vol. lxiv. p. 365.

In the early 'forties attention was being directed to a subject that even now has a great attraction for agriculturists, namely, the stimulating and exhausting effect of artificial manures, especially nitrate of soda. The principle that "stimuli lose their full effect upon living matter when frequently repeated" was generally held to account for the want of response that crops exhibited to repeated dressings of nitrate of soda; but Prof. Daubeny in 1841[1] pointed out what is now generally accepted as the true cause, namely, the exhaustion of the soil of other substances. This, he said, can be counteracted by giving other manures, of which he instanced bone meal. His suggestions for future investigations have been largely followed, though, as we now know, they are of theoretical rather than practical importance. He proposed the alternatives:

(1) Analysis of the soil, discovery of the amount of available plant food, and the application of the substances found to be deficient up to the probable measure of the crop's requirements.

(2) Discovery, by analysis of the yield, or estimation by calculation, of the amount of plant food removed in the produce, and the application to the soil in the form of manure of what was withdrawn by the crop.

Daubeny suggested that manuring should be undertaken on a system of book-keeping—on the one side being entered all the items of plant food taken out by crops, and on the other all that is applied in the form of manures, the two sides of the account being made to balance. This theory of manuring is distinctly suggestive, and often fits in rather remarkably with actual practice, though the comparative agreement between theory and practice is due to causes that the author of the theory probably hardly contemplated. Take, for instance, the case of wheat. An average crop removes from an acre about 50 lbs. nitrogen, 30 lbs. potash, and 20 lbs. phosphoric acid. This loss would be restored by the use of some 3 cwt. nitrate of soda, 2 cwt. kainit, and $1\frac{1}{2}$ cwt. superphosphate; and on many soils wheat could, no doubt, be grown continuously for many years on such a mixture, aided by good tillage, without the yield suffering materially. But we now know that much of the plant food offered in manure never enters the crop at all, so that the balancing of the account is due almost as much to chance as to calculation. This becomes more apparent when we regard such a crop as meadow hay, which in actual practice is often grown for a long series of years on the same land. To balance the withdrawal of phosphoric acid by an average yield of this crop only about $\frac{3}{4}$ cwt. of superphosphate per acre is theoretically necessary, but on most soils an average yield would not be maintained by the use of so small a quantity.

During the 'fifties the volumes of the Association contain several important contributions from the two distinguished Englishmen to whom the world's agriculture owes so much, Lawes and Gilbert. Their first contribution was made in 1851, and dealt with Liebig's mineral theory, a subject with which their names will always be associated. They drew upon their rich store of experimental data to prove that the yield of wheat is much more influenced by ammonia than by minerals, and they gave it as their deliberate opinion that the analysis of the crop is no direct guide whatever as to the nature of the manure required to be provided in the ordinary course of agriculture. With the reservation "in the ordinary course of agriculture," the dictum cannot be questioned, though in the circumstances of the continuous growth of wheat, as has been pointed out, conclusions indicated by the analysis of a crop happen to accord, at least approximately, with manurial practice.

Field experiments or demonstrations, which have been such a prominent feature of the educational work of the past decade, appear to have been first introduced at the meeting of the Association in 1861 by Dr. Voelcker.

While agricultural subjects have claimed a considerable share of the time of the Association, forestry has not been altogether overlooked. As early as 1838 we find attention being directed to what has of recent years come to be a burning question—namely, the maintenance of our timber supplies. At that early date, when the industrial develop-

[1] "On Manures considered as Stimuli to Vegetation."

ment of the country was, comparatively speaking, in its infancy, the estimate of our timber requirements was, in the light of present experience, amusing in its modesty. Captain Cook estimated that "100,000 acres of waste taken from the Grampian Hills for the growth of larch would in two generations not only supply the ordinary wants of the country, but enable us to export timber."[1] Assuming a rotation of eighty years, this estimate postulates that the produce of some 1200 acres, of a value of about 120,000*l.*, was sufficient to make us independent of foreign supplies. Such is the estimate of 1838; now let us turn to the estimate of 1904. Dr. Schlich, in his volume on "Forestry in the United Kingdom,"[2] passes in review Britain's timber requirements, and, after making allowance for woods like mahogany, teak, &c., which cannot be grown here, he comes to the conclusion that "if all these items are added up we find that we now pay for imports in timber . . . the sum of 27,000,000*l.*, all of which could be produced in this country." Assuming as before that the value of an acre of mature forest is 100*l.*, it means that our imports are drawn from 270,000 acres, and to maintain our supplies merely at their present level a forest area of more than 20,000,000 acres, worked on an eighty years' rotation, is necessary.

Although it has been reserved for the Cambridge Meeting of 1904 to witness the delivery of an Address from the Chair of an Agricultural Subsection, this is by no means the first occasion on which an agricultural subject has furnished the theme for a Presidential Address. In 1880 the then Dr. Gilbert presided over Section B, and chose for his subject Agricultural Chemistry; in 1894 Prof. Bayley Balfour inaugurated the work of the Biological Section with an Address on Forestry; while in 1898 the President of the Association focussed the vision of all thinking men on the greatest agricultural problem of all—the World's Supply of Wheat.

German Investigations on the Action of Conservation Agents on Farmyard Manure.

Those who have followed the progress of Agricultural Science in Germany must have noticed how much attention has been given during the past ten years to investigating the changes that take place in farmyard manure during storage under varying conditions. The stimulus and funds for this work have for the most part been supplied by the German Agricultural Society, which in 1892 resolved to carry through an exhaustive inquiry. For this purpose it enlisted the cooperation of several of the most fully equipped stations in the Empire, and the reports that have appeared bear testimony to the industry and analytical ingenuity that have been brought to bear on this important subject.

The experiments were originally designed to extend over four years, the first, 1892–3, being devoted to preliminary, chiefly laboratory, experiments; the others, to work on a scale more in accordance with farm practice. But although the period originally contemplated is now long past, the problem is by no means solved, and the Society has recently been making a fresh grant for additional experiments of a similar character. In point of fact, the subject has been found to bristle with difficulties, and the results obtained with small quantities of manure, or in summer, have not always been confirmed with large quantities of manure, or in winter.

In 1897 I published an account[3] of the more important results obtained up to that time, confining myself chiefly to questions of temperature and the loss of organic matter, and the conclusion arrived at was that "none of the conservation agents usually employed appears to have any very important influence on the decomposition of farmyard manure."

Since then several important reports[4] have appeared, and I propose shortly to refer to their contents.

[1] Cook, "On the Genera Pinus and Abies."
[2] Bradbury, Agnew and Co., 1904.
[3] *Journal Board of Agriculture*, September, 1897.
[4] Hansen and Günther, "Versuche über Stallmist-Behandlung," *Arbeiten der Deut. Land. Gesell.* Heft 30, 1898. Pfeiffer, "Stallmist-Konservirung," *Ibid.* Heft 73, 1902. Immendorff, "Ueber Stallmist-Bewahrung," *Mitt. der Deut. Land. Gesell.* Heft 21, 1903. Schneidewind, "Fünfter Bericht uber die Versuchswirtschaft," *Lauchstädt, Land. Jahrb.* xxxiii. p. 190.

While the experiments have in almost all cases dealt with the fate of nitrogen, phosphoric acid, and potash, the chief interest centres round the nitrogen, for, given reasonably satisfactory conditions of storage, it is only this constituent of farmyard manure that is likely to suffer loss. But much importance, from the experimental point of view, attaches to the analytical results obtained with the other two substances, for the reason that the quantities of these found are the surest test of the accuracy of the work. The general method of procedure has been to employ a fairly simple but sufficiently nutritious food-mixture, and to allow a definite quantity of this and of litter for a certain number of selected cows. The weight of nitrogen, phosphoric acid, and potash in the food is accurately determined, all of which ultimately reaches the manure, less what goes into the milk, and into the live-weight increase, if any. If the account of what the animals receive as food and litter, and what they furnish as liquid and solid fæces, milk, and animal increase, approximately balances as regards mineral matter, it may be assumed that the sampling and analysis have been sufficiently accurate to justify definite conclusions being based on any deficiency in nitrogen that may be found.

The work of Hansen and Günther, Pfeiffer, and Immendorff was carried out at consecutive periods from 1893 to 1902, at the experimental station of Zwätzen, near Jena, where stalls and dung-pits had been constructed for the purposes of this research. Schneidewind's experiments were conducted at the station of Lauchstädt, near Halle.

Effects of Kainit.—This was used by Hansen and Günther at the rate of 0·75 kg. per 1000 kg. live weight of stock per day, while Pfeiffer and Immendorff used twice as much. The kainit was in no case spread on the litter in the stall, as this would have caused inflammation of the skin of the udder, legs, and abdomen of the cows, but was sprinkled on the manure as spread and pressed into the pits. In certain series of the experiments the manure was removed from the stalls daily, in others it was only removed once a week. Two weeks was the usual time necessary to collect a sufficient quantity of manure, which, with the liquids, usually amounted to about 8000 kg. at Zwätzen, and about one-fifth of this weight at Lauchstädt. The period of storage was generally about four months.

Hansen and Günther found that in pits the untreated manure lost 11·5 per cent. of nitrogen; while the manure treated with kainit lost 14·4 per cent.

Pfeiffer found that the loss of nitrogen in untreated manure was 17·2 per cent., which compares with a loss of 19·5 per cent. in the presence of kainit. The loss of nitrogen when kainit was used by Immendorff was 21·3 per cent., the loss in the untreated manure not being given in his tentative report so far available. Schneidewind did not experiment with kainit. The results of these experiments are in complete relative agreement, and show that the loss of nitrogen is greater when kainit is used than when it is withheld.

Effects of Superphosphate.—This substance was spread twice daily over the litter in the stall at the rate of 0·75 kg. per 1000 kg. live weight. The results obtained were as follows:—

—	Loss of Total Nitrogen	
	In untreated dung	When super. used
Hansen and Günther ...	10·25	16·25
Pfeiffer	17·20	20·80
Immendorff	—	19·80

With superphosphate, as with kainit, the loss of nitrogen during the storage of dung has been increased. It may, however, be mentioned that Hansen and Günther and Immendorff found that superphosphate conserved nitrogen to an appreciable extent so long as the dung lay in the stall, but that its effects disappeared whenever its acid phosphate and free sulphuric acid had been neutralised by ammonia, and this rapidly occurred in the pit.

Effects of Precipitated Phosphatic Gypsum.—This at the

rate of 1 kg. per 1000 kg. live weight was tried by Hansen and Günther and Immendorff, the substance employed containing fully 8 per cent. P_2O_5. It was spread twice daily on the litter in the stall. The result obtained by Hansen and Günther was that after lying for seventeen weeks in the pits the manure that had been untreated had lost 10·35 per cent. of nitrogen, whereas that treated with the phosphatic gypsum showed a loss of 14·47 per cent. The loss of nitrogen found by Immendorff when this substance was used amounted to 19·8 per cent. This substance, like the others, would therefore appear to be valueless as a fixer of nitrogen.

Effects of Gypsum.—This substance has long been recommended as an agent for conserving nitrogen in the dung-heap. The results of its use, spread twice daily on the litter in the stall at the rate of 1 kg. per 1000 kg., live weight, in the experiments conducted by Hansen and Günther, were that in the presence of gypsum the loss of nitrogen amounted to 11·89 per cent., which compares with a loss of 8·56 per cent. when nothing was mixed with the dung.

Schneidewind, using a much larger quantity of gypsum, namely, 5 lbs. per 100 lbs. of dung, found that the loss of nitrogen was reduced from 35·69 per cent. to 15·22 per cent. In this connection he says: "The use of gypsum has markedly reduced the loss of nitrogen. Assuming the conserved nitrogen to have a good action on the crop, this agent may be said to have paid. But as the bulk of the nitrogen so conserved was found to consist of slow-acting albuminoid compounds, and seeing that the sulphate of lime was largely reduced to sulphides, which are directly injurious to plants, we cannot conclude that the use of gypsum has been profitable. Investigations with this substance will, however, be continued."

Hansen and Günther carried their experiments the length of using the various lots of manure on crops, but this part of their researches was hardly more favourable to the use of conservation agents than the other. They thus express themselves: "When the various manures were used on crops, five times in six the treated manure acted no better than the untreated. Only on one occasion was an improvement observable. Field and pit experiments alike have proved that the conservation agents employed are of no value." Schneidewind expresses himself equally forcibly when he says: "As the result of many experiments conducted by ourselves and others, we have arrived at the conclusion that chemical substances are valueless as conserving agents."

Pfeiffer also tried sulphuric acid sprinkled over the manure as it was placed daily in the pit, when it was found that the loss of nitrogen was reduced from 27·8 per cent. to 7·1 per cent. In this connection Pfeiffer says: "The cost, however, was nearly a mark for each kilo. of nitrogen conserved, and the use of sulphuric acid is associated with so many drawbacks that its employment cannot be recommended."

Schneidewind came to a similar conclusion, and thus expresses himself: "As a result of numerous conservation experiments carried out with various quantities of sulphuric acid, and with various acid sulphates, we cannot advise the use of these substances."

But although no benefits have been obtained from the use of the substances indicated, some useful information is available as to the advantages of giving attention in other directions to the management of farmyard manure. Hansen and Günther took four lots of manure of similar character, storing two of the lots in pits and placing the other two in heaps in the open field. From the end of September until the middle of December the pitted material had on the average parted with 13·25 per cent. of total nitrogen, whereas the loss in the manure in heaps averaged 25·3 per cent. When the behaviour of the ammoniacal nitrogen was investigated it was found that the loss was 35·73 per cent. in the pits and 82·5 per cent. in the heaps. The loss, therefore, is greatest in that part of the nitrogen which is the most active and the most valuable.

In another series of experiments by the same investigators the manure was all placed in pits, but in one case it was spread equally and trodden down, while the escape of liquids was prevented. In the other case the manure was simply thrown loosely and irregularly into the pit without spreading or treading, the surface being left uneven and therefore much exposed to the air, while the liquids were allowed to drain away. After lying for twenty-two weeks the loss of nitrogen was 15·76 per cent. in the pit containing the carefully treated manure, whereas in the other pit the loss amounted to 34·58 per cent.

Pfeiffer in a series of experiments proved that much of the nitrogen that disappears from manure is lost before the manure is transferred from the stall to the dungstead. He is strongly of opinion that stalls, boxes, and the like, should either be cleaned out twice daily, or, if the construction admits, the manure should be left to accumulate until it is some feet in depth, as in the system of management that prevails in cattle-courts and yards in this country.

The general conclusion arrived at, and clearly expressed by Pfeiffer, is that excessive loss in manure can be best avoided by storing it in a deep mass in a water-tight dungstead placed in a well-shaded situation, in which the material is firmly compressed. The necessary compression can be secured in various ways, perhaps most conveniently and effectively by means of the treading of cattle. The use of a considerable proportion of moss-litter is strongly recommended. This substance not only absorbs and retains the liquids, but, being acid, it fixes ammonia. In the absence of moss-litter, loamy soil rich in humus will prove a useful substitute.

The Chemical Fixation of Atmospheric Nitrogen.

It has for long been the dream of chemists to discover, or welcome the discovery of, a chemical process, capable of industrial application, by which the nitrogen of the air could be made available to replace or to supplement our rather limited supplies of nitrogenous manures. In his Presidential Address, Sir William Crookes had something to say on this fascinating subject, and looked hopefully to electricity to solve the problem. He pointed out that with current costing one-third of a penny per Board of Trade unit a ton of nitrate of soda could be produced for 26*l.*; while at a cost of one-seventeenth of a penny per unit—a rate possible when large natural sources of power, like Niagara, are available—the cost of such artificial nitrate of soda need not be more than 5*l.* per ton.[1]

Dr. von Lepel, in giving an account of recent work on this subject to the winter meeting of the German Agricultural Society in February of this year,[2] puts the cost of electric nitrate, as compared with Chili nitrate, in the proportion of 24 to 39, which is in close agreement with Sir William Crookes's estimate. Lepel points out that the material obtained, neutralised by some alkali, consists of a mixture of nitrate and nitrite. When used in pot-culture experiments it has given results closely agreeing with those furnished by Chili nitrate.

Good progress would also appear to have been made in another direction in the commercial fixation of atmospheric nitrogen, and a short account of the results was communicated by Prof. Gerlach, of Posen, to the meeting of the German Agricultural Society already referred to, and is published in the same issue of the *Mittheilungen.*

When air which has been freed of oxygen is conducted through finely disintegrated calcium carbide at a high temperature, one atom of carbon is displaced by two atoms of nitrogen, and calcium cyanamide ($CaCN_2$) is formed. This substance is also produced when a mixture of lime or chalk and charcoal is heated to a temperature of 2000° C. in a current of air.[3] When pure, this substance holds 35 per cent. of nitrogen, but in its crude commercial form it contains only about 20 per cent. Treated with acids, calcium cyanamide is changed into dicyandiamide, a substance holding nearly 67 per cent. of nitrogen, but directly poisonous to plants. Or, if heated in superheated steam, calcium cyanamide parts with all its nitrogen as ammonia, which, of course, is easily brought into a portable form.

But experiments conducted at Posen and Darmstadt during the past three years, both in pots and in the open field, have shown that calcium cyanamide itself is a useful nitrogenous manure, field experiments giving results about 20 per cent. below those obtained by the use of an equal amount of nitrogen in the form of sulphate of ammonia.

[3] Bull, *Imp. Inst.* June 30, 1904.

In prepared soil in pots the results fully surpassed those obtained both with nitrate of soda and sulphate of ammonia, the less satisfactory yields obtained in the field being perhaps due to the organic acids inducing the formation of a certain amount of the poisonous dicyandiamide.

So far as one may judge from the information available, it would appear that agriculture will not have long to wait until it is placed in the possession of new supplies of that most powerful agent of production, nitrogen, and Sir William Crookes will see the fulfilment of his prediction that "the future can take care of itself."

Nitragin.

A few years ago much interest was excited in this and other countries by the announcement that the scientific discoveries of Hellriegel and Wilfarth had received commercial application, and that the organisms of the nodules of the roots of Leguminosæ could be purchased in a form convenient for artificial inoculation. The specific cultures placed upon the market were largely tested practically and experimentally, but the results were such as to convince even the patentees, Nobbe and Hiltner, that the problem which promised so much for agriculture had not been satisfactorily solved. Since that time, however, investigators have not been idle, and the present position of the subject is to be found in a recent Report by Hiltner and Störmer.[1]

It was early recognised that the organisms (bacteria) which inhabited the root-nodules of the various species of Leguminosæ were not all alike, and that, in fact, they showed marked physiological if not morphological distinctions. Any particular species of leguminous plant is found to resist more or less successfully the attempt of these various organisms to effect an entrance into its root-hairs, and according to the power of the organism to gain access, and to establish colonies, so is the particular plant benefited and the stock of fixed nitrogen increased. This power of adaptability of the organism is designated its "virulence," a term, however, which is perhaps hardly suited to our English mode of expression, though it may for the present be retained. It has been found that organisms of what is called "high virulence" are capable of entering with ease the root-hairs of vigorous plants at an early stage of their growth, and of inducing the formation of nodules that are large, numerous, and placed high up on the roots. Organisms of low virulence, on the other hand, can only enter plants of feebler growth, or plants that have passed the most vigorous stage of youth, so that the nodules, in this case, are small and scarce, and distributed, for the most part, near the ends of the roots. The practical object, therefore, would appear to be the breeding of strains or varieties of organisms of high virulence, adapted to the symbiotic requirements of the various important species of farm and garden leguminous crops.

The nitragin put on the market a few years ago was used in two ways, being either applied directly to the fields, or mixed with water and brought into contact with the seed before sowing. Under the former method of procedure an increase of crop was obtained only when the nitragin was used on land containing much humus. The explanation given for failure under other conditions was that the bacteria artificially introduced perished for want of food before the leguminous seed germinated and produced plants.

Failure of the nitragin to effect an improvement in the crop when it was sprinkled on the seed is now believed to be due to the action of secretions produced by the seed in the early stages of germination. These secretions are found to be rich in salts of potash, and when brought into contact with the bacteria in question they induce changes allied to plasmolysis, and these changes are subsequently followed by death. This difficulty was found to be got over by moistening the seed and allowing it to sprout before the nitragin was applied; but manifestly such a procedure would always be difficult, and often impossible, to carry out in practice. The object, however, would appear to have been gained in another way, namely, by cultivating the bacteria in a medium that imparts to them the necessary power of resistance. Such nourishment may take various forms, but that which gave the best results consisted of a mixture of skim milk, grape sugar and pepton, and it is in this medium that the organisms of the nitragin now distributed are cultivated.

[1] "Bericht über neue Untersuchungen über die Wurzelknöllchen der Leguminosen und deren Erreger," *Arbeiten aus der Biol. Abteil. für Land- und Forstwirtschaft am K. Gesundheitsamte*, Band iii. Heft 3.

Early in the present year the new nitragin was being offered free of cost to all members of the German Agricultural Society on the condition that it was used in accordance with the directions that accompany it. In consequence of the large demand the free offer was in April withdrawn, but the substance may be purchased from Prof. Hiltner, of Munich, in quantities sufficient to treat the seed of a half to one acre at the price of one shilling. The United States Department of Agriculture are so convinced of the practical utility of the improved nitragin that they are distributing large quantities to American farmers. In this way the material will be thoroughly tried in two hemispheres under practical conditions, and abundant evidence should soon be forthcoming as regards its effects. It is to be hoped that British investigators will not be deterred by past disappointments from putting the new form of nitragin to the test.

Improvement of Varieties of Crops.

Speaking generally, the attention of agricultural investigators during the past fifty years has been directed more to manurial and similar problems than to the improvement of the yield of crops through the agency of superior varieties. This, it seems to me, is the outcome of the tradition that agricultural science is based upon chemistry, using the term in its old-fashioned and restricted sense, and as a consequence farmers have looked principally to the chemical laboratory for light and leading. It is true that much excellent work has been accomplished from the botanical side, but this has been performed rather by farmers, seedsmen, or amateurs, than by trained botanists. But fortunately the botanist is now getting his opportunity, and the possibilities before him are sufficiently attractive.

Judging by the results that have been obtained, it would appear that wide divergences as regards yield, nutritive qualities, resistance to disease, and other important properties exist between varieties of the same plant-species; so much so, in fact, is this the case that attention to the relationship between variety and locality would appear to be one of the most important matters to which a farmer can give consideration. But it has been found that new varieties are frequently unstable, reverting rather rapidly to an unsatisfactory form, or displaying a lack of power of resistance to disease. It therefore becomes necessary constantly to be producing new varieties to take the place of those that are worn out, and it seems reasonable to anticipate that the professional botanist will take a much larger part in this work than has been the case in the past.

Not only is the yield of a crop greatly influenced as regards quantity and quality by the variety of seed employed, but, as is well known to practical farmers, the local origin of the same variety of seed has a marked influence on many properties of plants (vigour, resistance to disease, and resistance to frost, and to weather generally), and these properties quickly react on the yield. In this country we have a prejudice in favour of the seed of English-grown red clover, Provence Lucerne, Scotch potatoes, Belgian flax, Ayrshire ryegrass, pine and larch from Scotland, Norfolk and Cambridge barley, Warp-land wheat, &c., and there seems no reason to doubt that such preferences are based upon sound experience. This subject would appear to be one that is still full of interesting and important possibilities, and last year I had the opportunity of seeing some striking results in a new and unexpected direction. During the past few years the Austrian Experimental Forestry Station of Mariabrunn has given much attention to the influence of the local origin of the seed on the resulting trees, especially the common spruce, and, although it is too early to pronounce a final judgment on the results, these are already so conspicuous as to warrant my placing some figures before you.[1]

In the autumn of 1896 a supply of seed was obtained from certain definite localities, the trees that yielded it being of varying dimensions and situated at various altitudes. The seed was sown in the spring of 1897 in the nursery attached to the station, and, having been transplanted into lines, a portion of the young trees are growing there now. Others

[1] "Programm der vierte Versammlung des Internat. Verbandes Forstlicher Versuchsanstalten zu Mariabrunn," 1903, p. 47.

were, in 1899, planted out in a wood (Loimannshagen) in the neighbourhood. In the autumn of 1902 the young trees were carefully measured, with the following results:—

Locality of Origin of the Seed	Height above Sea-level of the Mother-tree	Average Annual Height-growth of the Mother-tree	Average Height (1902) of the Young Trees		Average Growth in Height of the Nursery Trees in 1902
			In the Wood	In the Nursery	
	metres	cm.	cm.	cm.	cm.
Piesendorf, Salzburg ...	1400	24	62	85·2	34·7
,, ,, ...	1750	14	47	61·6	23·3
St Andra in Karnten ...	1420	25	57	71·1	27·1
,, ,, ...	1625	18	41	51·2	18·4
,, ,, ...	1650	15	35	39·1	14·2
Treibach, Karnten ...	900	28	56	81·6	30·7
,, ,, ...	900	29	53	80·9	29·7
Achenthal in N. Tyrol...	900	31	64	87·9	29·0
,, ,, ...	1300	28	67	80·5	27·9
,, ,, ...	1600	26	50	62·2	21·8

These figures show—

(1) That where, in any particular locality, mature trees were measured at different elevations, the tallest trees, as was to be expected, were found at the lowest elevation.

(2) That where the seed of such trees was sown the height of the resulting trees, at the age of six years, was in close relationship to that of the mother trees.

(3) That where mother trees of approximately equal height from the same locality and the same elevation (Treibach) were selected, the resulting progeny were also of approximately equal vigour.

The differences in the height-growth of the young trees are so striking as to lead to the conclusion that the financial returns of Forestry operations may be profoundly modified by the origin of the seed, and it would apparently pay nurserymen and planters well to give their careful attention to this subject.

Joint or Cooperative Work.

In conclusion, I may be allowed to direct your attention to a prominent feature of experimental or demonstrational work which is found to exhibit itself in all countries of the world where serious attention is given to the improvement of agricultural production. While, no doubt, it is the individual who plants the germ of a new idea and fosters its growth until it is fairly established, it is by systematised cooperative effort that the practical value of the idea is tested, and that the knowledge is made available and acceptable to the workaday farmer. Various objections have been urged against field experiments, and it need not be denied that they are incapable of supplying a satisfactory answer to many scientific questions. Such experiments are exposed in no small degree to the disturbing influences of inequalities of soil, irregular cultivation, the attack of animals, and the vicissitudes of climate; but when reasonable precautions are taken to guard against these, and given a sufficient number of tests, the results of field trials are of the highest value as a guide to practice. Apart from attention to the preliminary details of the scheme, and to care in carrying it out, the main point to aim at in field-trials is to have them so frequently duplicated or repeated that the disturbing factors inseparable from field-work will be largely eliminated. Such duplication may take the form of repetition of the same test on the same area year after year, when one obtains some such series of results as those that have helped to make the reputation of Rothamsted. But however convincing may be the results of a series of experiments that have marched majestically on for half a century, they lack attractiveness for the investigator who desires to solve not one but many problems during his lifetime. For him, therefore, duplication in time gives place to duplication in space—in other words, he secures the same end, or an end that is in many respects equivalent, by repeating the test at several places in the same season, or in a short series of seasons. This method of work is, of course, by no means new. It was utilised with great advantage by the late Dr. Voelcker, and by our more recently departed friend Dr. Aitken, and it is a line that is still being followed by the two great societies with which these distinguished workers were so long associated. The method is also being practised extensively, chiefly through the agency of societies, in Germany, France, and other European countries, and it has taken firm hold in the United States and in some of our colonies. One of the largest and most successful agencies in cooperative demonstrations is to be found in Canada, where, during the past nine years, an average of 37,000 farmers have annually received small parcels of improved seeds through the Government experimental organisation directed by Dr. Saunders. It is claimed that the financial results to the country as a whole run to many millions of dollars, and there seems to be no reasonable doubt as to the accuracy of the statement.

I trust you will pardon my referring in this connection to a matter that is personal to a considerable proportion of this audience, and of saying that, in my opinion, one of the best pieces of work that has been done in this country in recent years is the preparation of the scheme of joint experiments by the Agricultural Education Association. The problems set for solution under that scheme are of the simple, direct, practical kind that field-work is thoroughly qualified to deal with. But the essence of success lies in the power of numbers, and the control of this factor rests with the members of the Association themselves. Now, most of the members of that Association are not only investigators but also teachers, and many of the institutions that they represent have recognised the advantages of keeping in touch with their past pupils through the agency of collegiate Associations. These old students, it seems to me, represent a large mass of most valuable material for carrying through cooperative experimental work of the class referred to, and I am convinced that the agriculture of the country would benefit in no small degree were this powerful agency fully utilised.

SECTION L.

EDUCATIONAL SCIENCE.

OPENING ADDRESS BY THE RIGHT REV. THE LORD BISHOP OF HEREFORD, D.D., LL.D., PRESIDENT OF THE SECTION.

I AM moved to begin this address with a word of personal apology, the strongest feeling in my mind, as I rise to deliver it, being that in the fitness of things some one of the many distinguished representatives of education in this University would have been the natural occupant of this chair on the present occasion; and for my own part I could hardly have brought myself to accept the invitation with which I have been honoured had I not been led to understand that on occasions of this kind it is preferred by the members of the University visited that some one from the outside should be invited as I have been.

Thus I have accepted, not without hesitation and misgiving, but with the more gratitude, as feeling that I am here because of the wish of the Cambridge authorities to have someone connected with the University of Oxford, and I desire that the grateful acknowledgment of this courtesy and kindness should be my first word as President of the Educational Section.

The inclusion of Education among the various sections of this Association for the Advancement of Science is sufficient evidence that a new educational era has begun in this country.

Whatever may be the defects of our educational system or want of system, whatever changes may be necessary to bring it, in the current phrase, up to date, the days of unthinking tradition are over.

Scientific method is entering on its inheritance, and it has begun to include the field of education along with other fields of life and thought within the sphere of its influence.

And scientific minds are asking on every side of us what is the end of true education, and are we on the right way to it?

True education, almost insuperably difficult in practice, has been often defined in words.

Plato told us long ago how it is music for the soul and gymnastic for the body, both intended for the benefit of the soul, how it is a life-long process, how good manners are a branch of it and poetry its principal part, though the

poets are but poor educators, how great is the importance of good surroundings, how the young should be reared in wholesome pastures and be late learners of evil, if they must learn it at all, how nothing mean or vile should meet the eye or strike the ear of the young, how in infancy education should be through pleasurable interest, how dangerous it is when ill directed, how it is not so much a process of acquisition as the use of powers already existing in us, not the filling of a vessel, but turning the eye of the soul towards the light, how it aims at ideals and is intended to promote virtue, and is the first and fairest of all things.

In this description, I take it, we most of us agree, though some of Plato's views would doubtless elicit differences of opinion amongst us, as, for instance, that education ought not to be compulsory, or that it should be the same for women as for men.

One of his statements may be soothing to our English self-complacency, for as is the habit of idealists in every age, he says that even in Athens they care nothing for educational training, one of the most brilliant of their younger statesmen pleading that it does not matter, because others are as ignorant as he.

Or again, our own Milton sums it up in fewer words, but very impressively, when he says true education fits a man to perform justly, skilfully, and magnanimously all the offices, both private and public, of peace and war.

It is a noble aim which he thus sets before us, to make our sons skilful, just, magnanimous, and every description of aims and methods can be little more than an expansion of it.

Of the importance of right aims and ideals there can, as Plato reminded us, be no question, because of the danger of ill-directed aims, and the lasting nature of early impressions.

What we learnt at school, when all the world was young to us, whether we learnt it with weariness or pain, or under happier influences with a quickening pulse and the glow of enjoyment, passed into the blood, as Stevenson said somewhere, and became native in the memory.

True education, then, as we all acknowledge, aims at cultivating the highest and most efficient type of personality, men not only appropriately and technically equipped for their professional business, but men endowed with the best gifts and inspired with high purposes, men who desire to follow the more excellent ways and to lead others in them, who love knowledge, truth, freedom, justice, in all the relations of life, whether individual or social, men marked by sense of duty and moral thoughtfulness, public spirit, and strength of character.

Such an education is the true basis of individual and national welfare, and experience has abundantly shown how necessary this is to save men from distorted views of history, from wrong conceptions of patriotism and public duty, from mistaken aims and disastrous policy.

Thus, for instance, a good and true education shows us that the true basis of life is moral and economic and not military, and the true aim of both individuals and nations is knowledge, justice, freedom, peace, magnanimity, and not pride, aggression, force, or greed.

Scientific consideration of our subject will of course deal largely with such details as the relative claims of the humanist and the realist, subjects and methods of instruction, the correlation of different grades of education, the adaptation of this or that system to special needs, and so forth; but through all this these fundamental requirements of the true education, as placarded before us by Plato or by Milton, must always hold the chief place, and all others must be kept in due and conscious subordination to these.

This very obvious remark calls for repetition, as we are so apt to lose sight of ideals amidst the dust of controversy about details or methods or practical needs.

How, then, does our English education stand when thus considered? And what signs are there in our life of our having fallen short or fallen behind, or missed the best that was possible in our circumstances?

It may, I venture to think, be fairly said that to a reflective observer various things are patent which seem to make it expedient that the subject of education should have its place in the proceedings of a scientific association like this, although there may be difference of opinion as to how it should be handled there.

In saying this I have to admit that some educational reformers seem to have doubts as to the propriety of its inclusion in your programme.

The element of personality is so preeminently vital in all education that some men say it cannot be treated as wholly scientific in the ordinary sense, and that there is serious risk in subjecting it too rigidly to the methods of investigation which naturally hold the field in the main departments of this Association, and that men who are wholly accustomed to such methods are not the best equipped for dealing with the problems involved in the education of the young.

If I endeavour in a few paragraphs to express what, so far as I understand it, is the ground of this fear in the minds of some thoughtful objectors, I trust I may not be thought to be wasting your time.

This Section is still in its swaddling-clothes. It has to justify its existence in the coming years. It is therefore of moment that it should be started on its course of early growth as free as may be from prejudice and with the sympathy and support of all who, whatever be their views as humanists or realists, as men of letters or men of science, as teachers of religion or men of practical affairs, desire to see the education of the young in our country advancing and expanding on the best lines.

On this account the misgivings or warnings of every thoughtful critic deserve our attention and may be helpful.

In what I am saying it will be understood, I hope, that I am not expressing views of my own, but endeavouring to act as the recording instrument, a very inadequate and old-fashioned instrument, of views which come to me from one quarter and another.

The inclusion of the study of education by the British Association for the Advancement of Science among its subjects of investigation is, they say, not altogether free from risk.

If you treat education too exclusively according to the analytic naturalistic methods of scientific men you incur the danger of unfitting teachers for the best part of their work, which depends on the inspiring influence of personal ideals breathing through all their lessons, on a vivid sense of the subtle element of personality in the pupil, and on their responsible exercise of the power of their own personality.

In giving the scientifically educated teacher the analytic knowledge of the dissecting chamber you may possibly rob him of the magnetic power of personal sympathy and influence. In this sense, at all events, you must not dehumanise him. The most eminent psychologists, the critics tell us, are beginning to recognise the danger, and they bid the educator beware of science which has a great deal to say about mental processes but takes too little account of the emotions and the will, and seems inclined to forget that men are personalities and not plants or trees or machines and that boys will be boys.

The combination of a living and fruitful experience, these critics assert, with systematic organised scientific methods and processes is more difficult in education than in any other realm of knowledge, because the data are so complicated and so subtle and elusive.

Hence, they say to me quite frankly, the risk of failure to do much that will be of real value in your Educational Section.

In particular I have the impression that they set no great store by presidential addresses, although the address to which you are now listening has at least one merit, that it has no claim to be technically scientific, but is wholly based, so far as any positive conclusions or recommendations are concerned, on practical personal observation and experience.

This section, say the critics, will do its best work by seeking first of all to determine and to set forth :—

(1) What field is to be covered when education is to be treated as a scientific study, and what are the limits of the field, taking care to give due regard to right ideals of moral and social progress as a primary part of the whole.

(2) What methods of investigation are appropriate and what are inappropriate to the study of education.

Such are some of the warnings with which we are asked to begin our discussions. The critics ask the men of science to remember that they are leaving their accustomed field of purely natural phenomena, and entering a field of investi-

gation which is largely, if not mainly, social, political, religious, moral, and lends itself only in a limited degree to those problems which men whose sphere is natural science are more accustomed to handle.

These are some of the criticisms which, as men of science, you have to meet, and I may safely leave them to your tender mercies.

For myself my attitude in the whole matter must of necessity be a humble one. For many years of my life I was a teacher, but entirely untrained, or rather self-taught, that is to say, relying for my instruction and guidance entirely on my own reading, observation, experience, and practice.

I belong to the pre-scientific age of Englishmen engaged in education. I grew up to my profession anyhow, like so many others; and now for some years I have ceased even to teach, and so even as an untrained teacher I am out of date.

It is due to this audience and to my subject that I should say thus much. It is my appeal for your kind indulgence.

As regards the critics whose views I have endeavoured to express, I may say at once that I do not go with them, because I am profoundly convinced that our English education needs the influence of more light and more thought from every quarter, and especially from those who are familiar with scientific methods. "Blessed are they that sow beside all waters."

Moreover, I hail the application of scientific intelligence and scientific methods to this subject, because, looking back, I am profoundly conscious that I should have done my own educational work far less imperfectly if in my youth I had undergone any rational scientific illuminating preparation for it.

In such a process I should have lost no personal gift or aptitude that I possessed, and I should have gained some early knowledge and confidence and power which would have saved me much discomfort and anxiety and some mistakes and failures, and would have saved my pupils some loss and possibly some distress.

When I turn with these thoughts in my mind and look out over the field of English life I see very strong and valid reasons why our education, its merits, its defects, its methods and results, should be seriously considered here, as also in very different assemblies elsewhere.

Above all, the persistently traditional and unscientific spirit that still pervades so much of it from top to bottom, its lack of reasoned reflection, demands our special attention.

"The want of the idea of science, that is of systematic knowledge," said Matthew Arnold, "is, as I have said again and again, the capital want at this moment of English education and English life. Our civil organisation (including our education) still remains what time and chance have made it."

This was written about thirty-six years ago, and it is, to say the least, a surprising thing that in an age of unusually rapid scientific development it should be, in the main, still so true, as it undoubtedly is, of a great part of our English educational system.

There is the lack of any systematic preparation for the business of teaching which still prevails throughout our middle and upper-class education, although here in Cambridge and in Oxford some excellent pioneer work is being done in the training of teachers.

There is the general lack of interest in education which is still so noticeable in a great deal of English society of all grades, the spirit of indifference to it, and even the tendency to depreciate the intellectual life.

There is the excessive influence of tradition and routine on our great schools and universities, and in some quarters an inert or suspicious conservatism.

There is throughout our middle-class education a state bordering on chaos, a country largely unexplored, a mixture of things good and bad, involving a vast amount of wasted opportunity and undeveloped faculty.

Even in elementary education, which has received the largest share of public attention, there is much that needs to be done in a more thoughtful and scientific spirit.

Party politics have to be eliminated as far as possible, especially ecclesiastical politics.

The fitness of a great deal of the teaching to the special needs and requirements of the children has to be considered afresh.

The tendency to overlook the interests and the attainments of each individual child has to be checked.

The wastefulness of our absurdly truncated system of elementary education stopping abruptly at about twelve years of age and then leaving the children to drift away into an unexplored educational wilderness has to be superseded by some rational system of continuation classes made obligatory. Truly the harvest is a plenteous one for those who desire to uplift our English life by helping forward the best modes of educating the rising generation in a scientific, or, in other words, a wise, intelligent, and large-minded spirit.

Much, it is true, has been done in almost every part of the educational field during the last half-century, but not nearly so much as ardent friends of education anticipated forty years ago.

I have already quoted some significant words from Mr. Arnold's illuminating Report on the Schools and Universities of the Continent as he saw them thirty-seven years ago. If that report had been turned to immediate practical account at the time, if some English statesman, like William von Humboldt, had been enabled with a free hand to take up and give effect to Mr. Arnold's chief suggestions, as Humboldt and his colleagues gave effect to their ideas in Prussia in the years 1808 onwards, the advantage to our country to-day would have been incalculable.

In our insular disregard or depreciation of intellectual and scientific forces actually working in other countries, we have undoubtedly wasted some of that time and tide in human affairs which do not wait for either men or nations.

But, putting regrets aside and turning to some of the practical problems that seem to confront us to-day, I venture to put before you for consideration such cursory and unsystematic observations or suggestions as my personal experience has led me to believe to be of practical importance. For more than this I have no qualification.

In the first place, the growth of crowded city populations and the conditions under which multitudes have for at least two generations been growing up and passing their lives in our great cities have set us face to face with the very serious preliminary problem of physical health.

If our physical manhood decays all else is endangered, so that the first business of the educator is to look well to the conditions of a healthy life from infancy upwards.

Hence the great educational importance of the petition presented by 14,718 medical practitioners, including the heads of the profession, to the central educational authorities of the United Kingdom.

This petition opens with these impressive words:—

"Having constantly before us the serious physical and moral conditions of degeneracy and disease resulting from the neglect and infraction of the elementary laws of hygiene, we venture to urge the Central Educational Authorities of the United Kingdom (the Board of Education of England and Wales, the Scotch Education Department, the Commissioners of National Education in Ireland and the Intermediate Education Board of Ireland) to consider whether it would not be possible to include in the curricula of the Public Elementary Schools, and to encourage in the Secondary Schools, such teaching as may, without developing any tendency to dwell on what is unwholesome, lead all the children to appreciate at their true value heathful bodily conditions as regards cleanliness, pure air, food, drink, &c. In making this request we are well aware that at the present time pupils may receive teaching on the laws of health, by means of subjects almost invariably placed upon the Optional Code. By this method effective instruction is given to a small proportion of the pupils only. This does not appear to us to be adequate. We believe that it should be *compulsory* and be given at a much earlier age than at present."

And it concludes as follows:—

"In many English-speaking countries, definite attempts are being made to train the rising generation to appreciate from childhood the nature of those influences which injure physical and mental health. Having regard to the fact that much of the degeneracy, disease, and accident with which medical men are called upon to deal is directly or indirectly due to the use of alcohol, and that a widespread ignorance

prevails concerning not only the nature and properties of this substance but also its effects on the body and the mind, we would urge the Board of Education of England and Wales, the Scotch Education Department and the Irish Education Authorities to include in the simple hygienic teaching which we desire, elementary instruction at an early age on the nature and effects of alcohol. We gladly recognise (1) the value of the teaching on this subject given in some schools in Ireland and in a proportion of the schools of Great Britain, by means of reading primers, moral-instruction talks, &c., and (2) the excellence of the occasional temperance lessons provided in certain schools by voluntary organisations: but until the four Central Educational Authorities of the United Kingdom include this subject as part of the system of National Education, it appears to us that the mass of the pupils must fail as at present to receive that systematic teaching of hygiene and of the nature and effects of alcohol, which alone we consider adequate to meet the national need. Finally, we would venture to urge the necessity of ensuring that the training of all teachers shall include adequate instruction in these subjects."

This petition, coming, as it does, with all the weight of the medical profession, as the expression of their experience and convictions, is, to my mind, one of the most important educational documents which have been published in our time, and it can hardly be disregarded without incurring the charge of folly.

It may be worth while to set it for a moment side by side with the fashionable cult of athleticism, as bringing into relief our curiously unscientific inconsistency in such matters.

On the one hand, in our absent-minded way, we have allowed these generations of town-dwellers, to say nothing of rural villagers, to grow up and live under insanitary conditions which inevitably produce a physically degenerate, enfeebled, and neurotic race of men and women.

On the other hand, in the upper and middle classes, we have been sedulously cultivating the taste for physical exercises, outdoor life, athletics, and sport, thinking nothing of such importance as the development of the body, admiring nothing so much as bodily prowess; carrying all this to such an extent that a natural and wholesome use of athletic exercise has been fostered into a sort of fashionable athleticism, with all its parasitic professionalism, possessing both soul and body.

And the result has been curiously significant; at one end of the scale neglect of the rudiments of sanitation, the loss of the *corpus sanum*, at the other end the idol worship of athleticism, the depreciation of the intellectual life, and the loss of the *mens sana*.

Are we not then in some danger of drifting into the ways of the Greeks, not in their best days but in their decadence, and of the Romans under the demoralising influences of the Empire?

The Greeks, as we are constantly reminded, in the great period of their creative influence, found nothing so absorbing as the things of the mind; a preeminent characteristic of their life was their love of knowledge, their fine curiosity, their enjoyment of the things of the imagination and of thought. It has been noted that what specially conciliated an Athenian voter was the gift of a theatre ticket; and this is a very instructive and significant fact when we bear in mind that the theatre was the great teacher of religion, morals, poetry, patriotism, all in one; that it combined the influences of Westminster Abbey, the plays of Shakespeare, and the heroic achievements of the race; whereas to an ordinary English voter these things are too often only as caviare to the general.

If so, our education has before it the task of doing what can be done to alter this; and from the Greeks we may derive both lessons and warnings. It was in the days when this decadence was beginning that their excessive admiration of the professional athlete, what we might call their athletic craze, called forth the bitter jibes of Euripides, and his impressive warnings and exhortations to admire and to crown with their highest honours, not those who happened to be swiftest of foot or strongest in the wrestling bout, but the man of sound mind, wise and just, who does most to guide others in the more excellent ways, and to uplift the life of his community:

ὅστις ἡγεῖται πόλει
κάλλιστα, σώφρων καὶ δίκαιος ὢν ἀνήρ.

Here we have a warning by no means inappropriate to our own life and its tendencies. It is, indeed, high time to bring serious and, let us say, scientific thought to bear upon the whole matter.

As I look with such thoughts in my mind over those portions of the educational field with which I have been personally familiar, I note various things which seem to call for both consideration and action.

Taking first the elementary school, it is to be noted that our system does too little to draw out and stimulate the faculties or to form the tastes of each individual child.

Classes are still in many cases far too large.

The system of block grants, being inadequately safeguarded or supplemented by inducements to individual children to apply and prepare for certificates of merit or proficiency, however attractive it may be to inspectors and teachers, needs to be very carefully watched in the interests of individual children. The individual child requires the hope and stimulus of some personal recognition or distinction, if its faculties are to be fully roused and its tastes properly cultivated.

Moreover, the aid of scientific thought and experience is needed to bring both the subjects and methods of instruction into closer and more vital relationship with the environment of the children and with their practical requirements, and more weight has to be given to specific ethical teaching, that moral and spiritual training day by day, which has for its end the development and strengthening of character, and taste, and issues in conduct, which is the greater part of life.

And seeing that it is of the essence of any rational or scientific system to avoid needless waste, it is time that our elementary education should no longer be left in its absurdly truncated condition, which allows a child's education to be stopped abruptly and finally at or about the age of twelve, when in the nature of things it should be only beginning. As things are at present, just when the parent of the upper classes is anxiously considering what school will be the best for his son, a vast number of the children of the poorer classes are left by the State to drift out into a wilderness where all things are forgotten.

In this connection, however, it is due to the Board of Education that we take note of the reminders lately issued in the Introduction to the New Code and the memorandum prefixed to the Regulations for the Training of Teachers.

This Introduction to the Code reminds every parent, school-manager, and teacher, very emphatically, that the purpose of the school is to form and strengthen the character and to develop the intelligence of the children, to fit them both practically and intellectually for the work of life, to send them forth with good and healthy tastes and the desire to know, with habits of observation and clear reasoning, with a living interest in great deeds and great men, and some familiarity with, at all events, some portion of the literature and history of their country; and this being so, the special charge and duty of their teachers is by the spirit of their discipline and of their teaching, by their personal example and influence, to foster in the children, as they grow up in their hands, habits of industry, self-control, endurance, perseverance, courage, to teach them reverence for things and persons good or great, to inspire them with love of duty, love of purity, love of justice and of truth, unselfishness, generosity, public spirit, and so not merely to reach their full development as individuals, but also to become upright and useful members of the community in which they live and worthy sons and daughters of the community to which they belong.

Hardly less valuable, as a contribution to education which shall be more thoughtful than hitherto, is the memorandum prefixed to the new Regulations for the Training of Teachers.

I confine myself to one significant quotation from this valuable document:

"Much of the instruction which is given in all subjects must necessarily be founded upon the statements and the experience of other persons; but every education which deserves to be called complete must include some training of the student in those systematic methods of inquiry which are necessary for any assured advance in knowledge, and which are the most truly educative of all mental processes.

"If this scientific spirit is to find its right expression in

the teaching given in elementary schools it must be made to imbue the whole study of the intending teacher during his course in the Training College. It must not be confined to any one branch of the curriculum. It is true that, partly as the result of tradition and partly from other reasons, the term 'scientific method' has come to be associated more particularly with the study of natural phenomena. But as a matter of fact, scientific method is of equal importance, and is indeed of ancient application, in the fields of history, literature, language, and philosophy; and wherever knowledge of these has made advance, it may be discerned that the essential processes of scientific inquiry have been employed. When Matthew Arnold declared in 1868 that the want of the idea of science, of systematic knowledge, was the capital want of English education and of English life, he was thinking of science as a method and not as a prescribed portion or subject of a curriculum. It cannot be doubted that this want has been seriously prevalent in a large portion of the education and training hitherto provided for elementary school teachers."

We might, indeed, widen the scope of these observations and say that this want of regard for scientific method has been and is a prevalent want in almost every department and grade of English education.

These unaccustomed utterances from Whitehall may very well prove memorable in the history of English education, as the words of William von Humboldt, quoted by Matthew Arnold, are so memorable in connection with the education of Germany: "The thing is *not* to let the schools and universities go on in a drowsy and impotent routine; the thing is to raise the culture of the nation ever higher and higher by their means."

Passing from the sphere of the elementary schools to that of secondary education, we enter on a sphere in which there is much greater need of careful study and the guidance of those who know.

Our secondary education has by the Act of 1902 been handed over very largely to county councils, excellent but heterogeneous bodies, and for the most part not only ignorant of educational needs, methods, and possibilities, but quite unaccustomed to their practical consideration—altogether unprepared and untrained for the responsible work now thrown upon them, and hampered by their besetting fear of the ratepayers.

Add to these difficulties the prejudice, so common in the ordinary English mind, against what is known as the "expert," that is, the man who knows from experience, and is therefore likely to be earnest for improvement, and to believe that wise educational expenditure will repay itself, and you see how manifold are the obstacles in the way of immediate progress.

These county authorities need first of all to be themselves instructed and persuaded as to the right subjects for their schools, the coordination or proportion of subjects in any scheme to be encouraged, the methods of instruction, the sort of teachers to be appointed, the wisdom of spending public money on good education, as exemplified in other countries, like Germany, Switzerland, the United States, Denmark.

Our local authorities feel and recognise that something is needed, but very often they seem to be like children crying in the dark. From lack of educational knowledge and educational experience they do not always know the difference between the right and the wrong method, or between the good and the bad school.

In our rural districts at all events it may be said further that one of our first needs is to persuade the local authorities by some convincing proof that expenditure on popular education higher than elementary is a wise economy, and that their bread cast on educational waters will come back to them, not after many days, but very soon and in their own homes. Thus my observation has led me to the conclusion that by way of preliminary to progress our new educational authorities need instruction or persuasion as to the importance of a sufficient provision for really good secondary education; and it would greatly expedite progress if the Government could and would offer more liberal secondary education grants to be earned by efficient schools, and initial grants towards buildings and scientific equipment, to be met by contributions from local rates or other local sources, public or private.

Many persons and localities would be ready to tax themselves with the view of securing a Treasury grant not available without such taxation. Meanwhile the wheels of our local educational chariots are tarrying on every side so far as higher education, whether general or technical, is concerned.

It would also stimulate our local educational authorities if they could be more fully informed as to the practical advantages which have been derived from a practical system of popular education in such a country as the United States of America; and still more if they had set plainly before them the wonderful results derived by a poor country like Denmark during the last twenty-five years, and in the face of every disadvantage, from the system of education initiated by Bishop Grundtvig and taken up by the Government.

And the need of our middle classes, especially that of the farmer and tradesmen classes, is very pressing. A great deal of the education they receive is given in schools of which the public know very little, whether as regards qualifications of the staff—moral and intellectual—equipment, or methods of teaching, or even sanitary arrangements; and it is to be feared that much of this education would on inquiry be found to be very poor, if judged by any reasonable standard of modern requirements.

When we pass to the class of schools generally spoken of as public schools, those that look to the ancient Universities as the goal of their best pupils, we enter on another very interesting and important field of study.

But for the beginning of our investigation we have to go behind these schools to the preparatory school, which has now assumed a definite place in secondary education, and therefore calls for serious attention. Some of these schools are very good, so far as the conditions under which they work admit of excellence; in others there is, it is to be feared, much room for improvement.

And such schools are now so largely used by parents that their condition becomes a matter of vital importance, as a boy's progress and prospects, his moral and intellectual future, are very frequently determined for good or ill by his experience in the preparatory school, by the bent which has there been given to his morals, tastes, ambitions, by the fostering of his intellectual gifts or the failure to foster them.

In the course of my own experience I have known many boys whose prospects in life were spoilt by their unhappy beginnings in some preparatory school, and who consequently entered their public school foredoomed to failure.

These schools are in most cases private-adventure schools, conducted for private gain. Their staff consists very often of young men untrained for the work of education, and sometimes underpaid. They are subject to no public inspection or examination; in fact, the general public have no knowledge of their condition.

Seeing how grave are the considerations involved, I hold it to be one of the things needed for the general improvement of our secondary education that every private school, of whatever kind, should be liable to public inspection and public report thereon; that a licence should be required for every such school; and that the staff and their qualifications, and the remuneration given to each of them, the sanitary condition, suitability, and educational equipment of the premises, should all be considered in connection with the giving or withholding of a licence.

As regards the curriculum of the schools preparatory to the public schools, the subjects taught, and the proportion of time allotted to each, it has to be borne in mind that they are not free agents. In this respect they are dependent on the requirements of the entrance examination at the public schools which they supply; just as those schools in their turn are dependent on the requirements of the university to which they send their pupils.

Thus, when we come to confer with the authorities of the public schools our first inquiry is whether their entrance examination is such as to conduce to the best system of education from infancy upwards.

Believing, as I do, that there is room for improvement, I would ask them to consider and come to a general agreement as to the subjects on which special stress should be laid. What place, for instance, is occupied in the Eton entrance examination by such subjects as English language and literature, English composition, spelling, handwriting,

and reading aloud? What weight is given to elementary drawing, or to an elementary knowledge of natural phenomena, so as to encourage in the preparatory school an interest in the mineral, vegetable, and animal world around us, and to stimulate in early years the habit of observation, and to impress the difference between eyes and no eyes?

Such subjects as these, it is now generally recognised, ought to be given a foremost place and equal weight with the modicum of arithmetic, French, and ancient languages, which have hitherto, as a rule, formed the staple of this entrance examination, and have consequently given an unnatural twist to the earlier education of our boys.

As regards the public schools themselves, if we consider them critically—though, on the other hand, I trust, by no means forgetting their many and great excellences—the points that invite attention would seem to be such as the following :—

There is undoubtedly a great deal of waste in these schools owing to the poor teaching of untrained masters, who in some cases cannot even maintain reasonable discipline, and in many more have no real knowledge or mastery of the best methods of teaching their subject, be it linguistic, or historical, or literary, or scientific, and have not acquired that first gift of an efficient teacher, the art of interesting their pupils and drawing out their faculties and their tastes.

It would, therefore, be reasonable, as it would certainly be stimulative and advantageous, to require that all masters should be bound to go through some system of well-considered and serious preparation or training for the teacher's work, or at the least a probationary period.

It should, I venture to think, be made a rule that no master could be placed on the *permanent staff* until he was certified and registered as having fully satisfied this requirement and given proof of his efficiency.

And here I would venture to point out to existing masters and mistresses in the leading schools how great a service they may do to the cause of good education if they themselves apply to be registered.

Seeing the advantages which registration is destined to bring to our secondary education by winnowing out inefficient teachers and otherwise, the higher members of the profession may fairly be expected to give their personal adhesion to it as a part of their duty to their profession.

We might almost say to them *noblesse oblige*.

Again, it must, I fear, be admitted that one of the chief defects in our public school education is still to be found in over-attention to memory work, and in the comparative failure to develop powers of thought, taste, and interest in the things of the mind.

And even in the teaching of languages attention has been too exclusively devoted to mere questions of grammar, as if to learn the language were an end in itself, whereas, in the words of Matthew Arnold, "the true aim of schools and instruction is to develop the powers of our mind and to give us access to vital knowledge."

For this end, as he reminds us, the philological or grammatical discipline should be more consciously and systematically combined with the matter to which it is ancillary, the end should be kept in view; whereas nine out of ten of our public-school boys seem never to get through the grammatical vestibule at all; and yet we agree that "no preliminary discipline should be pressed at the risk of keeping minds from getting at the main matter, a knowledge of themselves and the world."

This also was written by Mr. Arnold thirty-six years ago, and thoughtful critics are still repeating, and with some reason, that the majority of boys who grow up in our public schools seem hardly to have received an adequate training for many of the higher duties of life.

We hear much more than formerly about the public schools being the best training-place for good citizenship. Therefore, say the critics, it is reasonable to inquire how far their educational system, their ideals, their traditions, their fashions, and the pervading spirit of their life fit the mass of their pupils intellectually and otherwise for the duties of citizenship, and for grappling in the right spirit with the problems that will confront them.

"Any careful observer," says one of these writers, himself a loyal public-school man, and intimately acquainted with school life, "any careful observer, who has studied the political moods and opinions of the middle classes in this country during the past few years, can hardly have failed to notice two obviously decisive influences: an ignorance of modern history and a want of imagination. For both of these defects the public schools must bear their full share of blame.

"It may be doubted whether any other nation teaches even its own history so little and so badly."

The result is that "to the average public school and university man the foreign intelligence in his daily paper is of less interest than the county cricket; and though events of far reaching importance may be happening almost under his eyes he is in the dark as to their significance."

"As regards the duties and aims of citizenship in all the various affairs of his own country, political, social, economic, he goes out from his school almost wholly uninstructed by the lessons of history, or by any study of the life and the needs of our own times. Again, as it is urged, the lack of imagination is hardly less dangerous to us than lack of instruction in the lessons of history and the social conditions and needs amongst which we have to live and work. No doubt the gift of imagination is a natural gift—it cannot be created. But, given the thing in the germ, it can be stimulated and developed, or starved, stunted, or even crushed out. No system of education that neglects it is even safe. For, without it, principle becomes bigotry and zeal persecution. It is conscientiousness divorced from imagination that produces Robespierres. Now, it is precisely here that we should expect the public schools to be most helpful, for it is through literature that the faculty is most obviously cultivated, and they all profess to give something of a literary training. But though the intention is excellent the performance is often terribly meagre." Whatever may be thought of such criticisms as these, which come from within our public-school life, it is, I imagine, generally agreed by those who know both our national needs and the work and influence of our public schools, that there is much room for improvement in regard to methods of teaching, the cultivation of intellectual interests and tastes, and the stimulating habits of thought in the majority of their pupils. In close connection with these considerations there are two questions of practical importance which deserve a prominent place in any study of our public-school education.

The first of these is whether it is good for all boys alike to continue their life at school, especially at a boarding school, up to the age of eighteen or nineteen; and the other is whether more encouragement and pains should not be given to developing the best type of day school, or, to put it somewhat differently, whether the barrack life of the boarding school has not, through fashionable drift and class prejudice, become too predominant a part of our English education at the expense of the home life with all its finer educational influences.

As regards the first of these questions, it will be remembered that Dr. Arnold considered it a matter of vital importance to expedite the growth of a boy from the childish age to that of a man.

In other words, the boy should not be left to grow through the years of critical change from fourteen to nineteen without special regard to his growth in intellectual taste and moral purpose and thoughtfulness. His education during these critical years should be such as to rouse in him the higher ambitions of a responsible manhood.

Does, then, the actual life of a public school really conduce to this early development in the majority of cases?

My own experience has led me to the conclusion that it cannot be confidently held to do so.

The boys in any of our public schools may be said to fall into two classes—those who in due course reach the sixth form, and during their progress through lower forms have an ambition to reach it; and, on the other hand, a numerous class who do not expect to rise to the sixth, don't care about it, and never exert themselves to reach it.

For the first class, I doubt if any more effective preparation for life has been devised than that of our best English schools; but the case of the second class is somewhat different.

Many of these come to the end of their school time with their intellectual faculties and tastes and their sense of responsibility as men to a great extent undeveloped.

From sixteen to eighteen or nineteen their thoughts, interests, and ambitions have been largely centred in their

games and their out-of-school life, with the natural results that their strongest tastes in after life are for amusement and sport.

Some of these boys, after loitering at school to the age of eighteen or nineteen, go to the University as passmen, some begin their preparation for the work of a doctor or a solicitor, and many go straight from school into City life as men of business; and nearly all of them suffer from the lack of intellectual and moral stimulus during these later years of their school life.

Now many of these boys could without difficulty pass the entrance examination to the University at sixteen or seventeen, if well and carefully taught; and I have long held the view that such boys would greatly benefit by going to Oxford or Cambridge at the age of seventeen, or even sixteen, if suitable arrangements could be made.

It was with this conviction in my mind that I published a scheme showing how this experiment might be tried about twenty years ago.

The interval has confirmed me in the opinion that it would be a distinct gain to many boys to take advantage of such a scheme if made available. They would go out into the world from the University at the age of twenty far better equipped and prepared for life, both as regards knowledge and interests, tastes, and character, than by going straight from school at nineteen.

And looking to my own University of Oxford, I see no reason why such younger students should not be safely received.

There are at least three Colleges in that University which would find it easy to adapt their arrangements so as to secure this. Each of these Colleges has a hall in connection with it, well suited for the residence of a college tutor who might have special charge of these younger students, residing in the hall during their first year with somewhat stricter rules as to ordinary discipline and liberty, but in all other respects exactly on a par with the senior undergraduate members of the College.

On the subject of the day school, as compared with the boarding school, a subject which has not hitherto received the attention it deserves, I may venture to repeat here what in substance I have said on other occasions.

Many parents are so situated that they have no choice in the matter; but to the educational inquirer it is a question of much interest and importance.

The boarding school is admitted to excel in turning out strong, self-reliant, sociable, practical men of affairs, men who have learnt by early experience not to think or make too much of small injustices, to rough it, if need be, with equanimity and cheerfulness, and to count it a man's part to endure hardness in a manly spirit. It is a fine type of character which is thus produced, at its best; but the best is not always seen in the result, and the system too often produces an undue deference to public opinion, a spirit of moral compromise, and a loss of moral enthusiasm. The human soul in its finer parts is a very sensitive thing, and I do not think the barrack life of an average boarding school is always the most favourable for its healthy growth.

As I look back over the school days of my own pupils I feel that those of them had, on the whole, the best education who grew up as day boys in good homes at Clifton College. There they enjoyed all the advantages of the cultivated home, which I need not here enumerate, and at the same time, through the arrangements we made for them, all the best elements in the life of a great boarding school.

In the upper school of 500 boys, we had about 160 day boys living at easy distances from the school.

These boys were divided into two houses—North Town and South Town—about eighty boys in each house, and they were treated for school purposes just as if they were living together in a boarding house.

They were under the same rules as boarders in regard to hours of locking up, or the bounds beyond which they might not go without a note from their parents giving express leave.

Their names were printed in a house list, a master was appointed as their tutor, whose duty it was to look to their educational needs and progress, to their reports and conduct, just as if they had been boarders and he their house master. Each house had its own room or library on the College premises, with books of reference, and so forth, for spare hours, and took its part with the boarding houses, and held its own in all school affairs, games, and other competitions. And my experience of this system compared with others has led me to the conclusion that the form of education which may on the whole claim to be the best is that of a well-organised day school, in which it is clearly understood to be the duty of the masters to give their life to the boys in school and out of school, just as if they were at a boarding school, and in which the boys are distributed into houses for school purposes, just as if they were living in a boarding house. Under such a system they get the best of both worlds, home and school.

From the public school we pass naturally to the Universities, and the first question that meets us is the influence they exercise on school education, through their requirements on admission or matriculation and the bestowal of their endowments and other prizes.

On this part of my subject I have seen no reason to alter or modify what I said at Glasgow three years ago, and therefore I merely enumerate and emphasise the suggestions which I put forward on that occasion for the improvement of education both at school and college.

I hold that it would be equivalent to pouring a new stream of intellectual influence through our secondary education if Oxford and Cambridge were to agree on some such requirements as the following:

(1) In the matriculation examination (*a*) candidates to be free to offer some adequate equivalent in place of Greek.

(*b*) An elementary knowledge of some branch of natural science, and of one modern language to be required of all candidates.

(*c*) A knowledge of some period of English history and literature also to be required of every candidate, and ability to write English to be tested.

(*d*) The examination in Latin and any other foreign language to include questions on the subject-matter of any prepared books offered, some questions on history and literature, and translation of easy passages not previously prepared.

(*e*) Marks of distinction should be given for work of superior merit in any branch of this examination, as, indeed, of every pass examination conducted by the University.

Candidates should not be excluded from residence before passing this examination, nor should they be required to pass in all subjects at the same time; but the completion of this examination would be the necessary preliminary to entry for any other examination required for a degree.

(2) On the question of endowments and the minimising of waste in the administration of them there is much to be said, and I would suggest for consideration:

(1) That, as a rule, open scholarships and exhibitions might be reduced to free tuition, free rooms, and free dinners in hall, or thereabouts.

(2) That every holder of an open scholarship or exhibition, whose circumstances were such that he needed augmentation, should, on application, receive such augmentation as the College authorities considered sufficient.

(3) That care should be taken to discourage premature specialisation at school.

For this end it should be required that no scholar should enjoy the emoluments of his scholarship until he had passed the matriculation examination described above; and a fair proportion of scholarships should be awarded for excellence in a combination of subjects.

The Universities might also do good service in the way of stimulating secondary education, if some small proportion of their entrance scholarships were distributed over the country as county scholarships, on condition that the county contributed an equal amount in every case.

In this way some equivalent for the endowments, so cynically confiscated by the Education Act of 1902, might be recovered and used for the benefit of poor and meritorious students.

Other reforms, which would, as I believe, be productive of valuable results, are the requiring from every candidate for a degree a knowledge of some portion of our own literature and history, and the encouragement of intellectual interests and ambitions by abolishing all purely pass examinations. A pass examination, in which the candidates are invited simply to aim at a minimum of knowledge or attainment, is hardly worthy of a university. The opportunity

of winning some mark of distinction in this or that portion of what is now a pass examination would frequently rouse some latent ambition in an idle man, and transform the whole spirit of his work.

Thus a modest reform of this kind might be of great practical benefit to the nation by helping in its degree to intellectualise the life of a great many of our young men, and draw out unsuspected interests, faculties, and tastes.

My observations have run to such a length that I must, perforce, conclude, leaving untouched other aspects of University education and training, whether in the old or the new universities, as also the whole subject of the higher education of women, and its proper relationship to traditional systems of instruction and study, framed and intended for men.

And my last word is a word of practical inquiry. How is this Section to be made of most value as an instrument of educational progress?

I leave the answer to this question to those more competent to give it, merely putting on record my own feeling that it may do a valuable service and supply one of our special educational needs, if the working committee of the Section, enlarged by the addition of various representative persons, makes it a duty to collect and publish year by year in succession a series of papers, the best that can be written by recognised authorities, on the chief branches of our English education, dwelling on its immediate and pressing needs, and how best to supply them. To do this the Committee should set to work systematically, commencing in October with monthly meetings, and formulating, without delay, the scheme or series of papers to be prepared and presented to the next meeting of the Association.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Dr. H. Burrows has been appointed to the post of lecturer and demonstrator of chemistry at the Sir John Cass Technical Institute, Aldgate.

A conference of delegates appointed by the Welsh county councils to discuss the question of afforestation in the Principality was held at Swansea on September 7. Sir Charles Philipps, who presided, remarked that there was in Wales an enormous area which could be profitably afforested. It was necessary that professors of the subject should be appointed at the universities, and that practical demonstration areas should be set apart. The view was expressed, in course of discussion, that the establishment of a central school of forestry for Wales was of the utmost importance, and that such a school would become self-supporting after a few years. It was at length resolved that the members should urge on their respective councils the great importance of the study and practical application of forestry by providing lectures to be given at suitable centres and bursaries, enabling students to attend these lectures; also that a central school of forestry be established with example plants of three or more acres, and demonstration areas of suitable extent, and that the necessary expense be defrayed by the county councils on the basis of their respective rateable values, the whole amount now asked for not to exceed 5000*l*.

Addresses will be given at most of the medical schools on the occasion of the opening of the winter session early in October. At Charing Cross Hospital, the session will be opened by the delivery of the fifth biennial Huxley lecture, on "Recent Advances in Science and their Bearing on Medicine and Surgery," by Sir William MacEwen, F.R.S. At the St. George's Hospital an introductory address on "Some Landmarks in the History of Medical Education" will be given by Prof. A. Macalister. The opening meeting of the Physical Society of Guy's Hospital will be held on October 8, when Sir Samuel Wilks, F.R.S., will preside. At King's College Hospital Dr. Thomas Buzzard will deliver an address on "The Future Relation of King's College to its Medical School and Hospital." At St. Mary's Hospital the introductory address will be delivered by Prof. A. E. Wright. At the Middlesex Hospital the session will open with an introductory address by Dr. F. J. Wethered. At University College, London, an introductory address will be given by Prof. J. Norman Collie, F.R.S. The introductory address in connection with the opening of the winter session of the London (Royal Free Hospital) School of Medicine for Women will be delivered by Miss Murdoch at the Medical School on October 3. At the Pharmaceutical Society the inaugural sessional address will be delivered by Prof. A. W. Crossley.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 9.—M. Mascart in the chair.—On a gaseous interrupter: K. R. **Johnson.** The interrupter consists of two plates of aluminium placed in a solution of an electrolyte. The heating effect of the current evolves a bubble of steam, which temporarily breaks the circuit; this is rapidly condensed in the upper part of the cell, and so causes a series of makes and breaks. It has the advantage of working independently of the dimensions of the metallic circuit, and even in the absence of an induction coil or a solenoid. Its disadvantage is that the frequency is rather low.—On a reagent for the hydrides of phosphorus, arsenic, and antimony: P. **Lemoult.** These gases, when diluted with an inert gas, react with a solution of the double iodide of mercury and potassium, giving characteristic crystalline precipitates, orange, yellow or brown in colour. They have been analysed, and correspond to the formula RHg_3I_3, in which R may be P, As, or Sb.—Benzopinacone and benzopinacoline: Amand **Valeur.** Evidence is given that the compound obtained by W. Dilthey and E. Last by the interaction of ethyl oxalate and phenylmagnesium bromide is a pinacone and not a pinacoline as supposed by them.—The synthesis of estragol and aromatic derivatives with an unsaturated chain: M. **Tiffeneau.**—On the reproductive apparatus of the Mucorinæ: J. **Dauphin.** Glucose, levulose, and galactose favour the appearance of sporangia; lactose and saccharose give only sporangia and chlamydospores; maltose and mannite give uniquely chlamydospores.—On macles: G. **Friedel.**—The relations between the blood circulation and the measurement of tactile sensibility: N. **Vaschide.** It is shown that there is an extremely close relation between the circulation of the blood and the tactile sensibility.

THE SCOPE OF ANTHROPOLOGY.

Science de l'Homme et Méthode anthropologique. By Alphonse Cels. Pp. vi+467. (Paris: Félix Alcan; Bruxelles: J. Lebègue et Cie., 1904.) Price 7 francs.

THERE has always been a great difference of opinion about the scope of the science of anthropology. Huxley's view was that anthropology deals with the whole structure, history, and development of man. Another authority subdivides the subject as follows: (1) Man's place in nature, *i.e.* his relation or standing to the animal kingdom as a whole; (2) his origin, whether from one pair or otherwise; (3) classification of races, with delineation of their chief characteristics; (4) antiquity of man; (5) language; (6) development of civilisation as a whole. Mr. Fallaize, in a paper read last year before the Anthropological Institute, has given the following main subdivisions:—(A) man's place in nature; (B) physical structure; (C) physical functions; (D) specifically human activities; and makes divisions (2) and (3) of the previous classification subdivisions of his class (A).

These examples will illustrate the wide variety of opinions held by authorities about the scope and the method of classification of the subject-matter of anthropology. The impression one gets from the consideration of these schemes is that it is not within the capacity of any one man to be an anthropologist in the widest sense of the term. The definitions of the scope of anthropology given above include many separate sciences, such as anatomy, physiology, philology, archæology, which in themselves are sufficient to absorb the energies of any single student, and which were in existence before the science of anthropology was created. Many branches of the study of man must therefore as a matter of practical convenience be abandoned to special sciences, and if a science of anthropology is to have any *raison d'être* it must be content to take the results of the studies of the anatomist, the physiologist, the psychologist, the archæologist, &c., and to coordinate and correlate these results with the view of discovering the more general laws of human nature.

The sciences at present generally included among anthropological studies have not been created by a subdivision of the whole subject-matter relating to man into watertight compartments, but usually some end of special theoretical or practical interest has formed a centre around which the science has been built up. For example, the interest excited by the perception of the great differences in the characteristics of different races has led to the creation of the science of ethnology, and the object of this science is to utilise all knowledge which may throw any light on the question of race. It overlaps without completely including prehistoric archæology, anthropometrics, psychology, and many other sciences.

This appears to be the only practical way of studying anthropology, but there can be no doubt that a great deal might be gained by the careful setting out of the whole of the subject-matter which, in the widest sense, could be taken as included in a complete science of man. New subjects of study which were previously overlooked may in this way be suggested, and new subordinate sciences created.

This very useful work has been well done by M. Cels in the book under review in a very suggestive though somewhat diffuse and fanciful style. About one-half of the book is devoted to an exposition of the logical methods of science, and as these methods are not more specially applicable to anthropology than to any other science, this part of his work might very well have been omitted or given in a much more condensed form. The same information might be found in any modern treatise on logic.

When we come to the part of M. Cels's work which is more especially relevant to its title, we find his subdivision of the subject-matter of the science of man interesting, suggestive, and well worth the attentive study of anthropologists.

Anthropology, according to M. Cels, is to be divided in the first place into two main subdivions, namely, the study of the nature of man and the study of the life of man, *i.e.* man is to be studied from the static point of view and from the dynamic point of view. In the second place, each of these main divisions is again subdivided into the study of the intrinsic and extrinsic conditions of their existence. Finally, each of these four subdivisions is again subdivided into three, in the first of which man is regarded as a Unity, *i.e.* as an individual, in the second as a Duality, *i.e.* as made up of body and mind, and thirdly as a Harmony, *i.e.* as a bisexual being which is only completed by the union of the two sexes for the reproduction of the species.

This division of the subject-matter of anthropology appears in some respects a little fanciful, but it is very plausibly worked out by M. Cels in his treatise. The author's view of anthropology is that it includes the study of the body and the mind of man, in their constitution as well as in their activity. This part of the subject is fairly well covered by the existing sciences of anatomy, physiology, and psychology. M. Cels also emphasises the necessity of studying the environment of man, namely, the earth on which he lives, his fellow-men and lower animals, and any other influence which reacts on his organism and on its activity. The effects of the moral as well as the material environment must be studied. The study of the influence of environment on mankind has not received so much attention from anthropologists as it deserves.

As a matter of practical convenience, the detailed study of the body and mind of the individual man must be abandoned to anatomy, physiology, and psychology; anthropology can only concern itself with the coordination of the results of these sciences. It may compare the anatomy, physiology, and psychology of different races of contemporary men, or of men of the present with those of the past. This field is to a great extent covered by physical anthropology, prehistoric archæology, the study of culture, and experimental psychology.

Though M. Cels has devoted so large a part of his work to the logical methods of anthropology, he tells us little or nothing of the immense advance that has been made in recent years in anthropometrics. No science makes much progress until precise measurement is applied to the characters the distribution and correlations of which are to be ascertained. Measurement has been applied to the body of man for more than fifty years, but only within the last few years has a statistical method been devised which enables us to give the true interpretation of the vast amount of anthropometric statistics that has been accumulated. But the work of Galton and Karl Pearson receives no notice from M. Cels in his work on the science of man and anthropological method; we are referred rather to the works, published fifty or more years ago, of Cuvier, Krause, and Saint-Hilaire, whose ideas on co-relation were mere shadows of the precise knowledge we now possess.

As a highly abstract and suggestive exposition of the nature and scope of anthropology, the book deserves a place in the library of the anthropologist.

J. GRAY.

PROGRESS IN THE CHEMISTRY OF FATS.

Chemical Technology and Analysis of Oils, Fats, and Waxes. By Dr. J. Lewkowitsch, M.A., F.I.C. Third edition, re-written and enlarged. Two vols. Pp. xxviii + 1152. (London: Macmillan and Co., Ltd., 1904.) Price 36*s*. net.

IN this, the third edition of Dr. Lewkowitsch's well known work, there is naturally much that was not included in the former issues. And since the second edition was itself a somewhat bulky tome of more than eight hundred pages, the author has wisely divided the present work into two volumes, corresponding broadly to the analytical and technological branches into which his subject resolves itself.

Briefly, the first volume deals with general principles, the second with individual products. In the earlier chapters there is a discussion of the theory of saponification, and a description of the glycerides, esters, alcohols, and acids which form the proximate constituents of oils, fats, and waxes; the rest of the first volume is mainly devoted to an account of the chief physical and chemical methods now employed in the examination of these substances. In the second volume, after a short generalised description of their commercial methods of preparation, the individual oils, fats, and waxes are dealt with. Under each article are given its source, characteristic features, physical and chemical constants, and such miscellaneous information as the technical uses of the product and the nature of its probable adulterants. Finally, the last two chapters embody an account of modern manufacturing processes employed in the various industries soap, candle, rubber, glycerol, and so on—for which the raw materials are furnished by oils and fats.

To specialists, the foregoing summary will show the present arrangement of what is now the standard English book of reference on the subject. To chemists who have not followed the progress of the chemistry of the glycerides very closely it may be useful to indicate a few of the more recent developments which, among many others, Dr. Lewkowitsch has described or referred to in the book under review.

Looking back over the work of the last few years, what strikes one as being the most notable advance in the chemistry of fats is the recognition of mixed glycerides as frequent if not normal constituents of fats and oils. Since the days of Chevreul, until quite recently, these latter bodies have been almost universally regarded as mixtures of simple triglycerides —usually trioleïn, tripalmitin, and tristearin. True, evidence was adduced more than a quarter of a century ago, on the one hand by Bell and Lewin, and on the other by Blyth and Robertson, which pointed to the fact that butter-fat contained a mixed glyceride, oleopalmitobutyrin. But, probably owing to the difficulty of isolating and definitely proving the identity of such compounds, the observation long remained almost unnoticed. During the last few years, however, the mixed glyceride oleodistearin has been obtained by Heise from kokum butter, stearopalmitin by Hansen from tallow, oleopalmitostearin and oleodipalmitin by Klimont from cocoa-butter, and daturodistearin by Kreis and Hafner from lard. This does not exhaust the list; and, indeed, the probability is that on further investigation mixed triglycerides will be found in most oils and fats. Several have also been synthesised, chiefly by Guth; thus two isomers of stearodipalmitin have been prepared, the α variety from α-monostearin and palmitic acid, and the β form from α-dipalmitin and stearic acid.

Another point of interest is the frequent, and perhaps general, occurrence of fat-splitting enzymes such as steapsin in both vegetable and animal oils and fats. The author is strongly in favour of the view that the rancidity of fats is due initially to hydrolysis of the glycerides by these ferments. To this, however, one possible objection suggests itself. Enzymes are usually destroyed at moderately high temperatures—*e.g.* maltase at 80°. Is there any evidence to show that lard or tallow prepared at steam-heat, or any fat specially raised to a temperature of, say, 95° to 100°, does not turn rancid? If it does not, so much the better for the enzyme theory of rancidity. If it does, one would still like to have other evidence that the enzymes present are capable of withstanding these higher temperatures.

As regards the analytical chemistry of fats, the most important among recent advances is undoubtedly Hehner and Mitchell's method of determining stearic acid. It is not an ideal process, and shows at least one anomaly; but it does place in the chemist's hands a valuable and long-wanted means of estimating, with reasonable accuracy and expedition, the proportion of one of the most frequent constituents of natural glycerides. To the same investigators, following Hazura, is also due the working out of what promises to be a very useful aid to the study of unsaturated glycerides, namely, the quantitative determination of their hexabromide derivatives. Of new methods having an immediate value to the practising analyst there may be mentioned Bömer's phytosterol test for vegetable oils, and Polenske's process for detecting

cocoa-nut oil in butter. No reference, however, is made to the Muntz and Coudon method of estimating the latter adulterant.

These are but a few out of many points of interest which one notes on looking through the book. A number of new illustrations appear, including some, which might be improved upon, of lard, cholesterol, and phytosterol crystals. There are plenty of references to original sources, and the information generally is brought well up to date, several papers issued in the present year being laid under contribution.

"Adulteration," says Dr. Lewkowitsch, "has almost become a fine art." No doubt it has; and in the silent, ceaseless struggle between the cunning of the adulterator and the skill of the analyst such works as the present play an important part. They are very helpful to the former individual, certainly. But to the latter they are invaluable. C. SIMMONDS.

STOKES'S MATHEMATICAL AND PHYSICAL PAPERS.

Mathematical and Physical Papers. By the late Sir G. G. Stokes. Vol. iv. Pp. viii+378. (Cambridge: The University Press.) Price 15s.

IT was on all grounds fitting that the continuation of this reprint should be entrusted to Prof. Larmor. The energy with which he has addressed himself to the work is shown by the fact that, although it is little more than a year since the death of his great predecessor, we already have a new volume in our hands, containing, in addition to the text, some valuable annotations and a selection from some very interesting correspondence.

The papers here reproduced range in date from 1853 to 1876; they are about forty in number, and, as a rule, are shorter and more restricted to special points than is the case in the previous volumes. There are, however, some notable exceptions. From the mathematical point of view the most considerable is the memoir "On the Communication of Vibration from a Vibrating Body to a Surrounding Gas." Perhaps the highest testimony to the excellence of this investigation is that Lord Rayleigh, who usually transforms and illuminates what he touches, in this case found, as he tells us, no better course open to him than to print page after page *verbatim* in his "Theory of Sound." The memoir is important, historically, not solely for the interest of the particular phenomenon which it explains, but as leading the way for a whole series of investigations in acoustics, optics, and electricity, in which we have to deal with waves diverging from point- or line-sources. Especially characteristic of the author is the labour expended with a view of reducing the results to a definite numerical form. From another point of view the paper may be regarded as forming one of the long series (some other members of which fall in the present volume) in which Stokes attacked the difficulties of the Bessel functions; other methods of dealing with these have since been devised, but it is mainly through his labours that these functions have become real and intelligible instruments of the mathematical physicist, instead of merely abstract analytical expressions.

We also find in this volume the classical "Report on Double Refraction," presented to the British Association in 1862. This has entered into so many discussions, that it is unnecessary to refer to it in detail. Although elastic theories of light no longer excite the same interest, the report is still worthy of careful study, not only on intrinsic grounds, but also as a masterpiece of criticism, and as an embodiment of the clear and judicial mind of its author.

Among experimental investigations, we may note the very important paper "On the Long Spectrum of the Electric Light," and the verification of Huyghens's law of refraction in uniaxal crystals, which has served as a touchstone of optical theories.

A short, but extremely acute, paper "On the Effect of Wind on the Intensity of Sound," read before the British Association in 1857, was unfortunately unnoticed and forgotten until the explanation was rediscovered, and extended so as to include the effect of variations of temperature, by Osborne Reynolds in 1874.

It will not be supposed that the numerous other brief memoirs which we are obliged to pass over without special mention are unimportant. To the scientific worker the value of such a collection often resides chiefly in these minor investigations, which are otherwise in danger of being overlooked, as in the instance just referred to.

As has been already mentioned, the editor has appended a few notes, chiefly of a historical character. This delicate task has been exercised with great judgment and restraint. He has also included a most interesting correspondence between Stokes and Thomson on the early history of spectrum analysis. It is clear that long before Kirchhoff's first publication on the question Thomson was in possession of the leading ideas of the subject, and foresaw its wonderful possibilities, and that he had, moreover, publicly expounded these things in his lectures at Glasgow. But whilst he is emphatic that he derived his knowledge from Stokes, the latter is equally positive that his share in the matter was limited to suggestions which he had himself not been able to follow out with the same confidence. The whole correspondence is a lesson of magnanimity on both sides; we feel, as Lord Rayleigh recently expressed it, that the theory of spectrum analysis is practically there, but it would be contrary to the whole spirit of the friendly debate to attempt to analyse further how much of the merit of this prevision belongs to one rather than to the other. One point, however, remains indisputably associated with the name of Stokes, viz. the hypothesis that special absorption of light is due to coincidence, or approximate coincidence, of the period of the light waves with a proper period of a molecule. Hypotheses of this kind have played a great part in recent theories of anomalous dispersion and the like; but there can be no question as to their original source.

The remaining papers are to be included in a fifth volume, together with the biography by Lord Rayleigh recently issued by the Royal Society. We are also

encouraged to look forward to a selection from Stokes's scientific correspondence, which cannot fail to be of the highest interest.

All readers will combine in congratulating Prof. Larmor and the Cambridge Press on the success of this most acceptable volume. The portrait by Dickenson, of date 1874, is admirable; we trust that it may be supplemented later on by a likeness of a more recent date, recalling the aspect which is to many more familiar. HORACE LAMB.

ARGENTINE LIVE STOCK.

Argentine Shows and Live Stock. By Prof. Robert Wallace. Pp. 154. (Edinburgh: Oliver and Boyd, 1904.) Price 3s. 6d. net.

THIS volume is the outcome of a six months' tour of agricultural investigation and inspection in Argentina. While professing primarily to be an account of the annual live stock show of the Rural Society held at Palermo, it includes also notes on other Argentine shows, as well as an interesting description of the chief breeds of cattle, horses, and sheep bred in that country.

The European breeds of cattle represented at the Palermo show were the shorthorn, the Hereford, and the Aberdeen-Angus. Of these, the shorthorn cattle were far the most in evidence. We are told that this breed owes its success to its unrivalled capacity for beef-production where the climate is genial and pasture abundant, and to the fact that it has proved more serviceable than other imported breeds for crossing with the Criollo or native cattle, and so improving their quality for purposes of fattening. Hereford and Aberdeen-Angus cattle are stated to thrive well amid comparatively unfavourable surroundings, and, although not bred to nearly the same extent as the shorthorns, occupy a definite place in the rural economy of the Republic. The Aberdeen-Angus breed has not gained general favour partly because, unlike the other two breeds mentioned, it does not "nick" well with the Criollo cattle.

The horses at the Palermo show included all the more prominent British breeds, the introduction of which has been accompanied by considerable success. It is instructive to note that the importation has in many cases resulted in improvement, apparently owing solely to change of soil and environment. This is especially the case with certain strains of Hackney blood, while among cattle a similar tendency has been noticed for the Hereford breed.

Reference is made to the native Criollo horses, the degenerate descendants, according to most writers, of Barbs and Arabs introduced by the Spaniards at a very early period of the European occupation. Genuine Criollos—only now found in outlying provinces—are characterised by their dun colour, by stripes on the legs and shoulders, and by a dark dorsal band. These Criollos are said to be hardy to a degree, to possess great power of endurance, and, moreover, they are difficult to handle. Doubtless natural selection has been at work eliminating the unfit, with the result that the survivors present all the traits that Darwin and others associated with the ancestors of the common horse. That in the Criollos the mane in no way differs from the mane of Barbs and Arabs suggests that many centuries must have elapsed since horses acquired a long mane, from which it may be inferred that Prjevalsky's horse is not an escaped domestic horse.

It is worthy of note that so great is the vigour of the Criollos that crosses with but little of the native blood prove most useful, owing to their great stamina and endurance.

The section on horses is followed by one on the sheep bred in Argentina. The account includes some interesting information about the early history of the Pampa and Criollo sheep, besides containing suggestions for the improvement of the stock now existing in the country. The Pampa is stated to be derived from the Spanish long-wool, which was a hardy animal, and, like the Dorset Horns of England, in favourable circumstances bred twice a year. The Criollo sheep is a "degenerate offshoot of the Spanish Merino." The most numerous and best represented sheep at the present time are the Lincoln and its various crosses, though a good many other British breeds have been imported with varying degrees of success.

Chapters on dairying and on agricultural machinery follow the description of the live stock.

The book is of value for the interesting descriptions which it contains, and because it affords an idea of the altogether remarkable resources of Argentina for producing live stock. It is freely illustrated by photographs of prize animals taken at the show in Palermo.

OUR BOOK SHELF.

The Old Riddle and the Newest Answer. By John Gerard, S.J., F.L.S. Pp. vi+293. (London: Longmans, Green and Co., 1904.) Price 5s. net.

WE have derived much entertainment from Father Gerard's lively chapters. They constitute an ably constructed plea for agnosticism in science. Not Huxley himself was so rigid in demanding exact demonstration of the truth of every statement required to be believed, as is this latest critic of the doctrine of evolution.

Science does not consist purely of mathematical demonstration. Other methods and processes have a perfectly legitimate place in scientific thought. Even in pure logic a door is open to theory and hypothesis; nor are probability, analogy, or even conjecture excluded by those whose conception of the science and art of reasoning is of the widest and wisest kind. We have, of course, to refrain from treating an untested hypothesis, however likely to be true, as an immutable verity; but no one in his senses will fail to recognise that among the dicta of scientific writers there are many degrees of probability, ranging from the practically certain to the merely conjectural. Some of the conclusions of science are as certain as the nature of things will allow; but it is a mistake to attribute to those who lay stress on such certainty a claim of equal respect for every position that to scientific men appears probable.

All this is, of course, perfectly well known to Father Gerard; we can only say that in practice he appears to disregard it. His book is marked throughout by great charm of style and felicity of expression; its main defect is a too evident desire to "play to the gallery." The chapters which contain a root-and-

branch attack on the theory of genetic evolution are as brightly and easily written as the rest; their matter, however, will be entirely unconvincing to those who know the facts. The author has got up his case as a clever advocate might get up his address to a jury; but the cross-examination of witnesses would put a very different complexion on the whole business. Father Gerard seeks to prove too much. His plea amounts to an allegation in the name of science that a science of life is non-existent. F. A. D.

Occurrence of Aluminium in Vegetable Products, &c. By C. F. Langworthy, Ph.D., and P. T. Austen, Ph.D. Pp. v+168. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1904.) Price 8*s.* 6*d.* net.

After a careful perusal of this book we have been unable to arrive at any conclusion as to why it was written. The authors presumably had some reason for compiling a bibliography of the analytical work done on aluminium and its occurrence in plants, animals, and waters, but they give no idea as to their object in their preface.

The book, as already stated, consists of a compilation of work dealing with the occurrence of aluminium in vegetable products, animal products, and in natural waters. In the preface it is stated that "no attempt has been made to comment on the value of individual analyses cited." Now by omitting to do this the book loses any value it might have had, because the references given are so extremely scanty. One or two examples taken at random will give an idea of the style of compilation, *e.g.* on p. 9 we find:—

"Coppola, M. (*Gaz. Chim. Ital.*, 10, p. 9: *Jour. Chem. Soc.* London, 37 (1880), p. 382), found 11.16 per cent. ash in *Stereocaulon vesuvianum.* Of this 1.13 per cent. was Al_2O_3."

Again, on p. 73:—

"Finckh, C. (*Neue. Jahrb. Pharm.*, 34, p. 13; *Chem. Centbl.*, 1870, p. 615; *Jahresb. Chem. Naumann*, 1870, p. 1382), notes traces of aluminium in Ochsenhausen mineral water from Bieberach, Germany."

Both these illuminating passages are taken from the middle of the respective pages. On p. 73 there are seven and a half such references, and on p. 9 eight.

The contents of the book are not arranged in any order, except that the authors' names are placed alphabetically. Consequently, if one looks up tea in the index in order to ascertain whether it contains aluminium, one is referred to p. 32; after a lot of hunting we find tea under the name of Schriddl, P. (*Arch. Pharm.*, 1873, p. 375). . . . Again, if we wish to know the aluminium content of mushrooms, we are referred to p. 15, where we can find nothing about mushrooms, unless *Boletus edulis* is a mushroom; or is poke-weed the American name for mushroom?

In desperation we look up primrose, and are referred to p. 42, and at last we are satisfied; the root of the primrose contains 1.617 per cent., and the flower heads 1.145 per cent., of aluminium oxide.

Works of compilation are often of great value, but they can only be of value when the contents are systematically arranged. To arrange a dictionary such as this according to the names of the authors is absurd. The pitiable thing about the whole matter is that the authors must have wasted a great deal of valuable time, because a compilation of this kind is extremely tiresome and laborious.

Practical Chemistry. By P. A. E. Richards, F.I.C. Pp. viii+136. (London: Baillière, Tindall and Cox, 1904.) Price 3*s.* net.

So long as examinations in practical chemistry of the test-tube order are encouraged by examining bodies, there will be a steady consumption of chemical cram books. The peculiarities of such books are that the student is never allowed to step outside the limits of his syllabus without due warning, and his weary brain is not perplexed with explanations. Like the cattle in the large tinned meat factories, he is driven along a narrow gangway in which he cannot turn round, until he is delivered into the hands of the slaughterer.

Fortunately the more intelligent examining bodies are beginning to realise that the analysis of simple salts does not furnish scientific pabulum of a very nourishing kind; so preparations of a few inorganic compounds and a little volumetric analysis have been added to the syllabus.

The present volume has been prepared to meet the special requirements of the syllabuses of the conjoint board and the preliminary scientific examination of the London University.

It is only necessary to state that the author has completed his task in a thoroughly business-like manner. A student who worked through the book conscientiously might with confidence defy the conjoint examiner to do his worst. J. B. C.

Calculations used in Cane-Sugar Factories. By Irving H. Morse, B.S. Pp. viii+74. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1904.) Price 6*s.* 6*d.* net.

This collection of tables was primarily made for the use of the sugar chemists of Louisiana, but it is equally applicable to the operations of every manufacturer of cane-sugar. The work may be recommended to all who seek to use the laboratory as a control of the working of the sugar-house. In every well regulated factory the manager is dependent upon the chemist for information as to the amount of sucrose in the raw juice, the yield of sugar, the losses in manufacture, and whether or not all the available sugar is being extracted from the cane, and the efficiency and value of the laboratory largely depend upon the rapidity and accuracy with which this information can be furnished. The work is thoroughly practical, and is evidently the outcome of many years' experience of sugar testing.

Colours due to Intermittent Illumination.

Mr. C. T. Whitmell (Nature, September 1, p. 424) describes a method of producing coloured patches by means of a rotating disc, furnished with a ring of holes. It will be found that the phenomenon can also be produced by intermittent reflection. In the year 1881 I described in Nature (vol. xxiv. p. 140) a method whereby colour patches of great brilliancy, due to intermittent illumination, were easily produced by viewing sun-light reflected from the polished spokes of a cycle wheel. The relationship between the colour given and the velocity of rotation was clearly marked, and the effects can be easily reproduced by means of the simple apparatus described. In these experiments, a counter was attached to the axle of the rotating wheel, so that the rate of rotation could be accurately determined at the time of observation. The rotation of the cycle wheel was maintained by means of a motor the speed of which could be easily varied. In connection with the phenomenon of the change of colour due to intermittent illumination, several papers of much interest have been published since the year 1882 by Dr. G. Burch, F.R.S. F. J. Jervis-Smith.

Is Selenium Radio-active?

It occurred to me recently that a possible method of deciding between the two hypotheses which have been brought forward to explain radio-activity, namely, that of *atomic* degradation (Rutherford and Soddy, Ramsay, &c.) and that of *molecular* change (Armstrong and Lowry, *Proc. Roy. Soc.*, 1903), lay in attempting to realise radio-activity in the case of an element well known to undergo molecular change readily, but with an atomic weight small enough to exclude the probability of an atomic instability such as is assumed for radium and thorium. Such an element is selenium (at. wt. 79), which suggested itself to me as a suitable material to experiment with because, under the influence of light, it undergoes a remarkable alteration in its electrical resistance and E.M.F. of contact, suggesting an allotropic change of an altogether unusual character. As this change, whatever be its real nature, occurs almost instantaneously (Bellati and Romanese, *Atti R. Ist. Veneto*, 1881; Maiorana, *Atti dei Lincei*, 1894 and 1896), it seemed possible that the rapidity of the intermolecular vibration might be sufficient to cause a radiation similar to that of radium and thorium which, by "ionising" the selenium, would render it conducting. In order to ascertain whether such a hypothetical radiation could be detected photographically, I exposed a piece of selenium, placed on a photographic plate, wrapped in three thicknesses of black glazed paper, during thirty-six hours to the bright sunshine of July. On developing the plate a distinct black stain on a background of clear glass indicated the position the selenium had occupied. The first experiment was made with ordinary vitreous selenium, and the stain, although distinct, was not very pronounced. A second experiment with freshly prepared "metallic" selenium, obtained by heating the vitreous variety at 190° for half an hour and then cooling very gradually to the ordinary temperature, gave a much more intense stain on the negative.

I should have hesitated before publishing these experiments in their present form had I not, since they were made, seen a paper in the *Physikalische Zeitschrift* of August 25 in which similar results are recorded by J. J. Taudin Chabot. This observer, approaching the subject from a different direction, has also been led to the conclusion that selenium in a selenium "cell" is feebly radio-active to the extent of emitting radiations capable of passing through black paper and affecting a photographic plate. It may, of course, be urged that the stain on the plate is due to selenium vapour penetrating the paper in which the plate is enclosed. I am therefore making experiments in which this possibility is excluded. Further, I intend studying the behaviour of sulphur, as it is already known that the other members of the selenium family, namely, oxygen and tellurium, can in certain circumstances give rise to radio-active phenomena.

Rare Moths in England.

MRS. THOMAS'S letter in your issue of September 8 is interesting, both as affording definite proof that *Deilephila livornica* does sometimes breed in this country, and as rather tending to support the view that this species enters the country from abroad—for the proximity of Warmwell to the sea is certainly suggestive.

Apropos to rare moths, it may be of interest to state that I recently took a specimen of *Deiopeia pulchella* on the cliff here. This moth used to be so rare that Newman wrote:—"Mr. Doubleday has a single specimen taken at Epping, and we believe there are two or three other British specimens in different cabinets." Since that was written the number of English specimens has, of course, been increased, but I believe that the insect is still considered a rarity; and the scarce occurrence of a weak-flying moth like this, which one can hardly suppose could cross the Channel, and which has been found so far inland as at Epping, is a greater puzzle than the rarity, but occasional comparative abundance, of a strong-flying hawk moth.

THE HEART OF SKYE.[1]

THIS volume of detailed rock-description, raising in its successive chapters questions of profound interest in philosophic geology, proves that the Geological Survey of the United Kingdom is confident that the scientific spirit should permeate its public work. None of the rocks dealt with possesses at present an economic value; most of the area is untraversed by roads, and the exposures are not to be sought in quarries, but in rain-swept uplands, or high on desolate mountain-walls. Yet no detail is regarded as unimportant; the surveyor, for months together, leads a life as hard and remote as that of an Alaskan pioneer; and the result is a book in which the daily difficulties are concealed, while an array of facts is given to us, any one of which may help observation in other and more favoured lands.

Few lands, however, are more favoured in scenery, and the defects of Skye are mainly meteorological. The very audacity with which the black Cuillins rise from the edge of the Atlantic seems a temptation to the summer-storms. Yet the glaciated surfaces allow of small decay, and Mr. Harker directs our attention to the remarkable freshness of the rocks. Despite the absence of maps, the crystalline core of the island, with its striking scenic contrasts, long ago attracted geologists, and has been again described, in all its picturesqueness, by Sir Archibald Geikie in our own day. We well remember the seductive map, on the scale of four miles to an inch, with which we ourselves tramped across the boggy grasslands, or wandered in midnight prodigality above the Sound of Sleat; and Mr. Harker complains that, even now, names and details are not always exactly placed on the sheets issued by the Ordnance Survey. The work that he has now done, and the manner of it, will be honoured by all who know the island.

The view that the crystalline central masses represent the core of the volcano from which the abundant plateau-basalts flowed appears to be now untenable, although some kind of a volcano, and a fairly large one, may have existed on the crown of the great laccolitic dome. Certain earlier volcanic vents, moreover, provide curious evidence that gabbro and granite existed, in a consolidated form, down below, while the plateau-basalts were being extruded. In a very remarkable passage (p. 24), the author shows that even the sequence of these rocks was the same as that now known to exist in the central laccolitic area. The acid tuffs of Skye containing granite (p. 20), the basic tuffs crowded with fragments of gabbro (p. 21), go far as evidence of the continuity of lava-types with holocrystalline representatives below. It is interesting to remember that, when Prof. Judd wrote his well known papers, this natural-history view of igneous masses was very far from general acceptance; and the fact that he strove for it so successfully has been obscured by the subsequent controversy as to the local sequence in the Hebrides.

Mr. Harker, in dealing with the basalt plateaux (pp. 29, 239, and 435), shows excellently how large a part is played by the abundant intrusive sills. These form, indeed, on weathering, most of the terraced structure that observers were formerly apt to attribute to successive lava-flows. It is remarkable (p. 12) that the dykes or vents can so rarely be traced into the lava-sheets to which they gave rise; but this is a common complaint in all areas of copious and long-continued activity. The temporary theory of fissure-

[1] "The Tertiary Igneous Rocks of Skye." By Alfred Harker, M.A., F.R.S., with notes by C. T. Clough, M.A., F.G.S. Pp. xii + 482. (Memoirs of the Geological Survey of the United Kingdom. Glasgow: Printed for His Majesty's Stationery Office by James Hedderwick and Sons, 1904.) Price 9s.

eruptions has been practically modified into that of eruption from a large number of small and easily concealed vents, which were doubtless situated along fissures; and this theory is borne out by observed occurrences along rifts on Etna. Mr. Harker himself points out (p. 14) that "the great thickness and extent of the basalt group results only from the superposition and overlapping of a vast number of separate flows, each of which is of very insignificant dimensions."

The small group of trachytes and rhyolites (p. 56) in Skye occurs clearly between two series of basalts, a fact very satisfactory for Irish geologists, who have had to maintain similar views for their acid lavas on less convincing evidence. Much of the interest of the petrographic details furnished by Mr. Harker lies in the attack of one rock on another. The dissection of an early peridotite by an overpowering mass of gabbro (p. 64), the occurrence of "xenoliths" of one kind of gabbro in another (p. 121), the mutual modifications of gabbro and granite in the Red Hills (p. 183), which are justly attributed to a process of diffusion, may be named as examples of the important problems dealt with. We confess to a personal interest in the results of Mr. Harker's researches on composite sills (p. 209), where an acid rock is shown to pick up fragments of an earlier basic one, and to discharge, as it were, its own porphyritic crystals into the latter along its margins. Such facts make us doubtful of the necessity for assuming a distinction between "segregation-veins," with ill-defined edges, and "ordinary veins of intrusion" (p. 78), or for the belief that bands, the crystals of which interlock at the common surface, "must have existed side by side in the fluid state" (p. 119). The discussion of the banded gabbros, with the beautiful plates accompanying it, forms a chapter of exceptional value, though it hardly does justice to Mr. Harker's own recent work, in which he has explained the genesis of a Cainozoic banded gneiss. The reference (p. 115) of the "pyroxene-granulites" of Skye to "altered representatives of basic lavas entangled in the gabbro complex" is in happy agreement with the most modern views as to similar rock-masses in the Saxon metamorphic area.

A local rock of hybrid origin is termed *marscoite* (pp. 175 and 192); this occurs as sills, and is regarded as a basic magma modified by the absorption of granitic material prior to its intrusion. Mr. Harker holds that such "hybrid rocks are essentially abnormal in composition"; yet it may be urged that in the deeper plutonic regions many rocks, which we have come to consider normal, have arisen by processes of admixture and diffusion. The junction of the granite and the Cambrian limestone in Skye (p. 135) presents evidence of solution of the limestone, without addition of lime to the granitic magma. We prefer to believe that a slow diffusion and transference of the lime occurred into the great subterranean mass, or that the locally modified granitic magma flowed on elsewhere, leaving new and unmodified material in contact with the limestone, rather than to conclude that a rock which absorbed gabbro and Torridon Sandstone behaved in a mysteriously different manner towards dolomitic limestone. The singular absence of veins passing from the granite into the limestone rather suggests rapidity of solution. But the case is certainly an uncommon one, as other contacts of these two rocks show. Down below us as we write, an ancient granite sends off zig-zag veins abundantly into the "Dalradian" limestone of Donegal; behind us, the same granite produces a coarse quartz-diorite, by interaction with a basic sill of the same series. A little south, at Summy Lough, the pre-Devonian gabbros have brought up inclusions of an earlier gabbro, which "weather into little hollows," like those of the corrie of Tairneilear. In the universality of the problems discussed by Mr. Harker lies their wide geological attraction; and we venture to think that many of his questions will receive their answer in more distinctively plutonic regions. For a long time, Continental geologists maintained that some fundamental difference separated our modern lavas from the crystalline masses revealed in older regions of the crust. Similarly, our fluidal gneisses, with their mutual interactions, have been held to be something primordial and apart. This purely mental barrier is now rapidly breaking down, and we may find that the phenomena so carefully set before us in the case of Skye have deep-seated and more impressive representatives in the floor of Saxony or Norway.

FIG. 1.—View of Sgurr nan Gillean. (From "The Tertiary Igneous Rocks of Skye."

Mr. Harker's book, with its handsome photographic illustrations, is published at a very moderate price, seeing that it appeals entirely to the professed geologist. Indeed, when dealing with so superb an area, we think that a little more descriptive power might have been used to unite the scenic and the petrographic features. We thus wish that chapter xxvi., on "physical features and scenery," had sent off intrusive sheets into those that went before it, and had even wrapped round much of their contents as literary "xenoliths." With the manner of the text we have little fault to find. It is always clear and direct—far clearer, in fact, than the explanatory diagram on p. 433. The Americans have given us many worse names than "mugearite"; and other authors beside Mr. Harker have written "amygdule" in place of the obvious "amygdale." "Phenocryst," like "cab" and "bus," must probably be accepted as a compromise, though we expect better things of scientific men; and the incorrect use of "granophyre," introduced by Rosenbusch, has become widely tolerated through repeated publication. The term "ophitic plates," rather than "ophitic crystals"

or "ophitic nodules," where augite or hornblende are concerned, has been sanctioned by microscopists, but tends to mislead when actual rock-specimens are examined. Beyond these trifling criticisms, we have nothing but praise for this conscientious exposition of results, behind which lies a vista of personal sacrifice and prolonged observation in the field.

GRENVILLE A. J. COLE.

ENGLISH MEDICINE IN THE ANGLO-SAXON TIMES.[1]

FROM an educational point of view, an acquaintance with the history of scientific discovery is even more important than a knowledge of the results of scientific investigation up to the most recent date. The latter knowledge is essential for progress, as it is for practical application of results already gained. The former is needful in order to understand the methods of science, to imbibe the spirit of discovery, to appreciate the reciprocal action of hypothesis and experiment, and to acquire the mental habit of looking with scientific eyes upon every branch of human knowledge.

The history of mathematics, of chemistry, of geology, and of the inductive sciences in general, has been adequately treated by many foreign and by some English writers. But one of the most ancient branches of knowledge has been sadly neglected in this country. The history of medicine as the science of disease, and of medicine as the art of prevention and cure, has been far more studied by French and German, Dutch and Italian physicians than by those who write in English. It is therefore a matter of congratulation that the College of Physicians, which dates from the wonderful re-birth of learning in the days of Sir Thomas More, of Dean Colet, of Erasmus, and of Linacre, should have been entrusted by the widow of a learned member, the late Dr. Fitz-Patrick, with the endowment of a lectureship on the history of medicine.

In this volume Dr. Payne treats with remarkable learning and interest of the art of medicine as it existed among our ancestors before the Conquest. For his purpose he has not the help of such inscriptions as describe and delineate the duties of physicians in the Babylonian and the Egyptian empires, nor the rich and wonderful collection of medical instruments which is preserved in the Museum of Naples. He has only literature to depend on.

English learning dates from Archbishop Theodore of Tarsus (A.D. 669), who, with the Abbot Adrian, founded a school at Canterbury, where Greek as well as Latin, arithmetic, and astronomy was, according to the testimony of the justly Venerable Bede, successfully taught. Bede himself wrote on astronomy, and was probably the author of a treatise "De phlebotomia." In his "Ecclesiastical History of Britain" he described several epidemics of the true oriental or bubonic plague. St. John of Beverley recorded a case of aphasia in a youth who was also affected with impetigo of the scalp, and was cured of both. Among the West Saxons in the ninth and tenth centuries literature flourished. Poetry, history, and religious works were written in native English as well as in Latin, and have been adequately studied by more than one German scholar. This civilisation, with its numerous schools and libraries, was interrupted by the disastrous inroads of the Danes; but up to the Conquest and beyond, notable works appeared, and some of these were treatises on medicine. Among others published by Cockayne nearly fifty years ago were "The Leech-Book" of Bald (written when Alfred was king, or soon after his death), a book of recipes and a glossary of the names of plants, of which the manuscript is preserved in the library of the Cathedral of Durham.

The following remarks by Dr. Payne deserve to be widely read, for their application is general:—

"Before speaking in detail of the old English medical books, I will venture to say a word about the spirit in which they should be studied. Too often, those few persons who have interested themselves in these monuments of ancient science have treated them in one of two ways. Either they have picked out something especially unlike the ways of modern thought, and held it up to scorn as showing the folly of our ancestors, or else in kinder mood they have condescended to be amused, and calling anything old and unfamiliar 'quaint,' dismissed it with a smile. Neither of these methods will help us to understand the ancient world. The folly of our ancestors is no explanation. Their knowledge was no doubt extremely limited; they saw old and distant things through a dense and prevailing fog of ignorance. But that they tried to understand them at all is a proof of their wisdom, not of their folly.

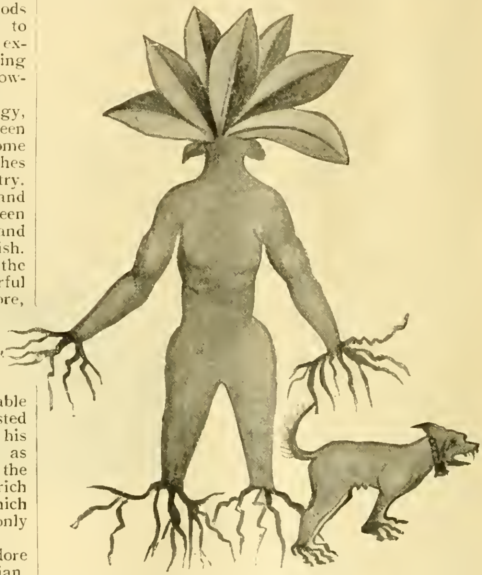

FIG. 1.—Mandragora, Mandrake, with the dog used to put it up. A simple and probably early form of the legend. (From "The Fitz-Patrick Lectures for 1903.")

"Still more misleading is the habit of regarding the rude features of primitive art, the stammering words of an infant literature, the childish fallacies of early science, as something to be amused at. Till we have got beyond the stage of calling these old things merely 'quaint,' there is no possibility of understanding them at all. Therefore, if we quote from the old books things which appear strange in our eyes, foolish things if you like, it is not with the object of raising

[1] *The Fitz-Patrick Lectures for* 1903. By Joseph Frank Payne, M.D. Oxon., Fellow and Harveian Librarian of the Royal College of Physicians, Consulting Physician to St. Thomas's Hospital. Pp. 162; with twenty-three illustrations from early English MSS. (Clarendon Press.) Price 7*s*. 6*d*. net.

a laugh or of flattering the modern sense of superiority. The only way to understand these old writers is to try to put ourselves as far as possible in their place, and conceive how nature and science presented themselves to the eyes of the early teachers and learners in the tenth and eleventh centuries."

A full account is given of the mythical "mandrake," with several instructive drawings from Anglo-Saxon manuscripts (see Fig. 1), and others of plants which can be recognised as characteristic, while some are gracefully conventional. Many drawings of foreign plants are copied from more original sketches, until they have become mere ornamental designs. These figures may be compared with the beautiful drawings published by Prof. Haeckel of animal structures adapted to suggest the decorative use of countless organic forms to carry on the conventional lines of Greek architects and Italian decorators.

An interesting section of Dr. Payne's volume is devoted to the old English names of plants. "Waybroad" has been ill exchanged for the so-called plantain, and "maythe" for camomile. On the whole, he agrees with Prof. Earle that there was a great decadence in botanical knowledge in England between the eleventh and sixteenth centuries.

The practice of surgery by the Anglo-Saxon leeches was for the most part confined to the external application of divers vegetable or animal concoctions which can have been only negatively useful. Some of them remind us of Alexis of Piedmont, who, after describing an unfailing remedy, adds, "If this will not do it, take this other." Here and there we come across curious anticipations of modern pathology and surgery, *e.g.* when we are told that if the insensible hardening of the liver is of too long duration, then it forms a dropsy which cannot be cured; or when the plastic operation for hare-lip is described. Amputation for gangrene of a limb is also recommended.

The last sixty pages are devoted to superstitious treatment by amulets and charms, some derived from Greek treatises, as they in their turn reproduced the magical lore of Egypt and of Babylon. One extract, however, from a sermon of St. Eligius, who furnished the gentle abbess of the "Canterbury Tales" with her only oath, might still be preached from English pulpits against the quackery and miscalled Christian science of the present day. If space permitted, it would be interesting to refer to Dr. Payne's comparison between the "Practica" of the famous school of Salernum and the old English "Leech-book," and to his account of the final decay of the native art of medicine and its replacement by the less vigorous and less original doctrines of Continental Europe in the later Middle Ages.

The work is of great value and interest not only to physicians, but to scholars, antiquarians, and philologists. It is admirably printed and illustrated, and will, we hope, be succeeded by the publication of future lectures by the same accomplished physician.

NOTES.

The *Atti dei Lincei* announces the death on August 19 of Prof. Emilio Villari, recently president of the Reale Accademia dei Lincei.

Mr. C. Fox-Strangways, who joined the staff of the Geological Survey in 1867, has retired from the public service.

An earthquake shock was felt in the Cowall district of Argyllshire shortly after 4 a.m. on September 18. In Dunoon the shock was most distinctly felt. Dishes rattled, doors were opened, bells were set ringing, and ornaments were broken.

Reuter reports that two distinct shocks of earthquake were felt at Ottawa at 7.53 p.m. on September 14. The first lasted five seconds, and after an intermission of three seconds came the second shock, which was of six seconds' duration. The direction was from south-west to north-east.

A congress of free thought was opened at Rome on Tuesday in the Grand Court of the Roman College. Prof. Sergi, president of the committee, welcomed the members of the congress, and the following were elected honorary presidents:—Prof. Haeckel (Germany), M. Berthelot (France), Dr. Maudsley (Great Britain), Señor Salmeron (Spain), M. Novimoff (Russia), Herr Bjoersen (Norway), and Prof. Lombroso (Italy).

At the St. Louis Exhibition a steel tower 300 feet high has been erected for wireless telegraphy by Dr. De Forest and his coadjutors, and communication has been established between St. Louis and Chicago. We learn from the *Times* that the United States Government is also exhibiting a working De Forest station, and there are seven working exhibits in the exhibition. The United States Government has contracted with the De Forest Company for five long-distance stations at Key West, Pensacola, Puertorico, South Cuba, and Panama. The longest distance between these stations will be 1000 miles, which will far exceed the distance attempted for wireless telegraphy by any Government before.

It is announced that the high-level observatory on Ben Nevis will be closed next month. The annual cost of the double observatory, high- and low-level, is close on 1000*l.*; of this sum about three-fourths is spent on the high-level and about one-fourth on the low-level station. The Treasury has offered to pay direct to the Scottish Meteorological Society on behalf of the Ben Nevis Observatory the 350*l.* recommended by the committee of inquiry into the administration of the Parliamentary grant for meteorology, instead of making this sum a charge on the meteorological grant. The continuance of the observatories could, however, only be undertaken on a guaranteed income of 1000*l.* a year. The directors have therefore decided to close the observatories.

The New York correspondent of the *Daily Chronicle* announces that Commander Peary will lead another expedition to the North Pole next year. The expedition will start in the summer, and will be gone probably not longer than two years. Its expenses are estimated at 30,000*l.*, which is 10,000*l.* more than the last Peary Expedition cost. American capitalists are supplying the funds. A vessel is now being built which, it is said, will be stronger and more suitable to the conditions prevailing in the Polar regons than any previous ship. One part of her equipment will be an ice-breaker bow, which is expected to enable the ship to break through to a point farther north than has hitherto been reached. The features of the expedition will be the fixing of a base within 500 miles of the Pole, the use of very light sledges and fast Esquimaux dogs to make a final dash for the Pole, and the adoption of conditions of living corresponding as nearly as possible to those of the Esquimaux themselves.

The expedition, on board the steamer *Frithjof*, which took out a supply of coal for the Ziegler North Polar Expedition, whose ship, the *America*, left for the Arctic regions nearly fifteen months ago, has returned to Norway without having communicated with the *America*. This is the second attempt which has been made this year by the relief expedition to reach Franz Josef Land, but on each occasion the severity of the weather, together with fog and ice, has

compelled the *Frithjof* to return; and now it is impossible that another attempt can be made until next year. There has been no news of the *America* since she left Norway in July, 1903, but, so far as can be ascertained, it was intended that on reaching Franz Josef Land the explorers should establish a supply base, from which forced marches would be made in the direction of the Pole. No apprehension is felt concerning the *America*, for the ship carried provisions for five years, and there are also stores of pemmican and clothes available.

Scientific critics in Berlin are now much exercised with regard to the remarkable performances of "Clever Hans," the thinking horse. According to the daily Press, a representative committee, which included the director of the Berlin Zoological Gardens, a veterinary surgeon, and a professor of the Physiological Institute of the Berlin University, witnessed these performances with the view of ascertaining whether they were the result of a trick, or whether they were due to the mental powers of the animal. Their verdict, it is reported, was unanimous in favour of the latter view. It is stated that when told that the day was Tuesday, and asked which day of the week this represented, the horse would give the correct answer by taps. Similarly he will tell not only the hour, but the minutes indicated by a watch; while he is also reported to be able to record the number of men and of women among a row of visitors, and to indicate the tallest and the shortest members of the party.

It is stated in the *Times* that Messrs. C. G. Spencer and Sons, of Highbury, have lately constructed, from the designs of Señor Alvares, a new aëroplane flying machine which does away with the gas vessel and its many risks. The structure consists of two swing-like aëroplanes having a superficial area of 400 square feet; these are attached to two outstretching and slightly curved arms and fixed to a bamboo framework, in shape like a cigar. In the front of this framework is fitted a 2 horse-power motor, which drives two two-bladed tractors—each of them 5 feet in diameter—which are placed one on each side of the frame, and level with the motor. At the back of the machine are three rudders, which are worked from the front by means of ropes. Two of the rudders are triangular, and are constructed to move horizontally, for the purpose of controlling the upward and downward motion of the machine, while the other, the largest of the three, which is rectangular, is fitted perpendicularly, and is intended to guide the machine to the left or right. The weight of the machine is 150 lb. without the aëronaut. It does not appear that the invention has any power of raising itself from the ground, as it is stated that during the next few days it is to be taken up by a balloon, at the Crystal Palace, to an altitude of 5000 feet, when it will be released for the purpose of testing its actual power of flight.

Sir Lowthian Bell was elected president of the Institution of Mining Engineers for the ensuing year at the meeting held at Birmingham last week. A paper by Prof. Redmayne read before the meeting is summarised on p. 524. Among other papers read was one by Mr. George Farmer, on the problem of gob-fires, in the course of which he pointed out that coal absorbs oxygen quickly, and more quickly as the surface open to oxidation increases and as the heat increases, so that any cause which will split up the gob-material will aid in initiating a fire. Moisture assists the oxidation and heating by splitting up the gob-material, so that this may be considered an important factor. In every case in which a fire has been properly located props left in the goaf, or ribs of coal left against faults, or falls in working stalls burying a rib of coal, have been found to be the origin. In any method of extinction means must be taken for cooling the hot material by the application of substances which will absorb the heat and reduce the temperature to such a degree that combustion entirely ceases in a natural atmosphere, or by the removal of the combustible material from the influence of the heat. Mr. J. Cresswell-Roscamp described an improved apparatus for laying dust in coal mines. Water (or other liquid) is forced by pumps into an air-cylinder, which causes a regular and unpulsating column to flow along the pipes and out of sprayers or nozzles fitted with a specially constructed screw apparatus round which the liquid is forced, so as to cause the spray to spread over a circular breadth up to 30 feet. The sprays are in the shape of inverted cones impinging on each other, and become broken up into extremely fine particles, which are carried along by the air current and can clearly be felt from 100 feet to 150 feet behind the apparatus when in motion.

In the year 1883 the late Sir Cuthbert Peek established an important meteorological station at Rousdon, Devon, midway between Lyme Regis and Seaton, and from time to time various self-recording instruments, including a Dines's pressure tube anemometer, have been added. The observations have been regularly continued under the superintendence of the Hon. Lady Peek, and we have received a copy of the results for the year 1903. As this volume completes a period of twenty years, tables are appended giving the average monthly and annual results for the years 1884–03. The observatory is a second order station of the Royal Meteorological Society, and the work is a valuable contribution to the climatology of the south of England.

We have received the report of the U.S. Weather Bureau for 1902–3. The first part of this elaborate compilation, containing a very interesting account of the administrative work of the year, was referred to in our issue of February 4 (vol. lxix. p. 328). The remaining portions consist of meteorological summaries, including hourly averages from the records of automatic instruments at twenty-eight stations, and monthly and annual means at stations in the United States and West Indies. Among the many valuable miscellaneous tables and reports we may mention especially those showing the accumulated amounts of precipitation for each five minutes at stations in the United States and West Indies supplied with automatic gauges, during all storms in which the rate of fall equalled 0·25 inch in five minutes or 0·75 inch in one hour. The volume also contains hourly observations at several localities in the West Indies; these are of importance in connection with the study of the destructive hurricanes which frequently occur in those regions.

It may be of interest to some of our readers to know that very complete meteorological observations, taken three times a day at the Central Meteorological Office at Vienna, together with daily and monthly means, are regularly published in the *Anzeiger* of the Vienna Academy of Sciences. Further, that the observations for each month are followed by the observations made in connection with the international scientific balloon ascents. We have before us the results of two ascents of manned and one of unmanned balloons in the month of June last. In addition to the summary of the principal facts obtained during the ascents, the actual observations taken every few minutes and explanatory remarks are given. The publication of these valuable data so soon after their occurrence is of considerable importance for the study of the processes at work in the upper strata

of the atmosphere, in connection with weather recently experienced.

THE Biological Survey of the U.S. Department of Agriculture has issued a *Circular* (No. 44) giving the names and addresses of officials connected with the preservation of birds and game in the United States and Canada.

WE have received Nos. 17 and 18 of vol. xlviii. of the *Memoirs* of the Manchester Literary and Philosophical Society. In the latter Dr. Hoyle gives a diagnostic key to the recent genera of dibranchiate cephalopods. In the former Prof. Dawkins describes a molar of the straight-tusked elephant (*Elephas antiquus*) from glacial strata at Blackpool. Apropos of fossil elephants, it may be mentioned that a few days ago workmen disentombed in a sand-pit at Erith an entire skull of a mammoth, which fell to pieces when brought to the surface. This is much to be regretted, as the specimen might doubtless have been saved had palæontologists been informed of the discovery before attempts were made to remove it from the bed.

THE August number of the *Brooklyn Edison*, published by the Edison Electric Illuminating Co., of Brooklyn, New York, contains several striking pictures of decorative and spectacular electric lighting at Coney Island, one of which, from a photograph taken at night, is here reproduced. Within a year the amount of electric illumination at this famous pleasure resort has more than trebled; and probably

FIG. 1.—Luna Park, Coney Island, showing the magnitude and extent of the electric illumination. From a photograph taken at night.

there is not now to be found anywhere in the world a place where the decorative possibilities of the electric incandescent lamp are so strikingly demonstrated. The Brooklyn Edison Co., which has successfully carried out the scheme of lighting at Coney Island, supplies light and power to an area of seventy-seven square miles and a population of nearly one and a half millions.

AN important discovery in connection with cotton-growing in the southern United States is recorded in *Bulletin* No. 49 of the Entomological Division of the U.S. Department of Agriculture. It appears that an ant has been discovered in Guatemala which preys on the adult cotton boll-weevil (*Anthonomus grandis*) and thus checks the ravages of this insect, and so permits the growing of cotton in districts where it would otherwise be impossible. It has been found that the kelep, as the ant is called in Guatemala, can be easily removed, and colonies have accordingly been introduced into the cotton plantations of Texas in the hope of checking the devastation caused by the weevil. It only remains to ascertain whether the kelep will be able to withstand the winter climate of Texas.

THE last published part of *Biometrika* contains a valuable paper by Dr. H. E. Crampton demonstrating the existence of natural selection during the pupal stage of *Philosamia cynthia*, a silk-producing moth. Dr. Crampton's observations differ from the experiments conducted by Prof. E. B. Poulton, Mr. F. Merrifield, and Miss C. Sanders in the fact that his pupæ were not exposed to the attacks of enemies; so that the elimination, which took place on a large scale, must presumably have been due to internal rather than external causes. In the author's opinion, the actual basis for selection in this particular instance is not use-advantage, but correlation. Prof. Pearson's important Huxley lecture on the inheritance of the mental and moral characters in man has been already noticed in the pages of NATURE. An elaborate memoir, illustrated by a very fine series of photographs, on the variation and correlation of the human skull, is contributed by Dr. W. R. Macdonell. The material discussed is the splendid series of skulls discovered some eleven years ago in Whitechapel, and now in the possession of Prof. Thane. Dr. Macdonell concludes that these crania, which date most probably from the time of the Great Plague, are in general appearance and biometric constants remarkably close to the Long Barrow British. As the result of an investigation on inheritance of coat-colour in the greyhound, A. Barrington, A. Lee, and K. Pearson conclude that the ancestral law of decreasing correlation holds no less for their present material than for man and horse. Prof. Weldon's research on the form of the shell spiral in a race of *Clausilia itala* failed to disclose the existence of any selective elimination between the young and the adult stage; reasons for this result are suggested. The number ends with an elementary proof of Sheppard's formulæ, with which are associated certain other formulæ for dealing with the ordinates and adjacent areas of frequency curves.

THOUGH graphical work is now rightly regarded as an essential part of an elementary course of mathematics, many teachers are still unfamiliar with the new methods, and do not comprehend clearly all that is implied in graphs. The "Solutions of the Examples in Hall's 'Graphical Algebra,'" by Mr. H. S. Hall, assisted by Mr. H. C. Beaven, just published by Messrs. Macmillan and Co., Ltd., will be of great service to those teachers and students to whom graphical methods are novel, in showing how problems may be easily and accurately solved by plotting graphs. The book will assist the introduction and extension of graphical methods in mathematical classes.

A CATALOGUE of apparatus for electric heating and cooking just issued by Messrs. Isenthal and Co., 85 Mortimer Street, London, W., contains particulars of many attractive ways in which electricity is used for heating purposes. The advantages of electric heating from a hygienic point of view are obvious; and, economically, the consumption of electric energy is not so excessive as is usually assumed. Messrs. Isenthal's list includes radiators of various types, ornamental stoves, cooking ranges and ovens, appliances for heating and boiling liquids, hot water geysers and cisterns, sterilisers, soldering bits, hot plates for chemical laboratories or photographic purposes, evaporators, and numerous other devices which would add to the comfort and cleanliness of many operations in laboratories as well as in houses. The adaptability of the electric current, and the efficiency of the various forms of apparatus described in Messrs. Isenthal's catalogue, should encourage the use of electric energy as a source of heat.

IN the August number of the *Gazzetta* E. Paternò and E. Pannain have established that, under certain conditions, electrolysis converts potassium cyanide in aqueous solution containing potash completely into cyanate. The latter separates during the electrolysis in a pure state in the form of white crystals.

ACCORDING to a brief report by J. Stěp, director of the Joachimsthal Mine, published in the *Proceedings* of the Vienna Academy of Sciences (No. 14), freshly excavated uranium ore, which has never been exposed to the light, is strongly radio-active. A comparative study of the activity of illuminated and unilluminated specimens of the ore has yet to be made.

IN vol. vii. of the *Fortschritte auf dem Gebiete der Röntgenstrahlen* Dr. Josef Rosenthal discusses the relative advantages of large and small induction coils for producing X-rays. When the tube used is not too highly exhausted, and consequently has not too great a resistance, a small coil giving a comparatively short spark may be used with good results. Small coils have, moreover, the advantage of being more portable and less costly than large coils. But when a tube with a high vacuum is used a higher tension coil has to be employed, and in such cases, in order to prevent the tube from changing during a long exposure, the number of interruptions per second must be reduced as much as possible.

OUR ASTRONOMICAL COLUMN.

THE RETURN OF ENCKE'S COMET (1904 *b*).—As announced in these columns last week, Encke's comet was re-discovered at Koenigstuhl-Heidelberg on September 11.

It was found by Herr Kopff, who describes it as being, at present, a faint object. According to a note by Mr. Denning, however, mentioned in NATURE for July 21, the favourable conditions of 1805, 1838, and 1871 should be repeated during the present apparition, and it is possible that the comet may become visible to the naked eye when near to Altair, early in December.

The accompanying chart given below shows, approximately, the apparent path of the comet among the stars from now until October 15, according to the daily ephemeris published by MM. Kaminsky and Ocoulitsch in No. 3962 of the *Astronomische Nachrichten* :—

VARIATIONS IN THE LUNAR LANDSCAPE.—A communication from Harvard reports that Prof. W. H. Pickering, at present located at the Lowe Observatory, California, observed a bright hazy object 2″ in diameter upon the floor of the lunar crater Plato on July 31. Six previous observations made between July 21–28 inclusive gave no indication of this novel feature.

On August 2 a black elliptical shadow two miles in diameter was seen in the place of the previously observed bright spot, whilst to the north-east and north there extended a large white area, the existence of which was confirmed by an observation made on August 3.

A telegram dated August 22 states that real conspicuous changes have taken place in this region during the past month, and confirms the existence of the new crater, which has a diameter of about three miles. The bright area has shifted considerably since August 3.

Several other objects which have not been mapped before were observed whilst examining Plato, and it was seen that the previously conspicuous white area surrounding craterlet No. 54 (Harvard College Observatory *Annals*, vol. xxxii., plate x.) has now disappeared.

SUN-SPOT PERIODICITY AND TERRESTRIAL PHENOMENA.—In a brochure published at Rochechouart (1904), Prof. O'Reilly, of Dublin, emphasises the important part which a knowledge of the periodicity of solar activity plays in the prediction of terrestrial meteorological events, and also demonstrates that the origins of several important historical events may possibly be attributed to the meteorological effects of solar changes.

After discussing the more recent droughts, such as have caused distress in Australia and India, and showing that these occurred at definite epochs of solar cycles, he shows that the successive floods which caused the formation of the Zuyder Zee probably occurred at epochs of sun-spot maxima. Similarly he points out that each of the ten centuries in Etruscan chronology were approximately 122·2 (*i.e.* $11 \cdot 11 \times 11$, or nearly 11^2) years in length, that is to say, they contained about eleven sun-spot periods, and he supposes that the Etruscan era probably commenced from a period of great cold, or maybe some memorable flood, which could be attributed to excessive solar activity.

From a study of Brückner's sun-spot cycles, Prof. O'Reilly believes that the year 1895 was the culminating year of a period of heat and drought, and that 1915 will be the corresponding centre-year of a period of cold and rain.

OBSERVATIONS OF THE RECENT PERSEID SHOWER.—M. Henri Perrotin, observing at Nice, saw 1184 meteors, of which 1041 were Perseids, during the nights of August 9–14 inclusive. The observations were made between the hours of 8 p.m. and 3 a.m. each night at the meteorological station of the Nice Observatory, situated at an altitude of 2740 metres on Mount Mounier.

The Perseids, as shown in his tabulated results, were very numerous, the maximum display of the shower occurring on the night of August 11–12, especially between 1 a.m. and 3 a.m. The maximum for each night occurred between midnight and 3 a.m.

A notable feature of the display was that the meteors appeared in groups of two or more, each group being followed by a break five to fifteen minutes in length.

The radiant of the shower was seen to be a fairly extensive area, not a point, having its centre near to γ Persei.

The Perseids were white and very swift, whilst the paths were comparatively short. On the other hand, the sporadic meteors observed were of a reddish-yellow colour, their paths were long, and they travelled slowly, leaving trails which lasted for some seconds.

These observations again emphasised the importance of selecting a station situated at a high altitude where the atmosphere is generally exceptionally clear (*Comptes rendus*, No. 9, 1904).

RADIATION IN THE SOLAR SYSTEM.[1]

I PROPOSE to discuss this afternoon certain effects of the energy which is continuously pouring out from the sun on all sides with the speed of light, the energy which we call sunlight when we enjoy the brilliance of a cloudless sky, which we call heat when we bask in its warmth, the stream of radiation which supports all life on our globe and is the source of all our energy.

As we all know, this ceaseless stream of energy is a form of wave motion. If we pass a beam of sunlight, or its equivalent, the beam from an electric arc, through a prism, the disturbance is analysed into a spectrum of colours, each colour of a different wave-length, the length of wave changing as we go down the spectrum from, say, 1/30,000 inch in the red to 1/80,000 of an inch in the blue or violet.

But this visible spectrum is merely the part of the stream of radiation which affects the eye. Beyond the violet are

[1] Afternoon address delivered at the Cambridge meeting of the British Association, August 23, by Prof. J. H. Poynting, F.R.S.

the still shorter waves which affect a photographic plate or a fluorescent screen, and will pass through certain substances opaque to ordinary light. Here, for instance, is a filter devised by Prof. Wood which stops visible rays, but allows the shorter invisible waves to pass and excite the fluorescence of a platinocyanide screen.

Again, beyond the red end are still longer waves, which are present in very considerable amount, and can be rendered evident by their heating effect. We can easily filter out the visible rays and still leave these long waves in the beam by passing it through a thin sheet of vulcanite. A piece of phosphorus placed at the focus of these invisible rays is at once fired, or a thermometer quickly rises in temperature. The waves which have been observed and studied up to the present time range over some nine octaves, from the long waves described to the section yesterday by Prof. Rubens, waves of which there are only 400 in an inch, down to the short waves found by Schumann in the radiation given off by hydrogen under the influence of the electric discharge, waves of which there are a quarter of a million in an inch. No doubt the range will be extended.

Radiant energy consists of a mixture of any or all of these wave-lengths, but the eye is only sensitive at the most to a little more than one octave in the nine or more.

This radiation is emitted not only by incandescent bodies such as the sun, the electric arc, or flames. All bodies are pouring out radiant energy, however hot or cold they may be. In this room we see things by the radiation which they reflect from the daylight. But besides this borrowed radiation, every surface in the room is sending out radiation of its own. Energy is pouring forth from walls, ceiling, floor, rushing about with the speed of light, striking against the opposite surfaces, and being reflected, scattered, and absorbed. And though this radiation does not affect our eyes, it is of the utmost importance in keeping us warm. Could it be stopped, we should soon be driven out by the intense cold, or remain to be frozen to death.

As the temperature of a body is raised, the stream of radiation it pours out increases in quantity. But it also changes in quality. Probably the surface always sends out waves of all lengths from the longest to the shortest, but at first when it is cold the long waves alone are appreciable. As it gets hotter, though all the waves become more intense, the shorter ones increase most in intensity, and ultimately they become so prominent that they affect our sense of sight, and then we say that the body is red or white hot.

The quality of the stream depends on the nature of the surface, some surfaces sending out more than others at the same temperature. But the stream is the greatest from a surface which is, when cold, quite black. Its blackness means that it entirely absorbs whatever radiation falls upon it, and such a surface, when heated, sends out radiation of every kind, and for a given temperature each kind of radiation is present to the full extent, that is, no surface sends out more of a given wave-length than a black surface at a given temperature.

A very simple experiment shows that a black surface is a better radiator, or pours out more energy when hot, than a surface which does not absorb fully, but reflects much of the radiation which falls upon it. If a platinum foil with some black marks on it be heated to redness, the marks, black when cold, are much brighter than the surrounding metal when hot; they are, in fact, pouring out much more visible radiation than the metal.

It is with these black surfaces that I am concerned to-day. But, inasmuch as it seems absurd to call them black when they are white hot, I prefer to call them full radiators, since they radiate more fully than any others.

For a long time past experiments have been made to seek a law connecting the radiation or energy flow from a black or fully radiating surface with its temperature. But it was only twenty-five years ago that a law was suggested by Stefan which agrees at all satisfactorily with experiment. This law is that the stream of energy is proportional to the fourth power of the temperature, reckoned from the absolute zero 273° below freezing point on the centigrade scale. This suggestion of Stefan served as the starting point of new and most fertile researches, both theoretical and practical, and we are glad to welcome to this meeting Profs. Wien, Lummer, and Rubens, who have all done most brilliant work on the subject.

Among the researches on radiation recently carried out is one by Kurlbaum in which he determined the actual amount of energy issuing from the black or fully radiating surface per second at 100° C., and therefore at any temperature.

Here is a table which gives the amount at various temperatures, as determined by Kurlbaum:—

Rate of Flow of Energy from 1 sq. cm. of Fully Radiating or "Black" Surface.

Absolute Temperature	Calories Grams of water heated 1° per sec.
0°	0·0
100° Air boils	0·000127
300° Earth's surface	0·0103
1000° Red heat	1·27
3000° Arc carbon	103
6000°	1650
6250°	1930

As an illustration of the "fourth power law," let us see what value it will give us for the temperature of the sun, assuming that he is a full radiator, or that his surface, if cooled down, would be quite black.

We can measure approximately the stream of energy which the sun is pouring out by intercepting the beam falling on a surface exposed to full sunlight, measuring the heat given to that surface per second, and then calculating what fraction the beam is of the whole stream issuing from the sun.

This was first done by Pouillet, and his method will serve to illustrate the principle of all other methods.

In his apparatus the sunlight fell full on a box containing water, and the rate at which the water rose in temperature gave the energy in the stream of solar radiation falling on the box.

Simple as the experiment appears, the determination is beset with difficulties, the chief being the estimation of the fraction of the energy intercepted by the atmosphere, and we are still unable to give a very definite value. Indeed, we cannot yet say whether the outflow of energy is constant or whether it varies. In all probability, however, it does vary, and Prof. Langley, who has devoted years of work to the subject, has recently obtained evidence indicating quite considerable variation.

We may, however, assume that we are not very far from the true value if we say that the stream of radiation from the sun falling perpendicularly on 1 sq. cm. outside the earth's atmosphere will heat 1 gm. of water 1/24° C. every second, or will give 1/24 calory per sec.

Now the area of a sphere round the sun at the distance of the earth is 46,000 times the area of the sun's surface. The energy from 1 sq. cm. of the sun thus passes through 46,000 sq. cm. at the surface of the earth. It is therefore $46,000 \times 1/24$ calories, or 1920 cal./sec. But from the table already given, a black surface at 6250° absolute, say 6000° C., gives 1930 calories per second, or the temperature of the sun's radiating surface is 6000°—if he is a full radiator, and there is good reason to suppose that no great error is made in taking him to be one.

Let us now take another illustration of the fourth power law.

Imagine a little black body which is a good conductor of heat placed in full sunlight at the distance of the earth. Let it be 1 sq. cm. in cross section, so that it is receiving 1/24 calory per second.

It will soon warm up to such a temperature that it gives out just as much as it receives, and since it is so small, heat will rapidly flow through it from side to side, so that it will all be very nearly at the same temperature. A sphere 1 sq. cm. in cross section has area 4 sq. cm., so that it must be giving out from each sq. cm. of its surface $1/96 = 0{\cdot}0104$ calory each second. From the table above it will be seen that this corresponds very nearly indeed to a temperature of 300° absolute or 27° C., say 70° F.

It is to be noted that this only applies to a little round body. A flat plate facing the sun would be about 60° C.

hotter, while if it were edgewise to the sun it might be very much colder.

Let us now see what would be the temperature of the small black sphere at other distances from the sun. It is easily seen that, inasmuch as the heat received, and therefore that given out, varies inversely as the square of the distance, the temperature, by the fourth power law, will vary inversely as the square root of the distance.

Here is a table of temperatures of small black spheres due to solar radiation :—

Distance from Sun's centre	Temperature Centigrade
$3\frac{3}{4}$ million miles	1200° C. Cast iron melts.
23 million miles	327° Lead nearly melts.
At Mercury's distance	210° Tin nearly melts.
At Venus's distance	85° Alcohol boils freely.
At Earth's distance	27° Warm summer day.
At Mars's distance	−30° Arctic cold.
At Neptune's distance	−219° Nitrogen frozen.

We see from this table that the temperature at the earth's distance is remarkably near the average temperature of the earth's surface, which is usually estimated as about 16° C. or 60° F. This can hardly be regarded as a mere coincidence. The surface of the earth receives, we know, an amount of heat from the inside almost infinitesimal compared with that which it receives from the sun, and on the sun, therefore, we depend for our temperature. The earth acquires such a temperature, in fact, that it radiates out what it receives from the sun. The earth is far too great for the distribution of heat by conduction to play any serious part in equalising the temperature of different regions. But the rotation about its axis secures nearly uniform temperature in a given latitude, and the movements of the atmosphere tend to equalise temperatures in different latitudes. Hence we should expect the earth to have, on the average, nearly the temperature of the small black body at the same distance, slightly less because it reflects some of the solar radiation, and we find that it is, in fact, some 10° less.

Prof. Wien was the first to point out that the temperature of the earth has nearly the value which we should expect from the fourth power law.

Here is a table showing the average temperatures of the surfaces of the first four planets on the supposition that they are earth-like in all their conditions :—

Table of Temperatures of Earth-like Planets.

Mercury	196° C.
Venus	79° ,,
Earth	17° ,,
Mars	−38° ,,

The most interesting case is that of Mars. He has, we know, a day nearly the same in length as ours; his axis is inclined to the ecliptic only a little more than ours, and he has some kind of atmosphere. It is exceedingly difficult to suppose, then, that his average temperature can differ much from −38° C. His atmosphere may be less protective, so that his day temperature may be higher, but then to compensate, his night temperature will be lower. Even his highest equatorial temperature cannot be much higher than the average. On certain suppositions I find that it is still 20° below the freezing point, and until some new conditions can be pointed out which enable him to establish far higher temperatures than the earth would have at the same distance, it is hard to believe that he can have polar caps of frozen water melting to liquid in his summer and filling rivers or canals. Unless he is very different from the earth, his whole surface is below the freezing point.

Let us now turn from these temperature effects of radiation to another class of effects, those due to pressure.

More than thirty years ago Clerk Maxwell showed that on his electromagnetic theory of light, light and all radiation like light should press against any surface on which it falls. There should also be a pressure back against any surface from which radiation is reflected or from which it is issuing as a source, the value in every case being equal to the energy in a cubic centimetre of the stream. The existence of this pressure was fully demonstrated independently by Lebedew and by Nichols and Hull some years ago in brilliant experiments in which they allowed a beam of light to fall on a suspended disc in a vacuum. The disc was repelled, and they measured the repulsion and found it to be about that required by Maxwell's theory. Nichols and Hull have since repeated the experiment with greater exactness, and there is now no doubt that the pressure exists and that it has Maxwell's value.

The radiation, then, poured out by the sun is not only a stream of energy. It is also, as it were, a stream of pressure pressing out the heavenly bodies on which it falls. Since the stream thins out as it diverges, according to the inverse square of the distance, the pressure on a given surface falls off according to the same law. We know the energy in a cubic centimetre of sunlight at the distance of the earth, since, moving with the velocity of light, it will supply 1/24 calory per second. It is easy to calculate that it will press with a force of 6×10^{-5} degree on a square centimetre, an amount so small that on the whole earth it is but 70,000 tons, a mere trifle compared with the three million billion tons with which the sun pulls the earth by his gravitation.

But now notice the remarkable effect of size on the relation between the radiation pressure and the gravitative pull. One is on the surface and proportional to the surface, while the other penetrates the surface and pulls every grain of matter throughout the whole volume.

Suppose we could divide the earth up into eight equal globes. Each would have half the diameter of the earth and a quarter the surface. The eight would expose twice the surface which the earth exposes, and the total radiation pressure would be doubled, while the total gravitative pull would be the same as before. Now divide up each of the eight into eight more equal globes. Again the radiation pressure would be doubled, while gravitation would be the same.

Continue the process, and it is evident that by successive division we should at last arrive at globes so small and with total surfaces so great that the pressure of the radiation would balance the pull of gravitation. Mere arithmetic shows that this balance would occur when the earth was divided up into little spheres each 1/40,000 cm. in diameter.

In other words, a little speck 1/40,000 cm., say 1/100,000 of an inch in diameter, and of density equal to that of the earth, would be neither attracted nor repelled by the sun.

This balance would hold at all distances, since both would vary in the same way with the distance. Our arithmetic comes to this: that if the earth were spread out in a thin spherical shell with radius about four times the distance of Neptune, the repulsion of sunlight falling on it would balance the inward pull by the sun, and it would have no tendency to contract.

With further division repulsion would exceed attraction, and the particles would be driven away. But I must here say that the law of repulsion does not hold down to such fine division. The repulsion is somewhat less than we have calculated owing to the diffraction of the light.

Some very suggestive speculations with regard to comets' tails have arisen from these considerations, and to these Prof. Boys directed the attention of Section A last year. We may imagine that the nucleus of a comet consists of small meteorites. When these come near the sun they are heated and explosions occur, and fine dust is produced not previously present. If the dust is sufficiently fine, radiation may overpower gravitation and drive it away from the sun, and we may have a manifestation of this expelled dust in the tail of the comet.

I do not, however, want to dwell on this to-day, but to look at the subject in another way.

Let us again introduce our small black sphere, and let us make it 1 sq. cm. in cross section, 1·13 cm. in diameter, and of the density of the earth. The gravitation pull on it is 42,000 times the radiation pressure.

Now let us see the effect of size on the radiating body. Let us halve the diameter of the sun. He would then have one-eighth the mass and one-quarter the surface. Or, while his pull was reduced to one-eighth, his radiation push would only be reduced to one-quarter. The pull would now be

only 21,000 times the push. Halve the diameter again, and the pull would be only 10,500 times the push. Reduce the diameter to 1/42,000 of its original value, that is, to about 20 miles, and the pull would equal the push.

In other words, a sun as hot as ours and 20 miles in diameter would repel bodies less than 1 cm. in diameter, and could only hold in those which were larger.

But it is, of course, absurd to think of such a small sun as this having so high a temperature as 6000°. Let us then reduce the temperature to 1/20, say 300° absolute, or the temperature of the earth. Then the radiation would be reduced to the fourth power of 1/20, or 1/160,000, and the diameter would have to be reduced to 1/160,000 of 20 miles, or about 20 cm., say 8 inches, when again radiation would balance gravitation.

It is not very difficult to show that if we had two equal spheres each of the density and temperature of the earth they would neither attract nor repel each other—their radiation pressure would balance the gravitative pull—when their diameters were about 6·8 cm., when, in fact, they were about the size of cricket balls.

It must be remembered that this is only true for spheres out in space receiving no appreciable radiation from the surrounding region.

It would appear that we have arrived at a result of some importance in considering the aggregation of small meteorites. Imagine a thinly scattered stream of small meteorites at the distance of the earth from the sun. Then, even if they be as large as cricket balls, they may have no tendency to move together. If they are smaller they may even tend to move apart and scatter.

In conclusion, let me mention one more effect of this radiation pressure. You will remember that radiation presses back against any surface from which it issues. If, then, a sphere at rest in space is radiating equally on all sides it is pressed equally on all sides, and the net result is a balance between the pressures. But suppose that it is moving. It is following up the energy which it pours forth in front, crowding it into a smaller space than if it were at rest, making it more dense. Hence the pressure is slightly greater, and it can be shown that it is greater the greater the velocity and the higher the temperature. On the other hand, it is drawing away from the energy which it pours out behind, thinning it out, as it were, and the pressure at the back is slightly less than if the sphere were at rest.

The net result is a force opposing the motion, a force like viscous friction, always tending to reduce the speed.

Thus calculation shows that there is a retarding force on the earth as it moves along its orbit amounting in all to about 20 kgm., say 50 lb. Not very serious, for in billions of years it will only reduce the velocity by 1 in a million, and it will only have serious effects if the life of the earth is prolonged at its present temperature to hundreds of billions of years.

But here again size is everything. Reduce the diameter of the moving body, and the retarding effect increases in proportion to the reduction. If the earth were reduced to the size of a marble, the effect would be appreciable in a hundred thousand years. If it were reduced to a speck of dust a thousandth of a centimetre in diameter, the effect would be appreciable in a hundred years.

Note what the effect would be. Imagine a dust particle shot out from the earth and left behind to circulate on its own account round the sun. It would be heated by the sun and would be radiating out on all sides. As it journeyed forward there would be a resisting force tending to stop it. But instead of acting in this way the resistance would enable the sun to pull the particle inwards, and the fall inwards would actually increase the velocity. This increase in the velocity would increase the resistance, and at the same time the approach to the sun would raise its temperature, increase the radiation, and so increase the resistance still further. The particle would therefore move in a more and more rapid spiral orbit, and ultimately it would fall into the sun. Small marble-sized meteorites would fall in from the distance of the earth probably in a few million years. Small particles of dust would be swept in in a few thousand years.

Thus the sun is ever at work keeping the space round him free from dust. If the particles are very minute he drives them forth into outer space. If they are larger he draws them in. It is just possible that we have evidence of this drawing in in the zodiacal light, that vast dust-like ring which stretches from the sun outwards far beyond the orbit of the earth, and is at once the largest and the most mysterious member of the solar system.

PHYSICS AT THE BRITISH ASSOCIATION.

THE number of communications made to Section A this year was again so large as to necessitate duplicate sittings on several days, an arrangement which appears to bring home to members in a forcible manner the impossibility of being in two places at once. For some undiscovered reason the subcommittee which arranges the order of the papers is generally held responsible for this limitation, and gets a considerable amount of abuse. The disadvantage of the division was particularly evident at the discussion on the units used in meteorological measurements opened by Dr. W. N. Shaw. A subcommittee of the council of the association appointed to consider the question, recommends the use of the absolute zero of temperature with either the centigrade or Fahrenheit degree as the unit, but preferably the former, and the introduction of a new "degree of pressure" which is equal to 2000 C.G.S. units, and involves a graduation of the barometer in nearly 1/16th of an inch (0·06 in.), and the use of a vernier down to 1/160 inch. The meeting before which the matter was discussed was disposed to dwell mainly on the cost of effecting the changes proposed, and owing to the scant attendance of physicists, rather lost sight of the advantages of adopting what is practically equivalent to the C.G.S. system.

Attwood's machine as an aid to the teaching of dynamics was much discredited during the discussion of a paper by Mr. Eggar on an apparatus for verifying Newton's second law. Mr. Eggar finds that the movement of a truck down an inclined plane the angle of tilt of which can be altered, is much more convenient and effective than the fall of a weight.

The coefficient of expansion of hydrogen at various pressures down to low temperatures was the subject of a communication from Prof. Witkowski. He finds that the coefficient increases with decrease of temperature, and decreases with increase of pressure, a result which must have an important bearing on our standards of temperature.

Dr. Glazebrook's account of the recent work of the National Physical Laboratory made one hope that the efforts to cope with the demands made on it by our manufacturers for tests of materials and for scientific help of other kinds, will not be hampered by the insufficiency of the financial support the institution receives from the Government. In order to establish a scale of temperature, Dr. Harker has compared up to 1000° C. the constant volume nitrogen thermometer with a thermojunction previously standardised at the Reichsanstalt, and a platinum thermometer. Mr. Smith has constructed and compared a number of mercury standards of resistance, Dr. Stanton has been engaged in determining the amount and distribution of the pressure on structures due to wind, Dr. Carpenter has investigated the solidification of iron-carbon alloys, and a number of other important investigations have been carried out for manufacturers and for the Government.

Problems connected with radiation played a prominent part in the proceedings of the section. Prof. Poynting's interesting afternoon address, which appears in another part of the present issue, dealt with the applications of the laws of radiation to the solar system. Taking Stefan's law as a basis, the temperature of the sun works out as 6250° C., and that of a black body at the distance of the earth from the sun at 27° C., which agrees well with the average temperature of the earth. A description of an apparatus by means of which he had measured the tangential stress on a surface due to the oblique impact of light, was also given to the ordinary sectional meeting by Prof. Poynting. If E is the stream of momentum per sq. cm. per second due to the light incident at an angle θ, and μ is the fraction of the incident light reflected, the tangential pressure on the surface is $(1-\mu)/2.E \sin 2\theta$, and although in general it is smaller than the normal pressure,

the difficulties of its measurement are less owing to the reduction of the disturbing effects due to the surrounding gas.

Prof. Rubens gave an account of his recent work on the optical properties of metals for long waves obtained by his method of "Reststrahlen." The radiation had about 100 times the wave-length of the sodium line, and it was found that in this region the reflecting powers of metals are independent of the wave-length. In these circumstances Maxwell's theory gives for a good conductor $1 - R = 36{\cdot}5/\sqrt{\kappa . \lambda}$, where R is the amount reflected from the surface when unit radiation is incident on it, κ is the conductivity of the metal, and λ is the wave-length. The observations on pure metals and alloys agree with the theory, and show that the electrical conductivity of a metal may now be determined by a measurement of its reflecting power.

Prof. Wien, in discussing the question as to whether the ether moves with the earth or not, pointed out that according to the recent work of Lorentz, in which the electron is assumed to be ellipsoidal in form, attempts to settle the question based on interference or the rotation of the plane of polarisation would be without result. He thought himself the most promising method was a duplication of Foucault's revolving mirror method, the reflection taking place at the two ends from mirrors revolving with the same velocity. If the ether has a component movement along the line joining the mirrors the deflections observed at the two ends should differ.

Prof. Kayser directed attention to the defects of Rowland's scale of wave-lengths in view of the accuracy now attainable by interference methods of measuring wave-lengths. He considered that concave grating spectra were only suitable for interpolation purposes, and that the preparation of a standard scale should be taken in hand at once. Mr. Newall suggested that dark lines were more suitable than bright ones for this purpose.

Dr. Lummer, in describing his parallel plate spectroscope for the resolution of close spectral lines, pointed out the importance of high resolution if the effects of the mode of excitation or of an electrostatic field on the lines of a gas are to be investigated. Dr. Lummer showed his instrument in use in the Cavendish Laboratory, and was able to detect a difference between the lines of mercury, sodium, hydrogen, and helium when produced by Hertzian waves and when produced by the induction coil spark.

In connection with the preparation of the plates of the spectroscope, Lord Rayleigh mentioned that he had found the use of dilute hydrofluoric acid very effective in putting on the finishing touches to glass surfaces.

Prof. Wood described the interference method he had used to determine the dispersion of sodium vapour. The vapour was produced in an exhausted tube with plane ends surrounded by a wire by which the tube was electrically heated. Over a range extending to $\lambda^2/(\lambda^2 - \lambda_m^2) = 3900$ the results agree well with the formula $n^2 = 1 + m\,\lambda^2/(\lambda^2 - \lambda_m^2)$.

The discussion on "n-rays" was very one sided, as no one who spoke had succeeded in convincing himself that any effects he may have observed were not subjective.

Throughout the whole of the meeting communications dealing with radio-activity attracted a large amount of attention. Lord Kelvin described his models of radium atoms to give out α and β rays respectively. The former consisted of an "electrion" e placed at the point of contact of two spheres, through the volumes of which charges $-4e$ are uniformly distributed. When equilibrium is destroyed and the spheres move apart the electrion accompanies one sphere and we have the α particle. In the same way if two electrions e are in equilibrium at opposite extremities of a diameter of a sphere through the volume of which a charge $-\frac{1}{4}e$ is uniformly distributed, and equilibrium is destroyed, one of the electrions moves away from the sphere and gives the β ray.

Prof. Schuster described his apparatus in which radium is utilised in measuring the rate of production of ions in the atmosphere. Changes in the state of the atmosphere are found to take place much more rapidly than was anticipated, so that it is not advisable to use any method of measurement which involves the constancy of the state for more than five minutes.

Prof. Thomson gave an account of the work which has been done recently at the Cavendish Laboratory to determine whether ordinary matter possesses to a small extent the property of radio-activity so strongly shown by radium and polonium. His criterion for the possession of this property is that the substance shall be capable of producing electrical conductivity in the gas in a closed vessel in its neighbourhood. The difficulties of the investigation are due to the wide distribution of radium in soil, water, and air, and to the fact that the emanation from it settles on bodies left exposed to the air. A small quantity of radio-active material present in the body from either of these causes may be sufficient to mask the effect due to the substance itself.

From his observations Prof. Thomson concludes that each metal gives out a specific radiation which differs in its properties from the radiation sent out by other substances, and appears not to be a secondary radiation due to the impact on the substance of some form of penetrating radiation present in the atmosphere. The search for a radio-active gas produced by each metal has so far proved unsuccessful, but Prof. Thomson thinks there is some indirect evidence for the existence of such a gas.

Dr. Elster and Dr. Geitel pointed out that any results obtained by the use of the conducting property of a gas were open to the objection that the effects observed might still be due to traces of radio-active matter left in the apparatus, and not to the metals themselves.

Prof. Thomson's description of his work was necessarily much condensed, and physicists will look forward to the publication of a more complete account which will set aside this objection.

On the last morning of the meeting Prof. Fleming exhibited his apparatus for measuring the lengths of Hertzian waves such as are used in wireless telegraphy. A wire helix has attached to one end a metal plate which, with a similar plate attached to the apparatus in which the electrical oscillations originate, forms a condenser. The effective length of the helix is altered by a sliding conducting saddle, and the positions of the antinodes along the helix are determined by a Neon vacuum tube held perpendicular to the axis of the helix. From the dimensions of the helix the velocity of the waves along it can be calculated, and hence the frequency of the oscillation and its wave-length in air. Prof. Rubens stated that a similar method had been in use in Berlin for some time in connection with a portable apparatus for measuring the lengths of the waves used in the Slaby system of wireless telegraphy.

From the above notes of some of the matters brought forward it will be evident that the Cambridge meeting will hold its own as one of the most interesting of recent years.

C. H. LEES.

CHEMISTRY AT THE BRITISH ASSOCIATION.

THE proceedings of Section B (chemistry) were characterised not only by the general interest attaching to the numerous papers presented, but also by the unusually large attendances at the meetings, and chiefly by the presence of more than twenty distinguished Continental chemists, who made several important contributions to the business of the section.

The foreign visitors included Prof. Aschan (Helsingfors), Prof. Brühl (Heidelberg), Prof. Max Busch (Erlangen), Prof. Dieterici (Hanover), Dr. Etard (Paris), Prof. Franchimont (Leyden), Prof. M. Freund (Frankfurt), Prof. Gabriel (Berlin), M. le Comte de Gramont (Paris), Prof. Groth (Munich), Prof. Guye (Geneva), Prof. Haller (Paris), Prof. Kayser (Bonn), Prof. Knoevenagel (Heidelberg), Prof. Leduc (Paris), Prof. Richard Meyer (Brunswick), Dr. E. Noelting (Mülhausen), Prof. van Romburgh (Utrecht), Dr. Rupe (Bâle), Prof. I. Traube (Berlin), Prof. Walden (Riga), Prof. Wedekind (Tübingen), Prof. Wegscheider (Vienna), Prof. Wien (Würzburg), and Prof. Wolffenstein (Berlin).

The following papers were read:—On the bearing of the colour phenomena presented by radium compounds: W. Ackroyd. On the pentavalent nitrogen atom: Prof. O. Aschan. Saponarin, a glucoside coloured blue by iodine: Dr. G. Barger. The relation between the crystalline and the amorphous states as disclosed by the surface flow of solids: G. T. Beilby. The action of certain gases on glass in the neighbourhood of hot metals: G. T. Beilby. The change of conductivity in solutions during chemical re-

actions: P. V. Bevan. The union of hydrogen and oxygen in contact with a hot surface: Dr. W. A. Bone and R. V. Wheeler. On the formation of salts in solution, especially in tautomeric bodies: Prof. J. W. Brühl. On the active variety of chlorine: D. L. Chapman and C. H. Burgess. Hydroaromatic compounds: Prof. A. W. Crossley. On the energy of water and steam at high temperatures: Prof. C. Dieterici. A suggested explanation of the phenomena of opalescence observed in the neighbourhood of critical states: Prof. F. G. Donnan. On double acetylides: Major A. E. Edwards and Prof. W. R. E. Hodgkinson. Sur les manganates et les permanganates: Dr. A. Etard. Mesoxalic semialdehyde: H. J. H. Fenton. Note on the influence of radium radiations on atmospheric oxidation in presence of iron: H. J. H. Fenton. A reaction for ketoses: H. J. H. Fenton. A colour reaction for methylfurfural and its derivatives: H. J. H. Fenton and J. P. Millington. Ueber Isocystein (Isothioserin): Prof. S. Gabriel. Sur le spectre du souffre dans la photographie de l'étincelle des minéraux: M. le Comte de Gramont. Quelques observations sur le groupement des raies du spectre du silicium d'après l'effet de la self-induction, et sur leur présence dans les spectres stellaires: M. le Comte de Gramont. On crystal structure and its relations to chemical constitution: Prof. P. Groth. Methods of investigating alloys illustrated from the copper-tin series: C. T. Heycock and F. H. Neville. On some reactions between ammonium salts and metals: Prof. W. R. E. Hodgkinson and A. H. Coote. The stereochemistry of nitrogen: Dr. H. O. Jones. The constitution of nickel carbonyl: Dr. H. O. Jones. Exhibition of photographs of sections of an Australian siderite: Prof. A. Liversidge. On dynamic isomerism: Dr. T. M. Lowry. The oxidation of carbohydrates by hydrogen peroxide in presence of ferrous sulphate: R. S. Morrell and A. E. Bellars. Studies in the dynamic isomerism of α- and β-crotonic acids: R. S. Morrell and E. K. Hanson. The constitution of phthalein salts: Prof. Richard Meyer. The decomposition and synthesis of ammonia: Dr. E. P. Perman. Changes produced by the β rays: Sir William Ramsay. The action of organic bases on olefinic ketonic compounds: Dr. S. Ruhemann. (1) The vapour density of hydrazine hydrate; (2) the combining volumes of carbon monoxide and oxygen; (3) the action of heat on oxalates; (4) some alkyl derivatives of sulphur, selenium, and tellurion: Dr. A. Scott. A hexachlor-α-picoline and its derivatives: W. J. Sell. A new theory of the periodic law: G. J. Stokes. On the presence of arsenic in the body and its secretion by the kidneys: W. Thomson. On the velocity of osmosis and on solubility; a contribution to the theory of narcosis: Prof. Isidor Traube. Exhibition of effects produced by precipitating silver chromate in gelatin: Prof. Isidor Traube. The asymmetric nitrogen atom: Prof. E. Wedekind. On the products obtained by the action of tertiary bases on some acid chlorides: Prof. E. Wedekind. Pseudomorphosis in organic persulphates: Prof. R. Wolffenstein.

As in previous years, the practice of inviting two special reports on subjects of current interest and making these the basis of a discussion, met with considerable success, the communications of this order at the Cambridge meeting being made by Dr. H. O. Jones and Dr. T. M. Lowry; forming comprehensive summaries of our knowledge of the subjects discussed, which will be found very valuable by all who are engaged in teaching chemistry. The business of the section was brought to a conclusion on Tuesday afternoon by an address from Sir James Dewar on new low temperature phenomena and their scientific applications; this attracted a very large and appreciative audience, who followed the novel experiments with the greatest interest. The committees of the previous year were re-appointed, and two new committees were formed to deal with the subjects of dynamic isomerism and transformation of diazonium compounds and allied substances.

Although the neighbourhood of Cambridge does not offer many opportunities for studying industries of chemical interest, a very successful visit was made to the woad works near Wisbech, a description of which has appeared already in the columns of NATURE. Visitors were shown the processes of cropping, milling, and balling, and examined the drying racks on which the balls are placed until the second milling process, which takes place in November.

GEOLOGY AT THE BRITISH ASSOCIATION.

FOLLOWING the president's address, which has already appeared in these pages, Dr. Marr gave an address on the geology of Cambridgeshire. He described the main physical features of the county, and showed their relations to geological structure. Opportunities were afforded during the meeting, by afternoon excursions, for visiting most of the typical sections of Jurassic and Cretaceous rocks exposed near Cambridge, including the interesting occurrence of Upper Gault at Barnwell, in which Mr. Fearnsides recently discovered an unsuspected fauna. The Boulder-clays and gravels which cover a large portion of the surface of Cambridgeshire were dealt with by Dr. Marr in his address, and were further described by Messrs. Fearnsides and Rastall, who gave an account of the boulders collected by the members of the Sedgwick Club. Mr. F. W. Harmer, in a comprehensive paper on the Great Eastern Glacier, showed that its product, the Chalky Boulder-clay, extending over a great part of the eastern counties, has a palmate form, its lobes radiating from the great depression of the Lincolnshire and Cambridgeshire fens. The fens were the centre whence the Chalky Boulder-clay was distributed, and formed the quarry out of which was excavated the enormous mass of Jurassic material which forms the matrix of this deposit.

Much of the Boulder-clay about Leicester, in his opinion, was due to the ice stream of the Trent Valley having been piled up, upon the high lands to the east of Leicester, by the pressure of ice descending from the Pennine Chain. He found no evidence to show that any considerable amount of ice entered East Anglia through the Wash gap.

Mr. W. Whitaker showed that in the valley of the Stour deep channels filled with drift have been proved by borings, one of them having a depth of no less than 477 feet. How these channels extending below sea level have been excavated is a moot point, and in this connection Mr. Lamplugh pointed out that Dr. Gilbert has found in Alaska that the excavating power of ice debouching on the sea is carried on below sea level, and until the depth of water is sufficient to float the ice.

In a note on a small anticline in the Great Oolite series at Clapham, north of Bedford, Mr. H. B. Woodward directed attention to a small fold trending N.N.W. to S.S.E. Its direction is contrary to the minor undulations affecting the Oolitic strata of the district, and while there is no evidence to connect the disturbance with glacial action, there is equally no evidence against such a supposition.

Mr. John Spiller gave an account of the recent coast erosion in Suffolk, between Dunwich and Covehithe. At Easton losses of 39 feet and 55 feet have occurred at different points during the past two years.

A report on the fossiliferous drift deposits at Kirmington was read by Mr. J. W. Stather. A boring conducted by a committee appointed by the association proved solid chalk to exist at a depth of 93 feet, and above this were two boulder-clays separated by a bed of shingle and 18½ feet of laminated warp with estuarine shells. Thin peat and sand containing fresh-water shells were found at the base of the warp. The plants in the peat, according to Mr. Clement Reid, indicate estuarine conditions, and suggest a subarctic climate. Another boring at Great Limber showed a similar laminated warp, but without shells, and it does not rest on Glacial clays.

Mr. Edward Greenly, in describing the glaciation of Holyhead Mountain, showed that the northern and eastern slopes are strongly rubbed and rounded in a general N.E. to S.W. direction, and striæ occur on the summit 721 feet above sea level, parallel with the trend of the general glaciation of Anglesey. Mica schists, occurring *in situ* at a level of 200 to 300 feet, have been raised 500 feet above their source. He ascribes the phenomena to the action of land ice, and some ill-defined moraines composed of local débris he thinks may be due to small local glaciers.

Prof. P. F. Kendall presented a report of the committee on erratic blocks, and later exhibited a model of the Cleveland area showing glacier-lakes. He incidentally referred to a boulder of Red Crag of the Waltonian type found near Sherringham on the occasion of the association excursion to Cromer. The Rev. W. L. Carter, in describing the

glaciation of the Don and Dearne Valleys, sought to extend the system of glacier lakes and overflows of the Cleveland area further south, and in another paper dealing with river capture in the Don system he explained the present condition of the Don and its tributaries as resulting from a series of river captures due to the deep cutting of its valley by the Sheaf, and its predominant power in capturing consequent streams north and south.

Other papers dealing with Glacial and post-Glacial geology were read by the Rev. Dr. A. Irving, on stratified high-level gravels and their relation to the Boulder-clay; by Mr. A. W. Gibb, on the occurrence of pebbles of white chalk in Aberdeenshire Clay; the Rev. O. Fisher, on an elephant trench at Dewlish, Dorset; Mr. H. N. Davies, on the discovery of human remains under Stalagmite in Gough's Cave, Cheddar; and reports of committees were read on Irish caves, tidal action in the River Mersey, and underground waters of north-west Yorkshire.

On the day devoted to palæontology, Prof. Sollas gave an account of his new method of examining fossils by means of serial sections and their reconstruction by means of wax models. In this way he contrasted the structure of Ophiurids of recent and fossil types.

The finding of Holoptychius scales in the Cornstones of Salisbury Crag has led Drs. Horne and Peach to regard some of the beds occurring near Edinburgh, and hitherto thought to be of Carboniferous age, as belonging to the Old Red Sandstone period. Dr. Horne described the beds, and exhibited a revised map of the district. Dr. Traquair dealt with the fish remains found in the above deposits, and then read a paper on the fauna of the Upper Old Red Sandstone of the Moray Firth area, in which he summarised the results of many years' work.

Mr. G. W. Lamplugh directed attention to the fact that many of the phosphatic casts of fossils found in the Lower Cretaceous rocks at Upware, Potton, and Brickhill, and usually regarded as derivative, really are indigenous. At Speeton and in Lincolnshire these same fossils are found at their proper horizons, and indicate the life of the period. In another paper Mr. Lamplugh showed, by means of the marine fossils from the Ironstones of Shotover Hill, that the Ironstone originated through the alteration of a band of Portland Limestone.

Mr. E. A. Newell Arber, discussing the fossil plants of the Upper Culm Measures of Devon, concludes that the flora indicates an Upper Carboniferous age, and the coal-bearing beds of the Bideford district are the equivalents of the Middle Coal-measures elsewhere in Britain—a higher horizon than has previously been assigned to these beds.

In the same measures, too, he has found mineralised plant remains in the form of rolled fragments of stems, arranged without order in a fine grained sandstone. These are not contemporaneous with the sandstone.

The committee on the life zones in the British Carboniferous rocks reported investigations made in the Culm Measures of North Devon, the Pendleside series of the Derwent Valley, Derbyshire, the North Staffordshire Coalfield, and in South Wales.

The second report of the committee on the fauna and flora of the Trias included an elaborate description of rhyncosauroid and chelonoid footprints, beautifully illustrated by photographs by Mr. H. C. Beasley, and lists of Triassic fossils in the Jermyn Street and British Museums by Mr. E. T. Newton and Dr. A. Smith Woodward.

Prof. H. G. Seeley exhibited and described fossil footprints of reptiles from the Stormberg beds of the Karroo of Cape Colony.

In petrology and mineralogy eight papers were read. One, by Prof. H. Bäckström, was of great interest as showing that the great iron ore deposits of Lappland have been brought up by volcanic agency from great depths.

Mr. A. Harker exhibited a series of Tertiary Plutonic rocks (including gneisses) from the Isle of Rum. He described the characters and distribution of the earlier ultrabasic group. Into these eucrite has been intruded, and later an acid magma. The complex was then streaked out by movement, and well banded gneisses of the Lewisian type were formed.

Mr. E. Greenly suggested that the recent lava-pyramid formed on Mont Pelée might afford a clue to the origin of the lava domes of the Eifel.

Prof. H. A. Miers, dealing with the occurrence of gold in pyrites crystals, showed that in the Urals fresh crystals contained the gold uniformly disseminated, whereas on weathering into limonite the gold formed a nugget in the middle with crystalline facets. As other examples of concentration due to the attractive forces of crystallisation, he cited gypsum in clay, marcasite, pyrites, barytes, and phosphatic nodules.

Mr. Lamplugh, in the discussion which followed, remarked that the "dead earth is alive all the time," and gave instances where the formation of nodules has crushed the surrounding shales.

The basic patches occurring in the Mount Sorrel Granite, according to Mr. R. H. Rastall, are all inclusions of foreign material, and are not the result of concretionary action.

Papers were also read on the different modifications of zircon by Mr. L. J. Spencer, and on three new minerals and curious crystals of blende from the Binnenthal by Mr. R. H. Solly.

The granite from Gready in Cornwall was described by Prof. K. Busz.

The geology of the Oban Hills, Southern Nigeria, by Mr. J. Parkinson, and the report of the committee on geological photographs, complete the list of papers read in Section C, with the exception of a paper by Prof. Kendall on evidence in the Secondary rocks of persistent movement in the Charnian Range, and the discussion on the nature and origin of earth movements, an account of which is subjoined.

Discussion on the Nature and Origin of Earth Movements.

The president, in introducing the subject, which proved to be one of the most attractive features of the section, observed that movements of the earth's crust manifesting themselves in the fracturing, overthrusting, and folding of strata had been in operation from the earliest to the latest geological periods, and though intermittent so far as any one region was concerned, there was reason to believe that they had been more or less continuously in action throughout the world as a whole. Their operations, in fact, were essential to the existence of land surfaces, for in their absence all rocks projecting above the sea would be worn away, and the globe would be enveloped in one continuous ocean. Notwithstanding these facts, no theory as to the cause of the movements has commanded universal acceptance.

While some hold that the shrinking of the globe by cooling and the efforts of the crust to adapt itself to the shrinking interior are the prime causes, others maintain that the scale on which folding and overthrusting in the crust have taken place is out of all proportion to the shrinking that can be attributed to such a cause.

Earth movements may be divided into two principal classes, namely, movements of expansion, which are evidenced by normal faulting, and movements of compression, such as are indicated by buckling, overthrusting, and shearing of strata, by the superinduced structures of cleavage and schistosity, and by the extrusion of granitic rocks and metamorphism.

Dr. Horne presented the evidence he had accumulated from observations in the north-west Highlands, and traced the types of movement from the unaltered areas to the areas showing the greatest disturbance of all, namely, the Moine schists. In one region the Moine schists have been pushed ten miles to the west, and are seen lying on undisturbed Cambrian Limestone. Some of the movements undoubtedly occurred in pre-Torridonian times, others succeeded almost up to the Devonian period.

The veteran geologist, the Rev. Osmond Fisher, said he used to think that the corrugations of the earth's crust were due to compression through the shrinking of the interior. To judge of the sufficiency of this cause, the first thing to be done was to seek a measure of the compression, and then compare the result of the effects of cooling with the actual amount of compression. The most satisfactory measure appeared to be the thickness of the layer which the corrugations would form if levelled down. In 1863 Lord Kelvin formulated a law of secular cooling upon the hypothesis of a solid interior. Adopting a probable value for the contraction of rocks in cooling, Mr. Fisher calculated

the thickness of the layer which would be produced by the corrugations resulting, and found it far short of that which the existing inequalities would form if levelled down. The discovery of a level of no strain within the crust by Mr. Mellard Reade and Dr. Davison further reduced the possible amount of corrugation. Even a substratum of liquid magma holding water gas in solution would not account for it, and he therefore argued that the substratum was affected by convection currents, which, ascending beneath the oceans, flowed horizontally towards and beneath the continents.

Mr. J. J. H. Teall discussed the petrological aspect of the general question, and divided the effects of movements upon rocks into two classes, easily separable, namely, local and regional. The former were confined to the immediate areas of dislocation, while the latter extended over tens or hundreds of square miles.

Local movements were characterised by fault breccias and mylonites, these being close grained, compact rocks formed by the crushing down of original rocks as in a mill. In some cases there was no crushing, the dykes being converted into foliated schists. In respect of regional effects, we have slaty cleavage due to mechanical deformation of extensive tracts of country. Foliation might be due to the original form of crystallisation or to earth movements after consolidation.

Prof. T. McKenny Hughes thought that lateral pressure, not necessarily horizontal, had produced almost every feature, and that faults were due to compression occasioned by such pressure rather than by extension.

The folding skin of an apple due to shrinkage of the interior was not wholly comparable to earth folding, for, in the case of the earth, many complex circumstances had to be taken into account. Time was one important point, as well as such forces as molecular deformation, temperature changes, volume and force of crystallisation, and transference of material from one region to another.

Prof. W. J. Sollas said that the belts of folding could usually be correlated with the margins of preexisting oceans, and those belts of folding which were comparatively superficial must be accounted for by deep-seated causes. The inequality of the present earth was the best guide to former folding. Inequality at the meeting places of oceans and continents, together with sedimentary deposits on the ocean floor, altered the isothermal lines—flattening them out—and so produced stresses and thrusts, which resulted in pushing part of the material seawards. Thus there was a redistribution of pressure, and this produced fluid magmas, with earthquakes and volcanoes resulting. He thought that all this, however, would hardly suffice for the results produced. There must be another cause. The earth was more pear-shaped in the past than it now is by reason of its relation to the moon. Constant deformation towards its present shape produced contraction of the two hemispheres, and thus the American and Australian beltings or folds were, he thought, accounted for. Deformation of this character produced the same effects as contraction, and the two causes together, he considered, might be enough to account for the existing phenomena produced by earth movements.

Sir John Evans remarked that thirty years ago he had argued that if a globe with a fluid nucleus and a solid crust were postulated, deposition or other causes would result in the solid crust moving over the nucleus, and this disturbance would produce a change in the position of the pole. There was evidence of such a change in the fossil fauna and flora of the Arctic and Antarctic regions. This might be an additional aid beyond those due to cooling.

Prof. Blake thought that, in speaking of thrusts, Dr. Horne had only given the description, and not the cause. In the north of Scotland, where did the force come from? He suggested that if mountains expanded upwards by lateral or upward pressure, a sufficient cause for such thrusts would be found. He had never, he said, seen a true isoclinal fold, and he considered it mathematically impossible for one to exist; the nearest to it in nature was a pleisioclinal fold.

Prof. Rothpletz, of Munich, referred to overthrusts he had observed in Saxony twenty-five years ago. The Scotch overthrusts were older than those of the Alps. In the Alps the plane of the overthrust got steeper and steeper as it approached Vienna. When the folding was a shortening of the earth's crust, the overthrust was a shortening too, in another direction. The matter was more difficult of observation in Scotland, as the overthrusts ended in the sea.

Prof. Boyd Dawkins referred to a case in the Derwent Valley where folding had taken place over level beds, and thought they were not necessarily formed at the root below mountains.

Prof. J. Milne submitted that the seismologist required a world like that of the physicist, one as rigid as cast iron. Earthquake waves traverse chords of the earth at 11 or 12 km. a second, *i.e.* twice as rapid as through steel. This indicates a world very rigid and uniform in the interior. He thought that if it were liquid with convection currents, as urged by Mr. Fisher, the velocity of tremors would not be uniform.

Dr. Knott advised caution in accepting the abrupt change from solid to liquid as supposed by Prof. Sollas. The changes from solid to liquid would probably be through a viscous condition.

Prof. Kendall, in winding up the discussion, pointed out that the special feature of continental margins was deposition. Deposits, acting as imperfectly conducting blankets, would cause the isotherms and the critical zone to rise, and the weakest spot would give way. Given stiff rocks above the critical zone and plastic rocks below, puckering must take place. He considered that in thrust planes the rocks were not forced over horsts, but the horst was wedged underneath them. While areas of sedimentation were weak, other and thinner rocks were stationary under deforming stresses.

Following the discussion, Prof. Kendall read a paper on the evidence in the Secondary rocks of persistent movement in the Charnian Range, in which he gave specific examples of the movements which had been discussed by previous speakers. He referred to the speculations of Godwin Austen, who stated that all recent anticlines are built on older anticlines.

The Charnwood rocks showed evidence of folding in a N.E. to S.W. direction even before Cambrian times. These movements were continued in pre-Carboniferous, Carboniferous, and Permian times, and grounds existed for the belief that they were repeated at intervals during the Jurassic and Cretaceous periods. The Charnian axis, he believes, constitutes the boundary of two important coal fields which extend under the Secondary rocks far to the south.

J. LOMAS.

RECENT STUDIES OF DISEASE ORGANISMS.

AT the recent Cambridge meeting of the British Association, the results of several investigations of organisms associated with various diseases were described before the section of zoology, and are here summarised separately from the general report of the proceedings of the section, which will appear in another issue of NATURE.

Mr. A. E. Shipley, F.R.S., on behalf of Dr. Elliot Smith, gave a brief account of Looss's observations on *Ankylostoma duodenale* (miner's worm), and directed attention to the series of preparations sent by Prof. Looss from Cairo illustrative of his recent work. The male and female of this worm are found hanging in numbers to the intestinal walls of the man affected, and produce enormous numbers of eggs, which are discharged from the body. These give rise to small active worm-like larvæ which live in mud, and enter the body of man either along with food or through the skin, which they can penetrate without causing any visible lesion of the part. They then enter the lymph- and blood-vessels, are swept into the circulation, and eventually reach the lungs, where they pass from the blood-vessels into the air cavities. From the time the larvæ perforate the skin until they reach the lungs they remain the same size, but as soon as they reach the air vesicle they begin to grow rapidly. They pass into the bronchioles, up the bronchi and trachea, and, emerging through the glottis, pass down the œsophagus to the duodenum, where they become sexually mature. The bare-footed races of the tropics and subtropics, both in the Old World and America, are widely and generally infected with this worm, which produces severe anæmia, often ending in the death of the host.

Mr. G. P. Bidder pointed out the great economic importance of Looss's researches. He stated that experts now believed the majority of cases in the Cornish tin mines were due to infection of the bare shoulders, arms and hands, through coming into contact with some polluted surface in the mine. Against such infection, cleanliness in feeding, which has been recommended as the principal precaution, is of no avail. The question is a serious one, as the disease is grave, and there are half a million men working in our coal mines. Though as many as 80 per cent. of the men were affected in some Continental mines, the disease does not at present exist in British collieries; but in many of these there are those conditions of temperature and humidity which would be favourable to its propagation.

Prof. Simmers (Cairo) commented on the paper from an experience of thousands of cases. Nothing resembling the "miners' bunches" which have been described as occurring in Cornwall has been met with in Cairo. Looss's experiments on puppies point to a definite toxic effect on the tissues penetrated by the larvæ. A remarkable feature about the adult parasite is the absence of any wounds or bleeding on the intestinal wall to which it adheres. The muscular mouth of the worm appears to draw up the tissues into a sort of bell, and at the same time to secrete into the blood some substance which has the power of breaking up the constituents of the blood, so causing the peculiar anæmia.

Prof. G. N. Calkins gave to the section an account of his work on *Cytoryctes variolae*, Guarnieri, the organism of small-pox. After the inoculation of a rabbit's cornea with vaccine virus, Guarnieri (1892) found in the cells peculiar homogeneous structures of diverse form and size, and regarded them as Protozoa. Pathologists, however, do not accept this conclusion, as the "Guarnieri bodies" have no apparent structure, and cannot be cultivated on artificial media. Prof. Calkins considered these objections were dispelled by the experiments of Wasielewsky (1901), who vaccinated a rabbit with a small quantity of virus; from this a second rabbit was vaccinated, from the latter a third, and so on until forty-seven had been successfully inoculated. In all the rabbits the "Guarnieri bodies" were found, and Prof. Calkins believes they had undergone growth and multiplication—the attributes of a living organism. In 1902 Councilman discovered, in addition to the usual bodies in the cytoplasm, peculiar and definite bodies in the nuclei of skin-cells infected with small-pox. Prof. Calkins has worked over this material (from fifty-five cases), and has formulated a life-history. The first appearance of the organism in the human skin is a minute homogeneous spherule which enlarges and differentiates into two substances, one destined to give rise to the multiplication elements, the other forming an enveloping matrix. The organism increases in size until it is larger than the cell nucleus. The gemmules repeat the cycle again and again, thus giving rise to auto-infection of the vaccinia type. In later stages the gemmules enter the nucleus, where they develop into two kinds of structures, possibly male and female gametocytes. From the latter a sporoblast stage arises, the sporoblasts increase in size, and ultimately give rise to spores. Meantime, the nuclear membrane has been ruptured and the sporoblasts liberated. The spores are hollow spherules $0{\cdot}5\mu$ in diameter. Spores may be found scattered in the cytoplasm and in the nucleus, but it is only in the latter that they can develop further.

After Mr. J. J. Lister, F.R.S., had commented on the apparent absence of a definite nucleus, Dr. S. Monckton Copeman, F.R.S., mentioned that in a paper by Dr. Gustav Mann and himself (1898–9) practically all the features described by Prof. Calkins are shown, but that their interpretations are entirely different. They regarded the "Guarnieri bodies" as masses of nucleo-proteid material which have been extruded into the perinuclear space as the result of specific irritation, and it is noteworthy that these bodies are all found, in cases of inoculated variola or vaccinia, on the side of the nucleus *remote* from the point of inoculation, whereas the reverse might be expected if they were Protozoa. Similar appearances have been described by Pfeiffer and others in carcinoma, sarcoma, chicken-pox, and various vesicular skin diseases, all of which diseases cannot be due to the same specific agent. The specific zymotic disease which in all respects—period of inoculation, progress, affection of the skin and mucous membranes, production of immunity, &c.—most closely resembles small-pox, viz. enteric or typhoid fever, is now acknowledged to be a bacillary disease, and there would seem to be reason for believing small-pox to be due to an invasion of the system by a similar organism. Dr. Copeman considers that the small bacillus, which he demonstrated at the Liverpool meeting, which stains with great difficulty and cannot be grown on any of the ordinary laboratory media, represents the specific virus of small-pox and vaccinia.

Dr. J. A. Murray, of the Imperial Cancer Research Fund, read to the section a paper on the biological significance of certain aspects of the general pathology of cancer. He stated that both benign and malignant new growths increase their characteristic parenchyma entirely from their own resources, and there is no evidence of the transformation of the original tissue into malignant tissue, although the latter may be indistinguishable histologically from that among which it takes its origin. The cells increase by division; amitosis does occur, but mitotic division is much more common in fully developed tumours. Multipolar mitoses are common. The active growth and extension of the malignant tissue as manifested at the growing surfaces of a malignant new growth, are effected by cell divisions which, so far as they are mitotic, conform to the ordinary type met with in early development. The number of chromosomes entering the equatorial plate is constant in each species, and they undergo the usual longitudinal splitting. Passing from the growing margin towards the older parts of the growth, it is seen that some of the mitoses are characterised by the presence of bivalent chromosomes (heterotype), in number half that found in the younger parts. These heterotypes must be regarded as occurring late in the life-history of the cells in which they are present. The analogy of spermatogenesis suggests that the heterotype initiates a terminal phase in the life-history of the cancer cell as in the spermatocyte. While studying the changes which occur immediately after transplantation in a tumour of the mouse, nuclear changes were observed which presented a close similarity to a conjugation process. Subsequent observations (on more than 1000 tumours of all ages from three different primary sources) have tended to confirm this interpretation. Numerous secondary centres of growth are always found around the periphery of older tumours, and these secondary masses may in time outgrow that which preceded them. It is suggested that the cells which conjugate are those which have passed through a reducing division, but until the complete cycle is elucidated this must remain only a working hypothesis.

THE EVOLUTION OF THE HORSE.[1]

PROF. H. F. OSBORN referred to the three independent lines of research being carried on by Profs. Ewart, Ridgeway, and himself, and hoped that they would be able to bridge the interval which at present existed between the fossil, the historic, and the recent races of horses. He gave an account of the explorations, begun three years ago, of the American Museum, which were rendered possible by a liberal gift from the Hon. W. C. Whitney. The object of this research into the fossil history of the horse was to connect all the links between the Lower Eocene five-toed and the Lower Pleistocene one-toed horses, and to ascertain the relations of the latter to the horses, asses, and zebras of Eurasia and Africa. The first result obtained is the proof of the multiple nature of the evolution of the horse during the American Oligocene and Miocene periods. Instead of a single series, as formerly supposed, there are five—one leading to Neohipparion, the most specialised antelope-like horse which has ever been found; a second, of intermediate form, probably leading through Protohippus to Equus, as Leidy and Marsh supposed; a third leading to the Upper Miocene Hypohippus, a persistently primitive, probably forest- or swamp-living horse, with short-crowned teeth adapted to browsing rather than grazing, and with three spreading toes; this horse has recently also been found in China. A fourth and fifth line of Oligocene-Miocene horses became early extinct. This polyphyletic or multiple law is

[1] Abstracts of three addresses given in Section D of the British Association on August 23.

quite in harmony with the multiple origin of the historic and recent races of horses as recently established by Profs. Ridgeway and Ewart. The Pliocene horse of America still requires further exploration before it can be positively affirmed either that all the links to Equus are complete or that America is indubitably the source of this genus. The Lower Pleistocene of America exhibits a great variety of races, ranging in size from horses far more diminutive than the smallest Shetland to those exceeding the largest modern draught breeds—yet all these races became extinct, and did not survive into the human period as was the case in South America. The relations of these North American races to those of South America and of Asia and Africa is a subject requiring further investigation.

The address was illustrated by photographs of a large series of models, of osteological preparations showing the mechanism and breeds of the horse, and of the mounted fossil specimens recently discovered.

Prof. Ewart referred to the fact that in pre-Glacial times there were several distinct species of Equidæ in the New World, and that one of the objects of present inquiry is to connect the recent Equidæ with these or other extinct forms. Before it is possible to point out the connection between the true horses and the pre-Glacial or Pleistocene horses it is necessary to determine the number of species and varieties of the horse now extant. He described at some length Prjevalsky's horse, the Norse type of horse still found fairly pure in the north-west of Scotland, and the recently discovered Celtic pony. He referred to Prjevalsky's horse as the least specialised of living Equidæ, as evidenced by the character of its mane and tail and the presence of a complete set of callosities, and he discussed the question as to whether it is a mule or simply the offspring of Mongolian ponies run wild. The Norse type of horse differs from Prjevalsky's in its heavy mane and tail, finer head, and smaller ears. The Celtic pony is the most specialised of living Equidæ, as shown by the absence of such vestiges as fetlock-pads and chestnuts from the hind legs, and the presence of a peculiar tail-lock which adapts it for a sub-arctic habitat. Photographs were shown to illustrate these various features.

Prof. Ridgeway then stated some of the evidence which led him to conclude that a distinct species or variety of the horse had been specialised in North Africa. Darwin supposed that not only was the Arab horse the result of artificial breeding by the Arabs, but that the dark colour of the English racehorse was due to the Arab dislike of light coloured horses. History puts it beyond doubt that the Arabs had no horses at the beginning of the Christian era, and that they obtained their famous breed from North Africa, and, so far from their disliking light coloured horses, they have a predilection, on religious grounds, for white or grey horses, as had the Germans, Greeks, and Romans. Bay and other dark coloured horses were well known in northern Africa and western Asia many centuries before the Arabs owned horses. The horse appears for the first time on Egyptian monuments about 1500 B.C., and is almost always painted brown, and those ridden by Libyans and depicted on pottery (at Daphne, B.C. 660–570) are always painted dark. These horses were not imported into northern Africa from Asia; on the contrary, Solomon (tenth century B.C.) and his neighbours imported horses from Egypt which must have been of a superior race. These horses were obtained from the Libyan tribes (as none of the other peoples in that region possessed them), and from them also came those of southern Spain, the ancestors of the Andalusian and Pampas horses. The Libyan horses passed into Sicily and southern Italy, and in the games of Greece and in Roman times they were the fleetest known. The bay horse therefore not only belongs to Africa from the earliest times, but was then, as now, the swiftest. The Libyan horses show a greater tendency to stripes than do Asiatic horses, and the former often lack hock callosities, which are present and of large size in coarse Asiatic horses. The tail of the Libyan horse differs in structure, covering, and carriage from that of Asiatic horses; the hoofs are longer, and the neigh is different. Libyan horses were docile, and could be driven without bit, while the peoples who used Asio-European horses invented the bit. Prof. Ridgeway concludes that *Equus caballus libicus* is to be regarded as a distinct variety.

THE ACTION OF WOOD ON A PHOTOGRAPHIC PLATE IN THE DARK.[1]

IT has been shown in former papers that many substances are capable of acting on a photographic plate in the dark and producing a picture of themselves. Further investigation shows that this property belongs probably to all woods, some, however, being much more active than others.

To obtain a picture the wood has to be in contact or at a little distance above the photographic plate, and has to remain there for times varying from half an hour to eighteen hours, and to be at a temperature not higher than 55° C.

The wood of the conifers is very active, and gives pictures which are very definite. Fig. 1 is a picture of a section of a branch of a Scotch fir, and shows well the rings of spring and autumn growth. It is remarkable that the former are very active, producing in this picture the dark rings, and so with the other pictures, the part which is active in the original is dark in the picture. The rings seen in the wood are very sharp and strongly pronounced in the picture. If the action exerted on the plate be owing to the presence of hydrogen peroxide, as has been previously suggested, no doubt it is produced by the resinous bodies

FIG. 1.

present in the wood, but it is remarkable that there is no action from the dark autumn wood. Experiments described in the full paper show that resin exists in the dark rings, but apparently under such conditions that it cannot escape. Other members of the pine group have been experimented with and have been found to behave in the same way as the Scotch fir.

With the spruces the action on the plate is not so definite and well marked; the white wood is always active, but in some cases the dark rings are also active, and the pictures are not so sharp as with the firs. Larch wood gives a very interesting result, for the picture is the reverse of that of the Scotch fir, that is, the dark rings in the wood are the active rings and the light rings are inactive.

With regard to woods other than conifers, oak and beech are both active and give very good pictures, so also does acacia (Robinia), Spanish chestnut, and sycamore; on the other hand, ash, elm, horse chestnut, plane are comparatively but slightly active. In the full paper lists of woods are arranged according to their activity.

Many foreign woods are very active, but as the annual rings are often not well developed, the pictures they give are of a somewhat different character. The African black wood, rose wood, cocobola, and many others are very active. Several of the foreign woods have a ring of white wood which is quite inactive.

[1] By Dr. William J. Russell, F.R.S. Read before the Royal Society, June 16.

Knots in a wood generally, but not always, give a good picture. Some of the resin in immediate contact with the knot is in some cases but little active. The marked difference in properties of resins from different sources is described, and it is shown how difficult it is to remove it so that the wood shall be no longer active. Boards that have been exposed to the air for a long time, an oak box a hundred or more years old, rotten wood from the stump of a tree, and even bog wood have all been found to be still active.

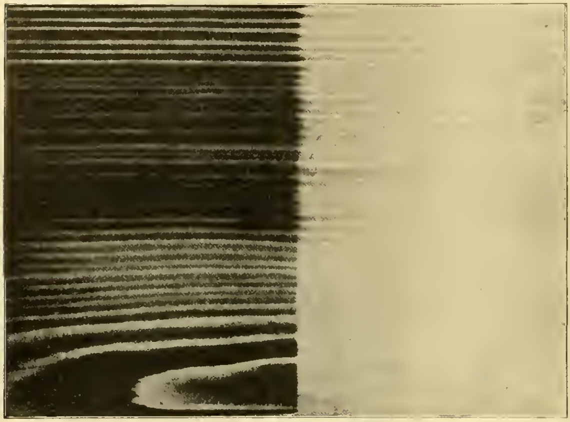

FIG. 2.

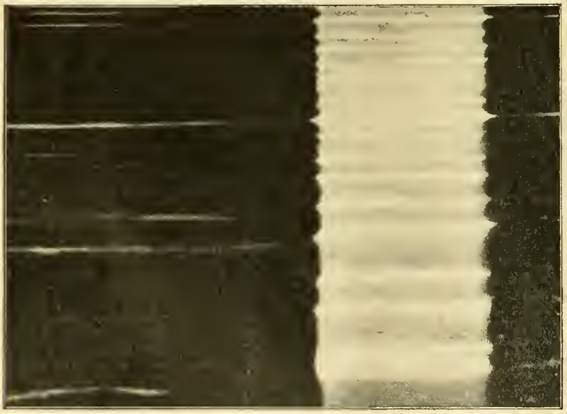

FIG. 3.

In addition to woods many different resins and allied bodies can, when used alone, be proved to be very active, some naturally much more so than others. Ordinary resins, Burgundy pitch, gum mastic, are very active, asphaltum, dragon's blood much less so, but true gums such as gum senegal and gum arabic are entirely without action on a photographic plate.

In certain cases the picture obtained on the plate does not resemble the markings which are visible on the wood. With some woods this more commonly occurs than with others. That this picture is persistent in the wood is shown by fresh sections giving the same result. The true bark of a wood is apparently quite without action on a photographic plate, so is the internal pith of a plant.

There is another and a very interesting action which occurs with wood; it is the great increase of activity which it exerts on a photographic plate after it has been exposed to a strong light. For instance, if a piece of deal be half covered by black paper or tin foil and be exposed for five to ten minutes to bright sunlight, and then put up in the usual way with a photographic plate, it will give a dark picture where the light has fallen on the wood and only a very faint picture of the part which has been covered. This is shown in Fig. 2. Even comparatively inactive woods such as elm and ivy after a short exposure to bright light give good and dark pictures. The action is not an indiscriminate darkening over the whole wood section, but an intensifying of the parts already active. This increase of activity by the action of light appears to occur with all woods. Artificial light, such as that from the electric arc, or from burning magnesium ribbon, act in the same way, so does even a faint light. A piece of wood put at a window for some hours will give a darker picture than a similar piece left in the middle of the room. This increase of power of a wood to produce a picture does not rapidly pass away. After twenty-four hours the action is visibly less, and decreases more rapidly at first than after some days, but it will be a fortnight or may be a month before the wood resumes its former condition. This action, like the former one, is entirely stopped by interposing the thinnest piece of glass or mica between the photographic plate and the active body. An inactive card painted with an alcoholic solution of resin acts in the same way, and turpentine which has been exposed to a bright light acts more strongly on a photographic plate than it does when it has not been so exposed. Again, old printing which is now nearly inactive becomes much more active after exposure to sunlight. Bodies other than those which may contain resin or allied substances are not affected in this way by light, for instance, flour, sugar, porcelain; metals are not rendered active by sunlight.

The next point was to ascertain which of the constituents of light was most active in producing these effects, and the first experiments were made by simply placing strips of different coloured glass on wood sections, exposing them to sunlight and afterwards putting them up with the photographic plate in the usual way. Pictures of the results are given in the paper. Red glass entirely prevented any increase in the activity of the wood, in fact, it acted in the same way as a band of black paper or tin foil would act, and a green glass acted much in the same way, but under a blue glass the activity of the wood was increased to much the same extent as under colourless glass or under no glass. Fig. 3 shows what happens when a red glass and a white glass are placed upon it and is exposed to sunlight. On the right of the figure there was no glass.

Further experiments were made by placing similar pieces of deal in light which had passed through different coloured solutions. Three double-cased bell jars were taken; one

was charged with a solution of potassium bichromate, another with copper ammonium sulphate solution, and the third with pure water, and all were exposed to sunlight for four hours. The deal in the red light gave only a faint picture, that in the blue light a dark picture, and that with the pure water was only a slightly darker picture. Resin, guaiacum, copal varnish, white oil paint and resin sized paper all acted in the same way and gave similar results.

The light from an arc lamp when passed through a red glass and allowed to fall on a wood section for one and a half hours produced no effect, but when the same light was passed through a blue glass and fell on a similar wood section for only one hour it produced a dark picture. With liquids this same increase of activity by the action of blue light is produced. Turpentine, which has been exposed to blue light, is more active than when in its ordinary condition.

THE DENSITY OF NITROUS OXIDE.[1]

IN the *Proceedings*, vol. lxxii. p. 204, 1897,[2] I have given particulars of weighings of nitrous oxide purified by two distinct methods. In the first procedure, solution in water was employed as a means of separating less soluble impurities, and the result was 3·6356 grams. In the second method a process of fractional distillation was employed. Gas drawn from the liquid so prepared gave 3·6362. These numbers may be taken to represent the corrected weight of the gas which fills the globe at 0° C. and at the pressure of the gauge (at 15°), and they correspond to 2·6276 for oxygen.

Inasmuch as nitrous oxide is heavier than the impurities likely to be contained in it, the second number was the more probable. But as I thought that the first method should also have given a good result, I contented myself with the mean of the two methods, viz. 3·6359, from which I calculated that, referred to air (free from H_2O and CO_2) as unity, the density of nitrous oxide was 1·52951.

The corresponding density found by M. Leduc is 1·5301, appreciably higher than mine; and M. Leduc argues that the gas weighed by me must still have contained one or two thousandths of nitrogen.[3] According to him the weight of the gas contained in my globe should be 3·6374, or 1·5 milligrams above the mean of the two methods.

Wishing, if possible, to resolve the question thus raised, I have lately resumed these researches, purifying the nitrous oxide with the aid of liquid air kindly placed at my disposal by Sir J. Dewar, but I have not succeeded in raising the weight of my gas by more than a fraction of the discrepancy (1·5 milligrams). I have experimented with gas carefully prepared in the laboratory from nitrate of ammonia, but as most of the work related to material specially supplied in an iron bottle I will limit myself to it.

There are two ways in which the gas may be drawn from the supply. When the valve is upwards, the supply comes from the vapourous portion within the bottle, but when the valve is downwards, from the liquid portion. The latter is the more free from relatively volatile impurities, and accordingly gives the higher weight, and the difference between the two affords an indication of the amount of impurity present. After treatment with caustic alkali and sulphuric acid, the gas is conducted through a tap, which is closed when it is desired to make a vacuum over the frozen mass, and thence over phosphoric anhydride to the globe. For the details of apparatus, &c., reference must be made to former papers.

The first experiment on July 13 was upon gas from the top of the bottle as supplied, and without treatment by liquid air, with the view of finding out the worst. The weight was 3·6015, about 35 milligrams too light. The stock of material was then purified, much as in 1896. For this purpose the bottle was cooled in ice and salt[4] and allowed during about one hour to blow off half its contents, being subjected to violent shaking at frequent intervals. Subsequently three weighings were carried out with gas drawn from the bottom, but without treatment by liquid air. The results stand:—July 18, 3·6368; July 20, 3·6360; July 25, 3·6362; mean, 3·63633.

Next followed experiments in which gas, still drawn from the bottom of the bottle, was further purified by condensation with liquid air. On one occasion (August 7) the condensed gas was allowed to *liquefy*, for which purpose the pressure must rise to not far short of atmospheric, and to blow off part of its contents:—August 1, 3·6363; August 3, 3·6367; August 7, 3·6366; mean, 3·63653.

The treatment with liquid air raised the weight by only 0·2 milligram, but the improvement is probably real. That the stock in the bottle still contained appreciable impurity is indicated by a weighing on August 13, in which without liquid air the gas was drawn from the *top* of the bottle. There appeared, August 13, 3·6354, about 1 milligram short of the proper weight.

It will be seen that the result without liquid air is almost identical with that found by the same method in 1896, and that the further purification by means of liquid air raises the weight only to 3·6365. I find it difficult to believe that so purified the gas still contains appreciable quantities of nitrogen.

The corresponding weight of air being 2·3772,[1] we find that, referred to air as unity, the density of nitrous oxide is $3·6365/2·3772 = 1·5297$. Again, if oxygen be taken as 16, the density of nitrous oxide will be $3·6365 \times 16/2·6276 = 22·143$.

The excess above 22 is doubtless principally due to the departure of nitrous oxide from Boyle's law between atmospheric pressure and a condition of great rarefaction. I hope shortly to be in a position to apply the connection which will allow us to infer what is the ratio of molecular weights according to Avogadro's rule.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. ERNEST SHEARER, Kirkwall, has been appointed lecturer on agriculture at the Pusa Imperial College, Bengal. This model agricultural college for all India, with a farm of 1300 acres attached, is one of the admirable developments resulting from the appointment two or three years ago of Mr. James Mollison as Inspector-General of Agriculture in India. Mr. Alexander Sangster, Montrose, has been appointed junior assistant with the Aboukir Land Reclamation Co., near Alexandria, Egypt, and Mr. John C. Leslie assistant conservator of forests in southern Nigeria.

THE approach of the new sessions at polytechnics and similar institutes is heralded by the appearance of calendars and prospectuses, several of which have been received within the past few days. At the Birkbeck College, Chancery Lane, the session will commence on Monday, October 3, when an inaugural address will be delivered by Dr. J. E. Mackenzie on "The Influence of Pure Science on Progress." The class-rooms and laboratories of the college will afterwards be open to inspection, and demonstrations will be given. A course in science with practical work has been organised to give complete preparation in metallurgy and mining for those qualifying for the mining profession. It is satisfactory to know that within the last few years valuable reference libraries have been provided for the separate departments of science; these have been aided by grants from the County Council. His Majesty's Treasury recently presented to the college forty-nine volumes of the scientific results of the *Challenger* Expedition.

THREE prospectuses have been received from the South-western Polytechnic, referring respectively to the day college for men and women, day school for boys and girls, and evening classes. The principal of the polytechnic is Mr. S. Skinner. The courses at the day college are arranged to occupy three years. On entering the student has to state whether he wishes to be trained as a mechanical, civil, or electrical engineer, or as a consulting or industrial chemist. In any of these cases he will find mapped out for him a complete course of study, involving laboratory instruction, tutorial work, attendance at lectures, exercises in mathematics, geometrical, mechanical and architectural drawing, and instruction in the workshops.

In the "Announcements" of the Northampton Institute, London, E.C., a table is given showing the courses which should be taken by various classes of technical students. This, as well as the sound advice given in many parts of the prospectus as to aims and methods of study, should be of great assistance in guiding the energies of students in right directions. Among the new developments of the institute are day courses in technical optics. These are believed to be the first complete day courses in technical optics attempted in this or any other country. In mechanical and electrical engineering complete day courses extending over four years are arranged. In mechanical engineering full evening courses for automobiles, their design, construction, and working, are offered. The courses in structural engineering have been re-modelled. The evening courses in electrical engineering have also been re-modelled, the complete course now covering five years.

The Board of Education has issued the following list of candidates successful in this year's competition for the Whitworth scholarships and exhibitions:—Scholarships, 125*l*. a year each (tenable for three years): Walter A. Scoble, London; Herbert G. Tisdall, Bedford; James Cunningham, Glasgow; Archibald D. Alexander, Portsmouth. Exhibitions, 50*l*. (tenable for one year): Sidney R. Dight, Plymouth; Edwin S. Crump, Wolverhampton; Harold H. Perring, Devonport; Sidney H. E. May, Portsmouth; William B. Wood, Sheerness; Alexander R. Horne, Edinburgh; Leslie G. Milner, London; John Wharton, Leeds; Thomas A. At the annual meeting of the Institution of Mining Engineers, held at Birmingham on September 14, Prof. R. A. S. Redmayne described the courses of instruction and study of the mining department of the University of Birmingham. The full three years' curriculum has been constructed on the principle of giving a thorough grounding in pure science during the first two years (with instruction in the theory and practice of mining), and devoting the third and last year entirely to the application of the scientific knowledge so acquired to engineering—mining, mechanical, civil, electrical, and metallurgical—all specialising and research work being relegated to a post-graduate or fourth year. The first year's work is devoted to such subjects as prospecting and boring, sinking, underground development and systems of working, surface and underground transport of minerals, winding, drainage, ventilation, sorting and screening of minerals, and surveying and planning. During the second year the details of colliery and mine management and mining jurisprudence are considered, in addition to which there is an advanced course in surveying and planning. To the third year is consigned the study of the foreign coal and metal mining conditions, and the dressing and preparation of fuels and ores for the market. There is a summer school of practical mining in every long vacation, the object being to devote several weeks in each year entirely to the detailed study of the plant and methods of working of a particular class of important mines, so that students may see for themselves in actual practice much that they have had described to them in the lecture theatre and class-rooms. An experimental coal-mine has been constructed a few feet below the surface, with which it is connected by a downcast and upcast shaft. The workings, the area of which somewhat exceeds three-quarters of an acre, will be ventilated by a single-inlet Capell fan, driven at 500 revolutions per minute by an electric motor of 20 horse-power, coupled direct; and they will be drained by a small electric pump placed at the bottom of the downcast shaft. The chief use to which this piece of apparatus will be put will be to enable practical instruction to be given in underground surveying and levelling, and connecting surface and underground surveys; and for demonstrating and investigating the peculiarities of mine-ventilation, such as the splitting of air currents and directing their course, the resistance to air currents, the loss of pressure due to friction, and the characteristics of mechanically produced ventilation.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 12.—M. Mascart in the chair.—On the comparative morphography of the cartilaginous cell: Joannes **Chatin**. The author disputes the generally accepted view that the normal shape of the cartilage cell is ovoid or spheroidal in the higher vertebrates, and shows that in cartilage from the badger there are undoubted examples of the stelliform type of cell.—The influence of grafting on the composition of the grape: G. **Curtel**. Clear evidence of differences in physical and chemical composition between grafted and non-grafted grapes has been obtained, and the facts observed explain the more rapid ageing of wines from grafted vines, and also their greater sensitiveness to pathogenic ferments.—Simple traumatic dislocation of the atlas on the axis on a skeleton found in a megalith of Vendée: Marcel **Baudouin**.—Observations on the preceding note: M. **Lannelongue**. The author regards the effects noted as probably due to *post mortem* changes.

PETROLEUM.

The Oil Fields of Russia, and the Russian Petroleum Industry. By A. Beeby Thompson, A.M.I.M.E. Pp. xviii + 504; plates and maps. (London: Crosby Lockwood and Son, 1904.) Price 3*l.* 3*s.* net.

THE aspect of this large and attractive, well printed, and freely illustrated addition to the enormous literature of the Russian oil fields (which extends to many hundreds of books and articles) excites hopes of a comprehensive summary of the principal facts dispersed through the unwieldy mass of record, and of a formulation of the laws of which those facts are the tangible expression. Such a summary is a great desideratum, for, apart from the polyglot condition of the recorded information, and the difficulty of access to the original sources in the files of Caucasian journals and unpublished records, the subject is one demanding the conjoint forces of the geologist, the chemist, and the physicist, whilst the past has shown that conclusions reached by the study of any of these branches separately may directly traverse those based on other categories of data.

The title-page sets forth the aim of the work as a practical handbook on the exploration, exploitation, and management of Russian oil properties, with collateral considerations on the origin of the petroleum and the modes of its utilisation as fuel. The statistics of production constitute Appendix A (pp. 399–432), and forty-five pages of official regulations form Appendix B, which is followed by some useful tables of physical and other data, and a few pages treating of the latest developments in exploration and utilisation.

The value of the work lies principally in its technical element, based on several years' practical experience in the region, whilst it merits attention, with or without acceptance, on the scientific side, which is dealt with somewhat too theoretically. In regard to geological matter the treatise is disappointing, as we have an excess of general lithological detail, but the scantiest stratigraphical information. Fuller indications in this respect, with less and better founded speculation as to primæval conditions of deposition, would have made the book of higher utility in regard to its first stated aim, that of assistance in exploration for oil. For this accurate details of composition and structure (including correlation from point to point) are essential, and such are regrettably absent from the work under consideration.

We must demur, at the outset, to the alleged conformability of the Aralo-Caspian surface-beds to the oil-bearing Oligocene and Lower Miocene strata, a view which is probably the cause of the author's rejection of the anticlinal structure as the predominant factor in concentrating the petroleum along the axes of flexure. The assumption (p. 60) of the existence of synclines equally rich with the anticlines is one not warranted by the results of operations in any oil field of known structure, and therefore where, as in the Baku fields, the structure of the petroliferous series is masked by an unconformable superincumbent mass, the flexures in which are discordant in strike with those of the subjacent rocks, positive evidence of productive synclinals may legitimately be demanded in place of mere hypothetical surmise of the existence of such beyond the depth accessible by the drill. The natural exudations, mud volcanoes, and gas discharges are all situated on anticlinal axes, exposed by denudation of the Quaternary cover.

We cannot, for the simplest of chronological reasons, accept the suggestion of the oleaginous quality of the sturgeon and other Caspian fish as having any bearing whatever on the origin of the Caucasian petroleum (p. 64), and no evidence is advanced of kinship of the Oligocene with the existing ichthyofauna. (It is not imagined, *per contra*, that caviare is a modified bitumen.)

Briefly reviewing various theories as to the origin of petroleum, and noting the possibility of its being of different source in separate areas, the author wholly rejects, on adequate geological grounds, the hypothesis of inorganic origin; whilst from the scarcity in the series of the remains either of fibrous vegetation or of diatoms, he doubts the contribution, from the vegetable kingdom, of much, if any, of the enormous bulk of Caucasian petroleum. The large percentage of carbonate and phosphate of lime in the rocks points, on the other hand, to abundant animal life, but the author, gratuitously assuming the æolian character of the oil sands, gives, we think, too much rein to imagination in invoking periodical sandstorms from hypothetical deserts to effect sudden extinction of these deep-sea organisms over limited areas, and their entombment in similarly limited patches of the deposited sand, now converted into "pockets" charged with the resulting petroleum. The belief in catastrophic hecatombs of this nature is some three generations out of date, and can only be regarded as a superstition. Not only is the abnormally lenticular structure of the oil sands hypothetical, the data obtained by boring being equally explicable by reference to faulting, but sandstorms that should, for a few score yards only, saturate a deep sea to the degree of suffocation of its denizens, must have been evoked by the Genius of Destruction from Arabian or other Oriental deserts, and the existence of such deserts in Oligocene times, when continuous sea united the Atlantic and Pacific Oceans in these latitudes, is more than doubtful.

In dealing with the Grosny field, and the isolated spots in Daghestan that have yielded evidence of oil, the author mentions the difference in lithological character between these and the Baku fields, but without the explanatory information that these northern fields are of a different geological series, the Lower Miocene, whereas most, if not all, the Baku oil comes from Oligocene beds, though traces of Miocene occur in the southern part of the province.

The term "excitement" is applied by the author in a new technical sense to designate the disturbance of the equilibrium of a region by the rapid discharge, through borings, of fluids and discrete solids previously under great pressure, and the effect of the sudden arrests and renewals of the flow owing to temporary chokings of the exit. The widespread vibrations pro-

duced necessarily afford partial relief or re-adjustment to somewhat remote and disconnected seats of pressure during the moments of oscillation. Similar causes in the American fields have led to the appearance of gas in wells that at first produced only oil or water, and *vice versâ*, and in some cases a renewal of commercial activity in an abandoned field has been the result of operations at some distance away.

Apart from the defects referred to, the work is worthy of praise, for the engineering details, which constitute the bulk, are given in a form convenient for reference, and it is only needful to warn technical readers against too implicit acceptance of the author's views on some still unsettled scientific problems.

CHEMISTRY OF ALKALOIDS.

The Vegetable Alkaloids, with Particular Reference to their Chemical Constitution. By Dr. Amé Pictet. From the second French edition. Rendered into English, revised and enlarged, with the author's sanction, by H. C. Biddle, Ph.D. Pp. i.–vii. and 1–505. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1904.)

THIS translation of the second edition of Pictet's "La Constitution chimique des Alcaloïdes végétaux," with the numerous additions made by the translator, will be welcomed by many readers, for nearly seven years have elapsed since the appearance of the original, and in the interval great advances have been made in our knowledge of the alkaloids. The book is in no sense a monograph, as references to the sources, modes of extraction and detection, and physiological properties of the alkaloids are of the briefest, attention being concentrated on their purely chemical behaviour, and the clues thus given to their constitution and synthesis. A brief survey of the history of this important group of compounds is followed by a section dealing with pyridine, quinoline, and their derivatives, including the carboxylic acids which have played so important a part in the elucidation of the molecular structure of the plant bases. The remainder of the book summarises what is known of the chemical behaviour of twenty-eight groups of alkaloids, and in a final chapter a list is given of forty-two alkaloids of unknown constitution. It should be added that numerous references to original papers are supplied in footnotes.

All attempts to define an alkaloid by reference to chemical constitution have proved to be unsatisfactory. Restriction of the term to derivatives of pyridine, as was proposed by Koenigs, would exclude morphine and the xanthine bases, such as caffeine, and its extension to cyclic bases found in plants, whilst including these alkaloids, would not embrace such substances as asparagine, choline, and trimethylamine. The author employs the term in its widest sense, and groups together as alkaloids all those substances which are directly obtained from plants and able to unite with acids to form salts.

The systematic chemical investigation of the alkaloids, dating from 1869, when the constitution of pyridine was made clear, has been pursued with a remarkable degree of success. Putting aside acyclic compounds, constitutional formulæ have been assigned to some twenty-five bases, including such well known substances as morphine, quinine, atropine, cocaine, nicotine, and caffeine; and although less is known of the molecular structure of the others, it is significant of the energy with which inquiry has been pressed in this direction, that more than one hundred alkaloids—about one-half of the number recognised as definite chemical substances—have been examined with at least some measure of success. Whether the formulæ now regarded as probable will survive in every case may be open to doubt; it is, however, a striking testimony to the success attending modern methods of unravelling molecular structure, that in the case of no fewer than twelve of the twenty-five formulæ just mentioned the constitution assigned on the basis of analytical evidence has been confirmed by the synthetical preparation of the alkaloid. Much of this work has been done since the appearance of the French edition, and reference in particular may be made to the syntheses of the belladonna and coca alkaloids, and of the xanthine bases, accounts of which have been supplied by the translator, and form, perhaps, the most interesting chapters in the book.

The translator has done his work successfully on the whole, but it is to be regretted that more attention has not been paid to the nomenclature of carbon compounds. The Chemical Society in this country—in the annual reprint of instructions to its staff of abstractors—and the Geneva Congress, have done much to associate definite suffixes with particular groups of compounds, and it may be hoped that, nowadays, no author of a chemical text-book in English on this side of the Atlantic would, for example, write "benzol" and "pyrrol" for benzene and pyrrole respectively. In a new edition the use of laboratory slang should be avoided. Expressions such as "nitrogen-methylated" (p. 135), "it does not react alkaline" (p. 143), "dimethylcytisine will add methyl iodide" (p. 180), and "as a starting substance" (p. 228) are not happily chosen; whilst curiosity is stimulated by the statement that "a decomposition similar to this [the elimination of methylamine from tropine] is effected by the destructive distillation of Hofmann" (p. 204), since details of the latter process have so far been withheld from publication.

W. P. W.

NICKEL STEELS.

Les Applications des Aciers au Nickel, avec un Appendice sur la Théorie des Aciers au Nickel. By Ch. Ed. Guillaume. Pp. vii + 215. (Paris: Gauthier-Villars, 1904.) Price 3.50 francs.

A PROMINENT feature of the progress of steel during the last quarter of a century or so is the continued advance in the discovery and ever-widening practical application of what are known to the maker as "special" steels. "Ordinary" steels contain essentially certain well defined and usually small proportions of carbon, silicon, and manganese, varied to suit specific purposes, while sulphur, phosphorus, and even arsenic, though not desired, are seldom entirely

eliminated. "Special" steels contain other elements, or contain the ordinary elements in unusual proportions, as in the well known examples of Mushet's air-hardening tungsten steel, Hadfield's manganese steel, railway tyre chrome steels, nickel chrome armour plate steels, and so on, until at the present day, besides the elements just indicated, aluminium, copper, molybdenum, and even vanadium, which last is dearer than silver, are added to steels for commercial purposes, while other alloys are under experiment. It may well be imagined, then, with what eagerness the metallurgist turns to a monograph on any series of special steels, and particularly if it happens, as in the present case, to be written by a well known worker on the subject. Perhaps the title may mislead some general inquirers, for no doubt we are all looking for accounts of the experience of others in the innumerable applications, some experimental, some well established, of the steels of lower nickel content; but unless they were looking merely for guidance in the immediate work of manufacturing or using those steels, the feeling of disappointment would give way to one of great interest at the thorough manner in which certain properties of the steels of higher nickel content are discussed.

Practically the only steels seriously considered are those containing more than 26 per cent. of nickel. Within limits these are "reversible alloys," that is, "when they are brought to a determined temperature after having been run through any cycle of temperatures they retake sensibly the same properties." It is interesting to note that these alloys

"take a beautiful polish, lend themselves admirably to engraving, are sufficiently elastic when cold rolled to make passable springs though sensibly inferior to those of steel hardened and tempered. Resistance to oxidation varies with the nickel content and for well polished bars it is sufficient to go up to 36 per cent. nickel in order to be able without fear to leave them lying some hours or even days in water at ordinary temperatures. The reversible alloys work well in the lathe, in the planing machine, with the file or the drill on condition that the tool be strong and the attack slow. In general, working at too great a speed makes the alloys act in the same fashion as a grindstone and produces an extremely rapid wearing of the steel tool."

The work consists of four parts and an appendix. Part i. gives the dilatation and modulus of elasticity of the reversible alloys, and goes into great detail as to the amounts and variations of these under special conditions. These properties of the alloy of least dilatation containing about 36 per cent. of nickel, and the special annealing at temperatures less than 100° C. required to bring its wonderfully low dilatation practically to zero, and to bring almost to perfection its *invariability* under the greatest extremes of atmospheric temperature known, are most carefully described. Two new terms, widely accepted, should be noted here, *étuvage* for the low temperature annealing as distinct from *recuit*, high temperature annealing, and *invar*, an appropriate name for the alloy.

Part ii. is devoted to the application of these alloys, and particularly of invar, to the making of standards of length, and more especially for the measurement of bases in survey work (see NATURE, June 2, p. 104), with full details of the special wire standard. Part iii. treats of the uses and the limitations of the alloys in connection with chronometer pendulums, balances, and even springs. Part iv. takes sundry applications, some tried, some suggested, such as parts of levelling instruments, cathetometer and similar supports, bodies of astronomical telescopes, gravitation pendulums, balances, wires for operating signals, &c. Finally, the existence of invar, an alloy with a dilatation practically nil, suggests alloys of varying dilatations, hence special alloys (42 per cent. to 48 per cent.), with an expansion about equal to that of glass, for mounts of object glasses, incandescent lamps, Crookes's tubes, &c. In an appendix of twenty-seven pages the author gives his theory of the nickel steels. He abandons his former theory of compounds of iron and nickel, and, under the influence of MM. Osmond and Le Chatelier, works out an allotropic theory, of which space will not permit even a *résumé*.

This work is one that should be read not only by those particularly interested in the special matters with which it deals, but by all students of metals, as it forcibly drives home to the mind some of the characteristic properties of a remarkable series of alloys.

A. McW.

OUR BOOK SHELF.

Le Radium et la Radioactivité. By Paul Besson. With a preface by Dr. A. d'Arsonval. Pp. viii + 170. (Paris: Gauthier-Villars, 1904.) Price 3.75 francs.

THIS little volume is undoubtedly one of the best summaries that has yet appeared of the investigations that have followed from Becquerel's discovery, in 1896, of the radio-activity of the salts of uranium. The author has been associated with Prof. and Madame Curie in working up on a large scale the uranium residues from Joachimsthal, from which the salts of radium were commercially prepared. His account of the discovery of the radio-active elements, of their separation from the inactive elements in the ores, and of the methods employed in detecting and estimating their radio-activity, is exceedingly lucid and simple, and will appeal strongly to those who wish for a simple account of the phenomena as they presented themselves to the pioneer workers in this field of investigation. In view of the large amount of speculation that these investigations have aroused, it is one of the merits of the book that, whilst seven chapters are devoted to the description of the preparation and properties of the radio-active salts, the theoretical considerations are brought forward only in the last chapter. The disintegration theory, which at the present time dominates almost all that is written on this subject, occupies only a secondary place in the author's discussion of the source of the energy of radio-active bodies. He appears to lean rather to the view advocated by Filippo Ré in a short paper published in the *Comptes rendus* in June of last year, to the effect that the radio-active elements act as sources of energy not because they are in an unstable or explosive condition, but rather because they are still in process of formation. This view, which is derived from analogy with the liberation of energy in the solar system, has much to recommend it, as it eliminates the difficulty of accounting for the relatively slow rate at which the elements in question release the vast stores of energy which they are supposed, by the advocates of the disintegration theory, to contain.

The physiological effects produced by the radium salts are described in considerable detail, and the author looks for important applications in this direction. Thus, whilst the book is addressed to all those who are likely to be interested in the subject, especial care has been taken to state in detail those observations that are of importance to students of medicine and surgery. The developments that have taken place in recent years in the application of physical methods to the cure of disease justify the argument, which forms the main part of Prof. d'Arsonval's preface, that the study of physics should occupy an important place in a medical curriculum.

Chemical Laboratories for Schools. By D. S. Macnair, Ph.D., B.Sc. Pp. 24. (London: George Bell and Sons, 1904.) Price 6*d*.

ON the title-page of this little pamphlet are the words: "Hints to teachers as to the method of planning and fitting-up a school laboratory and of conducting a school course in chemistry." As the term "school laboratory" is extremely vague, each school or group of schools nowadays having a definite place in an organised system of education, some indication of the class of teacher to which the author wishes to appeal would have been advisable. Apparently the instruction is to be essentially of an elementary nature, and judging by the numerous suggestions regarding balances, weights, &c., weighing operations occupy an important place in the work.

The chief features and fittings of the laboratory are briefly dealt with in a simple manner. One notices that several dimensions, such as width of benches, height of bench-shelves, &c., are somewhat less than those usually adopted. More information might have been given regarding inexpensive materials suitable for pipes and other surfaces exposed to chemicals and fumes. For drain-pipes, fireclay or glass-lined iron is suggested; the former is seldom employed, as stoneware is found to be less porous, and on iron a coating of Dr. Angus Smith's mixture is generally preferred to a hard, brittle lining of glass.

A plan is given of a laboratory for twenty pupils: it is probably from an existing building, but to place 17-foot benches with one end against the wall is not an ideal arrangement, and another side-window appears desirable; continuous desks would be cheaper and more convenient than dual desks arranged *en bloc*.

Much admirable advice is given regarding the management of practical classes. Finally, considerable space is devoted to a carefully compiled list of the apparatus and chemicals required for a class of twenty pupils; each piece of apparatus is approximately priced, but the allowance for some items is liberal.

After all, the contents of this pamphlet seem more suitable to be included in the author's "Introduction to Chemistry" than for separate publication, even at the low price of sixpence.

Photo Printing. By Hector Maclean, F.R.P.S. Pp. 100. (London: L. Upcott Gill, 1904.) Price 1*s*. net.

THIS is a second and revised edition of the author's "Popular Photographic Printing Processes," and forms a practical guide to the use of the leading kinds of the so-called printing-out papers, as well as bromide papers, platinum papers, and carbon tissues. We notice that no reference is made to "ozotype," though this is a carbon process that has been growing in favour for some years, and the materials for its practice are supplied commercially. The volume is what it claims to be, namely, a practical guide to the use of commercial papers, and a condensed price-list of the goods of the principal makers is added to each chapter. It may be safely recommended to those who wish to print by the processes described, for the author is himself a practical worker, and has evidently bestowed considerable care on the collection of the information that he gives. Deviations from strictly practical directions are rare and generally unfortunate, if not unintelligible. These are a few details to which we would take exception. The expression "half the foregoing temperature" may convey the meaning intended, but it is incorrect. The use of "photo" in the title as a separate word instead of as a prefix is unnecessary and objectionable. The statement that "gelatino-chloride prints may be completely washed in ten minutes, provided" . . ., &c., is set down as a fact, though we think the evidence is rather against it so far as practical work is concerned. Much less are we prepared to accept the statement that three changes of water, allowing one ounce in each bath for each quarter-plate print, will serve to free the prints "as completely as possible from 'hypo.'" The classification of platinum printing as a "partly print out" process is an illustration of the purely "practical" character of the work.

Œuvres scientifiques de L. Lorenz. Edited and annotated by H. Valentiner. Vol. ii. Second Fascicule. Pp. xxii + 319–583; with portrait. (Copenhagen: Lehmann and Stage, 1904.)

THIS concluding fraction of the papers of Lorenz is prefaced with an interesting critical account of his life and works. We see the young Lorenz largely self-taught, preferring to work out problems independently, although the result was usually to find out that they had been solved long before. It was in this laborious way that his mathematical gifts were developed. Owing to indifference to the usual courses of instruction, there was little sympathy between him and his teachers, and he left the Copenhagen Polytechnic without distinction. Be that as it may, by the year 1887 he had become a Councillor of State, and had received the honorary degree of Doctor of Philosophy of the University of Upsala.

Lorenz's scientific works are, in the main, on mathematical physics—sometimes leaning to the mathematical side, sometimes to the physical side. The editor of the present collection is alive to the lack of lucidity which characterises many of these. This is especially so when no experiments are forthcoming by which the results obtained can be tested.

The best known of his papers have appeared in preceding fascicules. The present one contains those of more mathematical interest. Of these the most important is probably one on the development of arbitrary functions by means of given functions, these being the functions of Bessel. Other memoirs are on the compensation of errors of observation, and analytical researches on the number of prime numbers. Lorenz's genius was, however, essentially physical; and although many of his mathematical conclusions are valid, they have been reached by insight more than by the application of logic such as a mathematician demands.

A portrait is presented with this instalment of the collection.

Botany Rambles. Part iii. In the Autumn. By Ella Thomson. Pp. 253—377. (London: Horace Marshall and Son, 1904.) Price 1*s*.

THIS is the third of a series of simple books in which the parts and functions of common wild plants are described for young readers. The present book is concerned chiefly with seeds and the means by which they are dispersed. Children who read the pages will have their attention directed to many points commonly overlooked, and if they test the statements by personal observation and practical study—as they are advised to do—they will be given both knowledge and pleasure.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Average Number of Kinsfolk in each Degree.

WHAT is the average number of brothers, sisters, uncles, nephews, nieces, first cousins, &c., that each person possesses? I had occasion to compute this for a particular collection of persons; the results were so far unexpected as to show that the question deserved a consideration which it has not yet received, so far as I am aware. The problem proved easy enough in the end, but not at first, for there are other ways of attacking it, in which I blundered and lost time.

The simplest conditions that will serve for a general theory are those of a supposed population (1) the numbers of which are statistically constant in successive generations; (2) the generations of which do not overlap; and (3) which are "completed" by having wholly passed into history; and again (4) where every person is taken into account, at whatever age he or she may have died. It will be a further great simplification if it be allowed (5) to suppose the males and females to be equal in number, and in all respects to admit of similar statistical treatment. This need be only a provisional way of looking at the problem, for it will be seen that corrections can easily be introduced if desired.

It will much facilitate matters to begin by dealing exclusively with either the male or the female half of the population, leaving the other half to follow suit. We will begin with the females.

Let d be the average number of female children born of each woman who is a mother, so if there be n mothers in the population the total number of females in the next generation will be nd. How many of these latter will prove fertile of female children? On the supposition of statistical constancy, the number of mothers in the two generations will be the same, therefore d out of the nd will be fertile of female children; conversely, the probability that any one of these female children will herself bear one or more female children $=1/d$. As a test of this, the average number of fertile daughters to each mother will be $d \times 1 \; d=1$, as it should be.

Next, as regards sisterhoods. Each mother bears on the average d female and d male children, or $2d$ individuals in all. Each of these will have $2d-1$ brothers and sisters, and half that number of sisters, namely, $d-\frac{1}{2}$.

The syllable *si* will be used to express "sisters" without regard to age or fertility, and *si'* to express "sisters who are fertile of female children"; similarly *da* and *da'* for daughters.

The number therefore of *si* is $d-\frac{1}{2}$, of *si'* it is $(d-\frac{1}{2})/d$, of *da* it is d, of *da'* it is 1. The number of *me'*, or of mothers to a child, is, of course, 1, and there is no occasion for using *me*, as a mother must be fertile.

A few examples of results are given in the following table; it could have been extended indefinitely, but these are quite sufficient for drawing conclusions:—

Specific kinships.		Average number in each	
ANCESTRY—			
me'	(mother)	1	1
me' me'	(mother's mother)	1×1	1
me' me' me'		$1 \times 1 \times 1$	1
COLLATERALS—			
si	(sisters)	$(d-\frac{1}{2})$	$d-\frac{1}{2}$
me' si	(mother's sisters)	$1 \times (d-\frac{1}{2})$	$d-\frac{1}{2}$
me' me' si		$1 \times 1 \times (d-\frac{1}{2})$	$d-\frac{1}{2}$
si' da	(sister's daughters)	$(d-\frac{1}{2})/d \times d$	$d-\frac{1}{2}$
me' si' da		$1 \times (d-\frac{1}{2})/d \times d$	$d-\frac{1}{2}$
si' da' da		$(d-\frac{1}{2})/d \times 1 \times 1/d$	$d-\frac{1}{2}$
DESCENDANTS—			
da	(daughters)	d	d
da' da	(daughter's daughters)	$1 \times d$	d
da' da' da		$1 \times 1 \times d$	d

The foregoing remarks and table are equally applicable to males if *bro* (brother) is substituted for *si*, *son* for *da*, *fa* (father) for *me*.

It will, then, be understood that each mother, father, or fertile couple has, on the average, d sons and d daughters, or $2d$ children altogether, of whom 1 is a fertile son, 1 a fertile daughter, and that the others die without issue. In the collection mentioned above, the value of d was about $2\frac{1}{2}$, that is to say, an average family consisted of about 5 children, which is a usual estimate.

It is unnecessary to prolong these remarks by considering the minor corrections to be supplied on account of the hypotheses not being strictly accordant with observation. The two most important of these relate to populations that are not stationary, and to the allowance to be made for inequality in number of the sexes. There are others hardly worth even the trouble of describing, being utterly insensible in rough work.

The general results are that kinships fall into three distinct groups:—(1) direct ancestry, (2) collaterals of all kinds, (3) direct descendants, and that the number of individuals in each *specific* kinship in these classes is respectively 1, $d-\frac{1}{2}$, and d. Also that $d=2\frac{1}{2}$ may be accepted as a reasonable and not infrequent value. To determine the number of individuals in each *general* kinship, the appropriate tabular number must be multiplied by the number of *species* that the *genus* contains; thus there are two species of aunts, *me si* and *fa si* (mother's sisters and father's sisters), each of which has the tabular number of $d-\frac{1}{2}$; therefore the average number of aunts is twice that amount, or $2d-1$, which, in the above case of $d=5$, is equal to 4.

FRANCIS GALTON.

The Mendelian Quarter.

A FEW weeks ago we heard in Section D at the Cambridge meeting of the British Association a paper by Mr. A. D. Darbishire on the bearing of his experiments in crossing Japanese waltzing and albino mice on Mendelian theory. He told us that on that theory we should expect a quarter of the offspring of the hybrids to be albinos—and we found them albinos—and a quarter of the offspring of the hybrids to waltz—and they did waltz. Somebody protested *sotto voce*, and Mr. Darbishire added "a rough quarter." Since that meeting I have been looking up the matter, for the point seems to me of great interest, and this is what I find in a recent paper by Mr. Darbishire in the *Manchester Memoirs*, "On the Bearing of Mendelian Principles of Heredity on Current Theories of the Origin of Species," vol. xlviii. p. 13:—"Let us consider the offspring of hybrids . . . . Secondly with regard to their progression, we should expect to find 25 per cent. waltzing mice: this is very roughly what happens; . . . Now let us look at the offspring of hybrids from *both* points of view at the same time: one mouse in every four is an albino; one in every four is a waltzer, so we should expect one in every sixteen to be an *albino waltzer*. Now these albino waltzers are new things . . .," and then Mr. Darbishire tells us that he has been unable to get offspring from them.

Here, from a quarter, we have got to a quarter "very roughly," but still "one mouse in every four is a waltzer." I must confess that Mr. Darbishire's "rough quarter" excited me to look further, and these are the words I find describing some actual experiments on these mice:—"*Waltzing* occurs in only 97 out of the 555 individuals resulting from the union of hybrids. When we compare this with the number of pink eyed individuals (131–134) or of albinos (137) we see that the proportion of waltzing individuals *cannot be regarded as a possible quarter*. The probable error of the expectation that a quarter of the individuals will waltz is, on the Mendelian hypothesis, $0{\cdot}6745\sqrt{\frac{1}{4}\times\frac{3}{4}\times555}=6{\cdot}88$ only, and the observed deviation is $138{\cdot}75-97=41{\cdot}75$, the odds against so great a deviation being rather more than 50,000 to 1. As the result here obtained differs from Mendelian expectation in the same direction as that already obtained by von Guaita and to an extent consistent with the agreement of both, *the evidence that the waltzing character does not segregate in Mendelian proportions is very strong*."

The sentences in italics are not in italics in the original,

but I want to emphasise them. The words quoted are from an article on the "Result of Crossing Japanese Waltzing with Albino Mice" in *Biometrika*, vol. iii. p. 20. The writer appears to be a Mr. A. D. Darbishire of Oxford, *not* of Manchester. The one Mr. Darbishire considers that the proportions cannot be regarded as a possible quarter, the other that a rough quarter, or "one mouse in every four," is waltzing. Mr. Darbishire of Manchester expects that one in every sixteen of the offspring of the hybrids will be an albino waltzer, and then proceeds to state that he has so far been unable to breed from these albino waltzers. Reading his paper, I presumed he would have told us had he *not* found albino waltzers to be 1 in 16. Consulting, however, Mr. Darbishire of Oxford, I find he had 20 instead of 35 albino waltzers among his 555 offspring. I presume that 20=35 is a "rough" sixteenth to our Manchester author, while he of Oxford would doubtless have been able to tell us that the odds against such an underestimate were two or three hundred to one! Which writer shall a member of the inquiring general public trust? Or, if the two writers should be the same, must we assume that in Oxford, under the influence of some recessive biometer, Mr. Darbishire failed to see that 97 in 555 was a reasonable quarter, or 20 in 555 a reasonable sixteenth, but that he has learnt in Manchester, or perhaps in Cambridge from some dominant anæsthetist, that these things really are so?

But if 97 be not even roughly 139, or 20 approximately 35, would it not be well at once to admit that the waltzing habit corresponds to a compound allelomorph, one element of which, the *chorophore*, may be credited to any mouse, but only becomes patent when combined with the *chorogen* to form the true waltzing habit? I am not sure this will work, but perhaps Mr. Darbishire will give it a trial. Should this in turn fail, a metaphysician might help him out of these procrustean difficulties by analysing straightforward advance into right-handed and left-handed elements, each with its own chorophore and chorogen—but I must not anticipate the details of such a remarkable progression at present.

KARL PEARSON.

The *n*-Rays.

THE inability of a large number of skilful experimental physicists to obtain any evidence whatever of the existence of the *n*-rays, and the continued publication of papers announcing new and still more remarkable properties of the rays, prompted me to pay a visit to one of the laboratories in which the apparently peculiar conditions necessary for the manifestation of this most elusive form of radiation appear to exist. I went, I must confess, in a doubting frame of mind, but with the hope that I might be convinced of the reality of the phenomena, the accounts of which have been read with so much scepticism.

After spending three hours or more in witnessing various experiments, I am not only unable to report a single observation which appeared to indicate the existence of the rays, but left with a very firm conviction that the few experimenters who have obtained positive results have been in some way deluded.

A somewhat detailed report of the experiments which were shown to me, together with my own observations, may be of interest to the many physicists who have spent days and weeks in fruitless efforts to repeat the remarkable experiments which have been described in the scientific journals of the past year.

The first experiment which it was my privilege to witness was the supposed brightening of a small electric spark when the *n*-rays were concentrated on it by means of an aluminium lens. The spark was placed behind a small screen of ground glass to diffuse the light, the luminosity of which was supposed to change when the hand was interposed between the spark and the source of the *n*-rays.

It was claimed that this was most distinctly noticeable, yet I was unable to detect the slightest change. This was explained as due to a lack of sensitiveness of my eyes, and to test the matter I suggested that the attempt be made to announce the exact moments *at which I introduced my hand* into the path of the rays, by observing the screen. In no case was a correct answer given, the screen being announced as bright and dark in alternation when my hand was held motionless in the path of the rays, while the fluctuations observed when I moved my hand bore no relation whatever to its movements.

I was shown a number of photographs which showed the brightening of the image, and a plate was exposed in my presence, but they were made, it seems to me, under conditions which admit of many sources of error. In the first place, the brilliancy of the spark fluctuates all the time by an amount which I estimated at 25 per cent., which alone would make accurate work impossible.

Secondly, the two images (with *n*-rays and without) are built of "instalment exposures" of five seconds each, the plate holder being shifted back and forth by hand every five seconds. It appears to me that it is quite possible that the difference in the brilliancy of the images is due to a cumulative favouring of the exposure of one of the images, which may be quite unconscious, but may be governed by the previous knowledge of the disposition of the apparatus. The claim is made that all accidents of this nature are made impossible by changing the conditions, *i.e.* by shifting the positions of the screens; but it must be remembered that the experimenter is aware of the change, and may be unconsciously influenced to hold the plate holder a fraction of a second longer on one side than on the other. I feel very sure that if a series of experiments were made jointly in this laboratory by the originator of the photographic experiments and Profs. Rubens and Lummer, whose failure to repeat them is well known, the source of the error would be found.

I was next shown the experiment of the deviation of the rays by an aluminium prism. The aluminium lens was removed, and a screen of wet cardboard furnished with a vertical slit about 3 mm. wide put in its place. In front of the slit stood the prism, which was supposed not only to bend the sheet of rays, but to spread it out into a spectrum. The positions of the deviated rays were located by a narrow vertical line of phosphorescent paint, perhaps 0·5 mm. wide, on a piece of dry cardboard, which was moved along by means of a small dividing engine. It was claimed that a movement of the screw corresponding to a motion of less than 0·1 of a millimetre was sufficient to cause the phosphorescent line to change in luminosity when it was moved across the *n*-ray spectrum, and this with a slit 2 or 3 mm. wide. I expressed surprise that a ray bundle 3 mm. in width could be split up into a spectrum with maxima and minima less than 0·1 of a millimetre apart, and was told that this was one of the inexplicable and astounding properties of the rays. I was unable to see any change whatever in the brilliancy of the phosphorescent line as I moved it along, and I subsequently found that the removal of the prism (we were in a dark room) did not seem to interfere in any way with the location of the maxima and minima in the deviated (!) ray bundle.

I then suggested that an attempt be made to determine by means of the phosphorescent screen whether I had placed the prism with its refracting edge to the right or the left, but neither the experimenter nor his assistant determined the position correctly in a single case (three trials were made). This failure was attributed to fatigue.

I was next shown an experiment of a different nature. A small screen on which a number of circles had been painted with luminous paint was placed on the table in the dark room. The approach of a large steel file was supposed to alter the appearance of the spots, causing them to appear more distinct and less nebulous. I could see no change myself, though the phenomenon was described as open to no question, the change being *very* marked. Holding the file behind my back, I moved my arm slightly towards and away from the screen. The same changes were described by my colleague. A clock face in a dimly lighted room was believed to become much more distinct and brighter when the file was held before the eyes, owing to some peculiar effect which the rays emitted by the file exerted on the retina. I was unable to see the slightest change, though my colleague said that he could see the hands distinctly when he held the file near his eyes, while they were quite invisible when the file was removed. The room was dimly lighted by a gas jet turned down low, which made blank experiments impossible. My colleague could see the change just as well when I held the file before his face, and the substitution of a piece of wood of the same size and

shape as the file in no way interfered with the experiment. The substitution was of course unknown to the observer.

I am obliged to confess that I left the laboratory with a distinct feeling of depression, not only having failed to see a single experiment of a convincing nature, but with the almost certain conviction that all the changes in the luminosity or distinctness of sparks and phosphorescent screens (which furnish the only evidence of *n*-rays) are purely imaginary. It seems strange that after a year's work on the subject not a single experiment has been devised which can in any way convince a critical observer that the rays exist at all. To be sure the photographs are offered as an objective proof of the effect of the rays upon the luminosity of the spark. The spark, however, varies greatly in intensity from moment to moment, and the manner in which the exposures are made appears to me to be especially favourable to the introduction of errors in the total time of exposure which each image receives. I am unwilling also to believe that a change of intensity which the average eye cannot detect when the *n*-rays are flashed "on" and "off" will be brought out as distinctly in photographs as is the case on the plates exhibited.

Experiments could be easily devised which would settle the matter beyond all doubt; for example, the following:—Let two screens be prepared, one composed of two sheets of thin aluminium with a few sheets of wet paper between, the whole hermetically sealed with wax along the edges. The other screen to be exactly similar, containing, however, dry paper.

Let a dozen or more photographs be taken with the two screens, the person exposing the plates being ignorant of which screen was used in each case. One of the screens being opaque to the *n*-rays, the other transparent, the resulting photographs would tell the story. Two observers would be required, one to change the screens and keep a record of the one used in each case, the other to expose the plates.

The same screen should be used for two or three successive exposures, in one or more cases, and it should be made impossible for the person exposing the plates to know in any way whether a change had been made or not.

I feel very sure that a day spent on some such experiment as this would show that the variations in the density on the photographic plate had no connection with the screen used.

Why cannot the experimenters who obtain results with *n*-rays and those who do not try a series of experiments together, as was done only last year by Cremieu and Pender, when doubt had been expressed about the reality of the Rowland effect? R. W. WOOD.

Brussels, September 22.

Porpita in the Indian Seas.

DURING five voyages to and from the East, I have been interested in watching for (and not always seeing) a species of Porpita common in the Red Sea, on the coasts of India, Ceylon, and the Malay Peninsula. From the deck of a steamer the colony, only the flat disc of which is visible, appears like a floating counter of bone or ivory. When examined at close quarters it has a greyish metallic lustre, and is seen to be surrounded with an aureole of azure tentacles, the tips of which are green. So long ago as 1579[1] Thomas Stevens appears to have remarked upon this animal (though he did not recognise its animal nature) as being one of the signs by which the vicinity of land might be known on the Indian coasts. During the monsoon, even in comparatively fine weather, this Porpita, so far as my observations go, completely disappears from the surface. It would seem to follow that the colony is an annual growth, as it has no power of sinking, and very feeble, if any, means of independent progression. This is borne out by an observation I was able to make on the shore at Colombo on July 15 last. On that date, when the monsoon had already been in progress for some weeks, the beach along the Galle face, which is open to the full force of the monsoon, was covered with biscuit-like discs, which I had no difficulty in recognising, from the sculpturing on their surface and the characteristic appearance in cross-section, as those of Porpita. They had quite lost their silvery appearance, and were very brittle; no trace of the living tissues of the animal remained. There were, however, large numbers of other Siphonophora, too decomposed for even partial identification (but obviously belonging to a different section of the group), mingled with the discs. My friend Dr. J. H. Ashworth tells me that he has observed much the same thing in the Mediterranean with regard to Velella, and it appears that Agassiz records having seen a broad blue band of Velella along the shores of Florida, but I have not the reference at hand. NELSON ANNANDALE.

Indian Museum, Calcutta, August 22.

[1] See Beazley's "Voyages and Travels," 1903, p. 158.

On van 't Hoff's Law of Osmotic Pressure.

VAN 'T HOFF imagines that a substance dissolved in a fluid medium behaves as if it were in a vacuum, and so exerts on the walls of the containing vessel a pressure which is precisely that which it would exert were the solvent imagined removed and the dissolved substance imagined present in a gaseous form.

The pressure thus exerted on the walls of the vessel is called the "osmotic pressure." Many authors of great mathematical repute have seriously questioned the correctness of van 't Hoff's views, and they find it exceedingly difficult to see how a dissolved substance *can* be present in the solvent in a state similar to the gaseous state.

For example, Prof. O. E. Meyer ("Kinetic Theory of Gases," p. 367, Eng. trans., 1896) remarks:—". . . osmotic pressure is not one of the phenomena which the kinetic theory of gases has to explain. I will also not conceal that I do not think van 't Hoff's views of the kinetic nature of osmotic pressure to be correct. For osmose does not arise from the kinetic pressure of the dissolved substance, but from quite different forces which cannot be neglected."

I think, however, these authors have neglected an important factor which would tend to make the dissolved molecules behave as if in a vacuum, and so would tend to give physical reality to van 't Hoff's views.

The factor I allude to is the fact that different kinds of molecules attract each other with enormously different forces. For example, the molecules of carbon exert on each other an enormous attractive force, as is shown by the remarkable hardness and involatility of certain forms of carbon. Oxygen, hydrogen, helium, and other molecules have in comparison but a feeble molecular attraction.

Consider a molecule A in the midst of a swarm of other molecules; for example, a molecule in the interior of a homogeneous liquid. Then if the molecule A be of the same nature as the other molecules, each will exert the same intensity of attractive force on the other, and so the molecules will all be on an average symmetrically arranged about A. The liquid will, in fact, have at every point a symmetrical structure. If, however, the molecule A be different in nature from the neighbouring molecules (as occurs in the case of solution), two cases in general occur:—

(1) The molecules of the liquid attract each other more strongly than they attract the molecule A.

(2) The molecules of the liquid attract each other *less* strongly than they attract the molecule A.

(1) In this case it is easy to see that under the influence of the molecular forces the molecules of the *liquid* would be *drawn* away from the molecule A (in precisely the same way, and for a similar reason, that the molecules of quicksilver are drawn away from glass), and so form about A a sort of *vacuum bubble*; and as A moves forward in the liquid the molecules surrounding it would be drawn away, and leave a free passage for A, which would thus behave very much as if it were actually in a vacuum. Here, then, van 't Hoff's conception becomes readily intelligible.

(2) In this case molecules of the liquid would combine with the molecule A to form an unstable compound, traces of which are so often met with in solution; and the combination would proceed until the compound thus formed exerted an attractive force on the neighbouring molecules equal to or *less* than the force which the neighbouring molecules exert on each other.

When this occurs the case would resolve itself into case (1) previously considered, the unit, however, being now not the molecule A, but the molecular compound of which it forms a part.

In this connection it should be observed that it is a general rule that when a molecule adds on atoms to itself, the resultant aggregate of atoms usually exerts an *intensity* of molecular attraction *less* than that of the original molecule. For example, high-grade types of combination are nearly always more volatile than lower types of combination of the same molecular weight. Saturated compounds are more volatile than unsaturated compounds of the same molecular weight. Chemically unstable compounds are invariably more volatile than stable compounds of the same molecular weight, and the addition of atoms to a molecule decreases its stability.

The point is discussed fully in a paper which appeared in the *Chemical News* some time ago (vol. lxxxix. p. 241).

We should therefore expect to find that when a substance A in a liquid combines with molecules of the liquid, the *intensity* of the molecular attraction which the new compound exerts would diminish as the number of molecules of the liquid added on to the molecule A increases.

When this is not the case, van 't Hoff's law cannot be obeyed at all closely by the dissolved substance.

Kiel, September 6. GEOFFREY MARTIN.

THE ROYAL PHOTOGRAPHIC SOCIETY'S ANNUAL EXHIBITION.

THIS exhibition will remain open until October 29. Although the scientific and technical section is disappointing, for, taken as a whole, it is below the standard of the last few years, there are several exhibits that are well worth attention. We are glad to notice an improvement in the arrangement, each department being kept more distinct than heretofore.

Zoological work is better represented than any other. Captain F. D. S. Fayrer shows several photographs of the daboia (a venomous viper), in one of which venom can be distinctly seen hanging from the fangs. As an example of photographic difficulties successfully overcome, the "Flying Sea Gull" of Mr. B. H. Bentley should be noticed. There are several sets of prints illustrating progressive changes. The one that will probably be considered the most notable is "A comparison of a jump of one foot in height as executed by a dog and a cat respectively." There are sixteen photographs of each animal showing as many stages of the jump, and they demonstrate that both animals judge with remarkable nicety the rise necessary to clear the obstacle, and that the movement of the legs is the same in both cases. "The Embryology of a Chicken," by Mr. W. M. Martin, is a series of seventy photographs, one by Röntgen rays, some by transmitted light, and some by a combination of transmitted and reflected light. It is clever and useful work which must have needed considerable patience for its execution. The Zoological Photographic Club has contributed a number of very interesting and meritorious photographs, including one by Mr. Douglas English of the Orkney vole, the last discovered British mammal.

Mr. R. H. Baskett shows how, by means of a simple original such as a piece of lace or a sprig of forget-me-not or bramble, many designs may be obtained by the use of mirrors as in a kaleidoscope, if the multiplied image is photographed. He says that millions of designs may be obtained for the cost of the plates. A truly amateur's view of the matter in neglecting the cost of the apparatus and the time of the worker!

Colour photography is but poorly represented. A basket of fruit by Mr. S. R. Brewerton, done by the Sanger-Shepherd imbibition process, is a notable example, but such fine work has been done by this method that we cannot pass over the background, which if not unfortunate in its tint has not been reproduced with the perfection that we expect. Of the specimens of commercial colour work there is little to be said. What is wanted for exhibition is the original with its reproduction, produced without any fine etching or other hand work; then we shall be able to see what colour photography pure and simple is capable of, and to judge of its progress. If the trichromatic prints produced by Dr. Jumeaux's process fairly show the capabilities of that process, we can only say that it is a long way behind other processes. Photographers should notice the "three-colour carbon print" by Mr. J. Gilbert Jackson, as for obvious reasons they are not likely often to have the opportunity of seeing prints produced in this way. The carbon tissue is triply coated, so that the high lights show blue, the half tones, ochre, and the low tones, green. Of course, the colour in the print is in no way dependent on the colour of the object. The interest of the exhibit lies only in the fact that the method has been seriously proposed for practical work.

A telephotograph of St. Paul's showing a direct magnification of twenty-four diameters demonstrates excellently the usefulness of this kind of work. A number of photomicrographs, some Playertype enlargements, some star maps, and a few other items are all worth examination; but the most notable of the remaining exhibits is a series of radiographs showing bone diseases by Mr. C. Thurstan Holland. The amount of detail obtained in difficult circumstances is remarkable, and the exhibit is further praiseworthy as forming a connected whole instead of, as we often see, a heterogeneous collection of examples that have happened to turn out well. We regret to notice that there is no apparatus whatever in this section of the exhibition. Probably the presence of the trade exhibits in the central court is the reason for the disappearance of what used to be one of the main sections, but general exhibits by the trade do not take the place of a classified selection of new apparatus. In the central court will be found new cameras, or modifications of old ones, by several makers, and some new sensitometric apparatus and a recording chronograph by Messrs. Sanger-Shepherd and Co., besides, of course, a large selection of the various specialities of the exhibitors.

Of lantern slides there is a fair number, and they appear to be of more than usual interest. A series by Dr. G. H. Rodman showing how by the use of Röntgen rays the structure of molluscan shells can be shown, and a series of studies in the biology of flowers by Mr. B. H. Bentley, are the most conspicuous. But we cannot discover when these can be seen properly displayed, for a slide is not made to be looked at, but to furnish an enlarged image on a sheet. It appears that at the lantern lectures, which are given at intervals, other slides are shown.

PROF. N. R. FINSEN.

THERE are many records of patient heroism in the history of scientific investigation, but there are few careers in which strenuous work for the alleviation of human suffering has been carried on at greater disadvantage than that of the late Prof. Finsen, of Copenhagen.

Twenty years ago, he was the victim of a severe attack of rheumatism, which left the heart seriously damaged, and this was followed by disease of the liver and dropsy. By the greatest self-denial, and the most careful regulation of his dietary, Finsen

lived on, in spite of his terrible affliction, devoted to his work, developing his theories, and putting them to practical use in the treatment of disease. For some time past he had been confined to his house, and could only direct the labours of others in the great Light Institute at Copenhagen. His death occurred on Saturday, September 24, at the early age of forty-three.

Niels R. Finsen was born in the Færoë Isles, and spent some of his earlier years in Iceland. After eight years' study at the University of Copenhagen, he was appointed lecturer on anatomy. But his attention was soon directed to the investigation of the influence of light on living organisms.

Starting from Widmark's observations on the inflammation of the skin caused by the ultra-violet rays of light, he developed in 1893 the red-light treatment of small-pox. The exclusion of the chemical rays by red curtains modifies the course of this disease, and diminishes scarring. A prolonged series of observations was then made on the influence of light upon various animals, proving that the chemical rays produce irritative and deleterious effects.

Later, Finsen investigated in a masterly manner the bactericidal power of the ultra-violet rays, a development of the work of Downes and Blunt. The practical application of these experimental researches was the treatment of lupus by light, an advance in therapeutics which has placed in the hands of the medical profession a means of combating this intractable and most disfiguring disease.

Fortunately, Finsen's work was not allowed to languish for want of financial support. His friends helped him, and then the State aided him with a loan, free of interest, and the Light Institute was built. Since it was opened, 2000 patients have been treated.

The interest taken by Queen Alexandra in the work of her countryman led to the introduction of the light treatment into this country, and her gift of the apparatus to the London Hospital was followed by generous assistance from private donors enabling that institution to carry out the Finsen treatment with remarkable success.

Finsen was a man of noble qualities, of high scientific attainments, and of a remarkably inventive mind. The construction of his apparatus is sufficient to indicate this. It was no chance discovery, but was laboriously built up by the adaptation of scientific principles. His modesty, quiet humour, and total absence of self-seeking brought him the esteem and affection of all who knew him.

Always a poor man, Finsen could with difficulty be persuaded to retain for the use of his family any part of the Nobel prize of 100,000 crowns which was awarded him. He wanted to give all to his institute, but eventually agreed that half should be placed at interest for his family, to revert subsequently to his great work. This institute and its beneficial cures are a fitting memorial of a splendid life of quiet heroism in the cause of science.

NOTES.

A CAREER of high promise was cut short by a lamentable accident at the "Devil's Kitchen," near Bethesda, North Wales, on September 20. Mr. Ronald William Henry Turnbull Hudson, lecturer in mathematics at the University of Liverpool, who, with Mr. J. F. Cameron, lecturer of Caius College, Cambridge, was climbing a difficult *couloir*, dislodged a mass of rock, and, falling with it, was instantly killed. Mr. Hudson, who was just twenty-eight years of age, was the son of Prof. W. H. H. Hudson, of King's College, London, and the brother of two sisters who recently distinguished themselves in mathematics at Newnham College. He was educated at St. Paul's School and St. John's College, Cambridge. He gained every college award that was open to him, and graduated as senior wrangler in 1898, his friend Mr. Cameron being second wrangler. The two comrades were alone in the first division of the first class in part ii. of the tripos in 1899, and in the following year each was a Smith's prizeman. In 1900 Mr. Hudson was elected a fellow of his college, and engaged with success in teaching and research. He graduated M.A. in 1902, and was appointed lecturer at Liverpool, where his powers rapidly matured. He published a number of papers, chiefly on analytical and geometrical subjects, which manifested much freshness and skill, as well as width of interest and of knowledge. He was unusually well read in classical and modern literature, and in experimental science. In athletic pursuits he was also keenly interested, and more than once steered his college boat to victory. It was confidently expected that ere long he would be promoted to a professorial chair, for which his gifts and acquirements specially fitted him. The news of his untimely death was received in Cambridge with the deepest regret, and with sincere sympathy for his family and college.

THE fifth annual Huxley memorial lecture of the Anthropological Institute will be delivered on Friday, October 7, in the theatre of the Civil Service Commission, Burlington Gardens, when Dr. J. Deniker, of Paris, will lecture on the different racial elements in the present population of Europe.

THE King has conferred the title "Royal" upon the Edinburgh Museum of Science and Art, and approved its designation being altered to "The Royal Scottish Museum."

EXTENSIONS made to Millport Marine Biological Station, including new laboratory, research rooms, tank-room, and library, all the gift of Mr. James Coats, jun., of Paisley, were opened on Tuesday by Sir John Primrose, Lord Provost of Glasgow.

THE Liverpool School of Tropical Medicine proposes to dispatch a second expedition to the Amazon in view of the necessity of further investigation of yellow fever. The expedition will probably start at the end of this year.

THE National Association for the Feeble-minded and the National Union of Special School Teachers have arranged a conference to be held at the Guildhall on October 13 and 14 to discuss various aspects of physically, mentally, and morally defective children.

REUTER'S correspondent at Naples states that the Vesuvius Observatory has issued the following notice:—"The activity of Vesuvius is very great. The walls of the crater, which have collapsed, tend to obstruct the bottom of the crater, whence proceed immense explosions and volcanic dust. The torrent of lava in the valley of Atrio del Cavallo is forming small volcanoes, the explosions from which attain a height of 150 metres. Large fissures have occurred in the great cone, the rupture of which is considered possible." The eruption of Mount Vesuvius on September 23 is said to have been the greatest within the last ten years. On September 25 explosions were frequent, and masses of igneous matter were hurled to great heights. Parts of the neighbouring woods have been burned, the funicular railway has been damaged, and the guides' quarters have been destroyed.

The following papers will be read at the autumn meeting of the Iron and Steel Institute to be held in New York on October 24 and 26:—Iron and steel at the St. Louis Exposition: Prof. H. Bauerman; a West African smelting-house: C. V. Bellamy and F. W. Harbord; the influence of carbon and phosphorus upon the strength of iron and steel: H. H. Campbell; the Rateau low-pressure turbine at steel-works and collieries: E. Demenge; a dry air blast apparatus: J. Gayley; high-speed tool-steels: J. M. Gledhill; the determination of carbon and phosphorus in steel: Baron H. Jüptner von Jonstorff, A. A. Blair, G. Dillner, and J. E. Stead, F.R.S.; acid open hearth manipulation: Andrew McWilliam and W. H. Hatfield; a power gas plant for Johannesburg: P. J. Mallmann.

The fourth general meeting of the International Fire Service Council was recently held at Budapest on the occasion of the International Fire Congress, which was organised under its auspices. The meeting was presided over by M. G. de Marie, of Luxemburg. All the European countries were represented, with the exception of Portugal, Turkey, and the Balkan States. It was decided that the seat of the council remain at Luxemburg for the next four years. Mr. Edwin O. Sachs, chairman of the British Fire Prevention Committee, was re-elected vice-president for the impending four years. The work of the council for this period will deal to a considerable extent with technical questions, with statistical questions in respect to fire losses, and with the preparation of a fire technical dictionary in the German, French, and English languages. The next general meeting of the council will be held at Milan in 1906. Among the resolutions adopted by the recent conference at Budapest were the following:—(1) That it is absolutely essential that all stage scenery and properties be rendered non-inflammable in a trustworthy and permanent manner, and that all the constructional parts of a stage be of a fire-resisting character. (2) That the greatest attention should be accorded to the chemistry of fire protection in the interests of fire prevention.

The twelfth annual report of the Sonnblick Society for the year 1903 contains a very interesting description by Dr. O. Szlavik, an assistant at the Vienna Meteorological Office, of a winter passed by two observers and himself on the summit of that mountain, at an altitude of 10,190 feet above the sea. For various reasons, including the want of educated companions and the difficulties of locomotion, Dr. Szlavik considers that a winter passed at such a station compares unfavourably with the privations endured at a Polar station. The meteorological summary for 1903 shows that the mean monthly temperature only rose above the freezing point in the month of August. The maximum (46°·8) occurred in September, and the minimum (−14°·4) in February. Snow or rain fell on 205 days. The pamphlet also contains an illustrated article on optical phenomena observed at the station, the results of observations at several high-level stations in the neighbourhood of the Sonnblick, and other useful information relating to mountain meteorology. We are glad to learn that the society has decided to combine the results of the last twelve years in one handy volume.

The *Journal* of the Sanitary Institute for August (xxv., part ii.) contains the addresses delivered to the congress of the Sanitary Institute at Glasgow, and Sir Douglas Powell's lecture to the congress on "The Prevention of Consumption."

We have received the September number of *Our Hospitals and Charities*, an illustrated monthly journal which gives interesting particulars of the various London and provincial hospitals, convalescent homes, and other charitable institutions.

Several papers have recently been published on the morphology and occurrence of the Leishman-Donovan body or parasite (see Nature, lxix. pp. 167 and 495, and lxx. p. 85). This parasite occurs in certain cases of irregular tropical fever of long duration, associated with enlarged spleen and marked cachexia. Major Donovan, I.M.S., in the *Lancet* (September 10, p. 744) describes fully the cases in which he has detected the parasite, and gives a number of coloured drawings of the latter. In the *British Medical Journal* (September 17, p. 642) the discussion on this parasite at the meeting of the British Medical Association is reported. Major Leishman, R.A.M.C., in opening it, stated that he had expressed the opinion that this parasite was a stage in the life-cycle of a flagellate protozoon, probably a trypanosome. Prof. Leonard Rogers described experiments he had performed on the cultivation of the organism, and stated that undoubted trypanosomes had appeared in two of his cultures.

The report of the departmental committee appointed to investigate experimentally and to report upon certain questions connected with the dipping and treatment of sheep has recently been issued. The composition of efficient dips, their method of use, and their effects upon the animals, the wool, and the parasites for which they are employed, and the life-history of the sheep-scab acarus and other parasites, are some of the subjects dealt with, and a series of recommendations is given for the periodical dipping of sheep. All the dips tested proved efficient; they consisted of arsenic and alkali, arsenic and sulphur, preparations of tar, tobacco and sulphur, and carbolic acid. The tobacco and sulphur preparations seemed to be the most active, rapidly killing the parasites, and having no injurious action on the wool; they are, however, somewhat costly. The arsenical preparations have to be used with care, or the animals may suffer. Some of the tar preparations had a deleterious action on the wool.

In the *Bulletin* of the Johns Hopkins Hospital for July (xv., Nos. 160–161), Dr. Harvey Cushing surveys the sensory distribution of the fifth cranial nerve, Dr. Percy Dawson continues his biography of the Rev. Stephen Hales, and Dr. Schmoll discusses the chemical origin of leucocytes. In the last named the question is discussed whether the organism is able to synthesise the nuclein of its tissue cells, or is obliged to build them out of the cell material contained in its food. From a study of cases of leucæmia, and the influence on the leucocytes of ordinary mixed diet and of a purin-free diet, the conclusion is arrived at that, while the organism prefers to draw upon preformed nuclein material, it is perfectly able to synthesise this if necessary.

Dragon-fly "nymphs" form the subject of a paper by Mr. J. G. Needham published in the *Proceedings* of the U.S. National Museum (No. 1371). The examination of a large series of the immature stages of these insects has tended to throw light on the mutual relationships of the forms to which they severally belong.

Considerable interest attaches to an article by Messrs. Castellani and Willey in the August issue of *Spolia Zeylanica* on the parasites found in the blood of vertebrates in Ceylon. The only trypanosome detected by the authors in the island is *Trypanosoma lewisi*, which infests at least 25 per cent. of the rats in millions, but without doing any appreciable harm to its hosts. Although the trypanosome

of cattle disease can be readily transmitted by inoculation into rats, the rat-parasite will only develop in its proper hosts. Some curious problems in development are presented by the life-history of a gregarine found in the blood of a water-snake.

In the September issue of the *American Journal of Science* Mr. E. H. Sellards continues his account of the Palæozoic cockroaches, with descriptions of several new Coal-measure types. Another article, by Mr. G. R. Wieland, is devoted to the structure of the turtles of the genus Lytoloma, as exemplified by specimens from the Upper Cretaceous of New Jersey. These turtles, it may be mentioned, are characterised by the backward position of the inner nostrils and the great length of the mandibular symphysis. The author considers that they were specialised for the purpose of feeding on shell-fish, and confirms Mr. Lydekker's reference of the English Eocene *Chelone planimentum* to the American genus

Drs. B. L. Robinson and J. M. Greenman continue to publish the results of their examination of Mexican and Central American plants in the first number of the current volume of the *Proceedings* of the American Academy of Arts and Sciences. Mr. M. L. Fernald presents a synopsis of species of Alnus, and describes a number of new species from the same countries.

It is tolerably well known that contact with certain plants, notably species of Rhus and Primula, often causes inflammation. This may be described as a form of eczema, or in some cases would be more correctly called dermatitis. Mr. J. H. Maiden has made these plants the subject of a short paper which he laid before the Therapeutical Society in March, 1903.

Since the first description with figures of Melocanna by Roxburgh in 1819, it was known that this genus of bamboos growing in eastern Bengal and Burmah was characterised by the production of a succulent fruit about the size of a pear, and containing one large oval seed; later it was observed that germination started before the fruit was shed. Only recently has a complete description been forthcoming in the paper which Dr. O. Stapf communicated to the Linnean Society, and which is published in the *Transactions* (June). The fruit of Melocanna differs from that of ordinary grasses in other respects, because the ripe seed contains no endosperm, the food being stored up in the pericarp, and the collapsed endosperm cells act as a diaphragm. One of the most striking features of the plant is that it forms large jungles or forests, in which after many years of vegetative growth all the plants produce their flowers and fruits simultaneously.

In view of the discussion of electrical units by the International Electrical Congress at St. Louis, the Physikalisch-Technische Reichsanstalt publishes in part xxxi. of the *Elektrotechnische Zeitschrift* a protest against defining the unit of electromotive force by reference to a standard cell. It is maintained that sufficiently large differences exist in the E.M.F. of any one type of cell with differences in constructional detail to prevent the adoption of such a unit from giving satisfaction. With our present knowledge of standard cells, it is contended, the unit of resistance should be the mercury unit, and current should be defined by reference to the silver voltameter; the unit of E.M.F. is then the derived unit obtained by assuming Ohm's law.

We have received from the author a reprint of a paper read before the German Physical Society by Mr. L. Austin on the alteration in length during magnetisation of Heusler's magnetic alloys of manganese, aluminium, and copper. It contains a description of a very simple apparatus for measuring minute changes in length, in which the magnifying principle adopted is the reflection of a beam of light from a plane mirror. Besides showing that the alloys increase in length during magnetisation proportionally to the magnetic force, the author describes a peculiar contraction which they subsequently undergo when exposed to a magnetic field of constant strength. The contraction seems to be roughly proportional to the square of the magnetic intensity.

In No. 18 of the *Physikalische Zeitschrift* Prof. F. Paschen publishes an experimental investigation of the γ rays emitted by radium. These extremely penetrating radiations have hitherto been regarded as most closely allied to the Röntgen rays, but as they carry with them a negative charge which they are capable of imparting to substances that they encounter, it appears more justifiable to regard them as a species of kathode rays. All attempts, however, to deflect the γ radiations in the same way as the β rays by means of an intense magnetic field were unsuccessful. Even in a field of 30,000 C.G.S. units a perceptible deviation from a straight line path could not be detected. By carefully measuring the thermal effect of the γ radiations, the surprising result was obtained that the energy of a γ electron must be at least 3200 times greater than that of a β electron. That the γ rays cannot be the Röntgen effect of the β or kathode rays of radium is shown by the fact that their total energy is to that of the β rays in the ratio 74 : 1. It is concluded, indeed, that the γ rays carry with them the greater proportion of the energy of radium.

An improved means of observing the beautiful scintillations exhibited by a sensitive screen under the action of Alpha rays has been devised by Mr. F. H. Glew, 156 Clapham Road, S.W. The little instrument, which is called the "Scintilloscope," consists of a simple magnifier of adjustable focus, as in the spinthariscope, but instead of the fixed screen and particle of radio-active substance a small double plate of glass is used. One of these pieces of glass is coated with a radio-active salt, and the other is a radio-sensitive screen. Upon looking at a combination of this kind with the lens the sparkling appearance is very clearly seen. The advantage of this method of observing the effect is that different combinations of radio-active substances and screens can be used. For instance, a sensitive screen placed upon a piece of pitchblende ground flat and polished shows the scintillations very well. Mr. Glew's device provides an effective way of exhibiting the brilliant display produced by radio-activity on sensitive screens.

In the *Proceedings* of the American Philosophical Society (vol. xliii. p. 123) Messrs. Edgar F. Smith and F. F. Exner give an account of an elaborate investigation of the atomic weight of tungsten. The authors, on the basis of a critical examination of previous determinations, consider it doubtful whether pure substances have been employed. The mean atomic weight calculated from concordant data obtained by converting the hexachloride into the oxide is 184·04, and by oxidation of the metal 184·065.

Some interesting results have been obtained by F. Garelli and F. Gorni in a study of the isomorphism of organic substances by the cryoscopic method. They are described in the August number of the *Gazzetta*. Substances may apparently differ very considerably in constitution, and yet crystallise together so as to form a solid solution. Thus, for example, phenyl benzoate, phenyl salicylate, and salicylhydroquinone, which differ by the

important hydroxyl group, readily form mixed crystals. That a definite law does not hold in such cases is shown by the fact that phenol and hydroquinone, which bear the same relation to each other as phenyl salicylate and salicylhydroquinone, are not perceptibly isomorphous. The results are of importance as indicating a limitation of the cryoscopic method of determining molecular weights.

SOME experiments which are of importance from the standpoint of the theory of dyeing are described in the *Proceedings* of the Vienna Academy of Sciences (No. 15) by Prof. W. Suida. On exposing several finely divided natural silicates to the action of coal-tar dyes, it was found that those silicates which were of an acid nature, containing free hydroxyl groups, were permanently dyed by the basic dyes of this series, whilst acid dyes were without action. Similarly, hydrated silicic acid readily absorbs the same colours, whilst silicic anhydride has no affinity for them. When kaolin is used, the different colour-bases combine with it in equivalent proportions, probably to form colour-salts, the original acid in the dye becoming attached to constituents of the clay. Similar results were obtained with potato-starch, and the general conclusion is drawn that the process of dyeing with basic colours is far more chemical than physical in its nature.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN OCTOBER :—

Oct. 1. 7h. Mercury at greatest elongation, 17° 54′ W.
5. 7h. 45m. to 9h. 7m. Transit of Jupiter's Sat. III.
7. 15h. Moon in conjunction with Mercury. Mercury 1° 1′ N.
12. 11h. 0m. to 12h. 24m. Transit of Jupiter's Sat. III.
15. Venus. Illuminated portion of disc = 0·897, of Mars = 0·956.
18. 11h. 0m. Jupiter in opposition to the Sun.
19. 14h. 13m. to 15h. 42m. Transit of Jupiter's Sat. III.
19–21. Epoch of October meteors (Radiant $92° + 15°$).
19. 10h. 8m. Minimum of Algol (β Persei).
22. 6h. 57m. Minimum of Algol (β Persei).
23. 10h. 0m. Moon in conjunction with Jupiter. Jupiter 1° 34′ N.
25. 6h. 37m. Jupiter's Sat. IV. in superior geocentric conjunction.
26. 16h. 48m. to 17h. 25m. Moon occults γ Tauri (mag. 3·9).

EXPLANATION OF THE MARTIAN AND LUNAR CANALS.—Prof. W. H. Pickering, writing to No. 7, vol. xii., of *Popular Astronomy*, offers an explanation of the formation and variation of the Martian canals which is based on their analogy to the similar features seen on the lunar surface. Whilst accepting the vegetal origin so ably supported by Mr. Lowell, Prof. Pickering finds the theory of artificial pumping suggested by that observer difficult to realise.

Instead of this, he supposes that the lunar canals, and hence, by analogy, those observed on Mars, are simply lines of volcanic action on the surface where the crust is weakened, and therefore is easily cracked by the internal stresses put upon it by the action of the heated interior.

This theory is supported by his observations that the canals, and also the lakes from which they appear to radiate, are dotted by small craterlets and are so symmetrically arranged about the craterlets as to suggest a causal relation between the two phenomena. Analogous formations are common in terrestrial volcanic districts; for example, in the 2000 mile stretch of volcanoes which occurs in the Andes.

This theory does not require the transference of water and carbon dioxide along the canals, but supposes that they issue directly from the interior along the whole length of each fissure, and in conjunction with sunlight promote the growth of vegetation. Owing to the rarity of the atmosphere, Prof. Pickering suggests that the vapours would not ascend on their emergence, but would quietly roll down the slopes of the craterlets, or "lakes," and canals, thereby sufficiently irrigating the immediate vicinity to produce the vegetation.

FURTHER OBSERVATIONS OF THE RECENT PERSEID SHOWER.—Communications from American observers confirm the comparative richness of the recent display of Perseids.

At Wilmington (N.C.) Mr. E. S. Martin saw between 25 and 30 Perseids per hour between 9 p.m. and 12 p.m. (local M.T.) on the nights of August 10 and 11, although very few were seen on August 12 and 13, and none on August 14.

At Barre (N.Y.) Mr. W. Wetherbee saw 154 meteors, of which 116 were Perseids, in less than three hours on the eve of August 11. He remarked that many of the Perseids appeared in pairs the components of which travelled in parallel paths and had equal magnitudes. According to this observer, the radiant has moved westward, and appeared to be near to the star ι Persei. One extraordinarily bright Perseid appeared in Aquila, and left a trail 10° long which lasted for about four minutes (*Popular Astronomy*, No. 7, vol. xii.).

POSITION OF SATURN'S NINTH SATELLITE.—A telegram from Prof. E. C. Pickering, published in No. 3969 of the *Astronomische Nachrichten*, announces that Prof. Barnard observed Phœbe, Saturn's ninth satellite, on September 12·6916 (G.M.T.). The apparent position at that time was as follows :—

$$\alpha = 21\text{h. } 12\text{m. } 29{\cdot}5\text{s.}, \quad \delta = -17° \ 25' \ 55''.$$

The motion of the satellite was south-west, whilst the magnitude was 16·7.

DISTRIBUTION OF NEBULÆ IN RELATION TO THE GALAXY.—In No. 3969 of the *Astronomische Nachrichten* Dr. C. Easton discusses the distribution of the nebulæ in regard to the galactic system.

Commencing with the usually accepted statement that the nebulæ not only occur some distance from the Milky Way, but that they actually tend to congregate about the galactic poles, he confirms this, from observational data, for the northern hemisphere, but questions its truth for the southern hemisphere. He further states that the accepted notion that it is simply the lack of observations which accounts for the apparent scarcity of nebulæ in the southern hemisphere is not founded on fact. If it were true, then that part of the northern galactic zone which lies south of the equator should apparently contain fewer nebulæ than that part which is above, because it has not been so well observed. The following figures show that although this is true for the faint nebulæ, which with the planetary nebulæ are placed in the category of "green nebulæ," in the case of the bright (*i.e.* "white") nebulæ the inverse is true :—

Northern Galactic Zone.

	A S. of the equator	B N. of the equator
Faint nebulæ	754	1043
Bright nebulæ	152	71

This leads to the conclusion that the nebulæ in the southern hemisphere are not arranged in the same manner as those in the northern.

Several other interesting points are developed by Dr. Easton in his paper, and are supported by the tabulated observational results which he gives. One other important conclusion at which he arrives is that the faint nebulæ are allied, as regards their phase of development, to the stellar conglomerations of the galaxy and occur in the same regions, whilst the bright (*i.e.* "true") nebulæ are similarly allied to the sparsely distributed non-galactic stars.

ASTRONOMY AND COSMICAL PHYSICS AT THE BRITISH ASSOCIATION.

GREAT vitality was shown in this subsection, and three mornings and one afternoon were hardly sufficient to get through the rather large programme. The meetings were well attended, and were of particular interest, since many distinguished foreigners were present, several of whom attended at Cambridge in consequence of the meeting there of the subcommittee of the International Meteorological Committee which was appointed at Southport last

year to discuss the means of advancing our knowledge of the relation between solar and terrestrial changes.

Sir John Eliot's address has already appeared in these columns, so that attention here will be restricted to the subsequent proceedings of the subsection.

With Sir John Eliot in the chair, the first paper on Friday was by Father Cortie, who summed up the results of all the observations of sun-spot spectra made at Stonyhurst during the period 1883–1901. One of the chief points of the paper was to show the great importance of the elements vanadium and titanium, the lines of these elements being more frequently widened than those of any other. Reference was also made to widened-line crossings and to oxygen in the spectra of sun-spots.

Sir Norman Lockyer then followed with a short summary of his work on the classification of stars according to their temperature since he gave the Rede lecture in 1871. The chief feature of the paper was to show that by paying special attention to the results obtained with a small camera having calcite and quartz to replace the glass lens and prism used in his earlier work, he was enabled to bring a more efficient check on the classification from the point of view of the extension of the spectrum in the ultra-violet than he could with the glass optical parts. The result of this inquiry confirmed the chemical classification in every respect.

The extension in the ultra-violet part of the spectrum as a criterion of stellar temperatures was the subject of a paper by Mr. H. F. Newall, who was inclined to question this criterion based upon the ultra-violet extension. He referred to observational evidence, which displayed sometimes perplexing discrepancies between the relative intensities of the blue and the red ends of the spectrum in different stars. The point raised was, how far was the present criterion of stellar temperature based upon the observed behaviour of gaseous radiation as opposed to the radiation of solid bodies? He said, in conclusion, that it was not impossible that we should be forced to regard extension in the ultra-violet regions as a sign of differences and not of high temperature.

The paper on the short-period barometric see-saw and its relation to rainfall, by the present writer, was an extension of a paper which has previously been printed in this Journal (vol. lxx. p. 177). The chief point was to show how very closely rainfall curves were associated with curves representing the inverted barometric changes. The regularity of the barometric see-saw mentioned above suggested that there may possibly be found to exist a method here of forecasting wet and dry years over a large portion of the earth's surface.

After a brief interval for lunch, the meeting was continued, Dr. Shaw taking the chair in the absence of Sir John Eliot.

Prof. Birkeland (Christiania) spoke about the relationship between sun-spots and auroræ. The chief feature was to indicate that "stream lines" from the sun could only reach the earth's atmosphere between very narrow limits, and these in high latitudes, and further that only spots on a restricted portion of the solar disc in relation to the position of the earth would have any terrestrial effect. In this way he suggested a means of explaining the narrow curtain-like form of the aurora and its occurrence chiefly in high latitudes.

A short paper by M. Angot (Paris) described a result which he had derived from an examination of Wolf's sun-spot numbers. He found that, by taking the relative number at a sun-spot minimum and also about a sun-spot maximum, small relative numbers at a minimum are followed by small numbers at a maximum, and large numbers at a minimum by large numbers at a maximum. As the last minimum (1901·7) was small, the next maximum, he suggested, will be small also. As another investigation points to the next maximum being comparatively large, it will be interesting to see which occurs.

The results of an investigation of the upper air over the Mediterranean by means of flying kites from a steamer were described by M. Teisserenc de Bort. He showed that although on the average greater elevation meant greater wind velocity, there were alternately strata of large and small velocities. This fact explains why sometimes attempts at getting kites to fly above certain elevations have failed. Both Mr. Rotch and Dr. Shaw spoke on this interesting question.

Commander Hepworth described the relation between pressure, temperature, and air circulation in the South Atlantic Ocean, the result of a large piece of research work in which 3300 ships' logs had been utilised. In the absence of Prof. K. Ångström, his two papers, on the ultra-violet absorption spectrum of ozone and the existence of that gas in the atmosphere, and an instrument for the measurement of the radiation from the earth, were taken as read, and the meeting closed for the day.

On Monday, the second day on which this subsection met, Sir J. Eliot being in the chair, the reports of the seismological and kites committees were briefly summarised by Dr. Milne and Dr. Shaw respectively.

Mr. A. L. Rotch (U.S.A.) described the results of the experiments he has been making with kites at the Blue Hill Observatory in order to determine the temperature of the air in cyclones and anticyclones. Sir David Gill spoke about an attempt he had made to state the problems in practical astronomy which press for solution. Among these he mentioned the apparent discordance between the value of the constant of aberration as derived from direct observation (20″·52) and that obtained by combining the measured value of the sun's parallax (8″·80) with the known velocity of light, which gives a value of the aberration constant (20″·48). The discussion in the paper confined itself to the means to be adopted for perfecting the determinations of the solar parallax, the constant of aberration, and the mass of the moon. Reference was also made to the variation of latitude, to the Lœwy-Comstock method for determining the aberration constant, to recent improvements in methods of meridian observation, and to the value of old series of observations.

Dr. W. N. Shaw opened the discussion on a memorandum adopted by the committee of the council on the suggested uniformity of units for meteorological observations and measurements. Several speakers gave their views on the subject, but no definite conclusion was arrived at. The general opinion seems to be that either to alter or put additional scales to the barometers and thermometers would, from a practical point of view, be detrimental to the observations themselves. It was suggested that such units might be adopted in the discussion of meteorological problems, the conversions to the new scales being made after the observations had been collected at the central office. From the physical standpoint the subject was not discussed.

In a paper on the masses of stars, Dr. H. N. Russell pointed out that the average mass of fifty-five binary stars is about three times that of the sun. Groups of stars with very different spectra, magnitudes, and proper motions have almost the same average mass. Thus it was concluded that stars vary much less in mass than in other characteristics.

The third and last meeting of this subsection took place on Wednesday, Sir John Eliot being in the chair. The first two items on the programme were the reports of committees on the Falmouth Observatory and on observations of Ben Nevis. In the absence of Prof. O. Backlund (St. Petersburg), his paper on some results of researches on the comet Encke was taken as read.

The writer described briefly the spectroheliograph recently erected at the Solar Physics Observatory, South Kensington. This instrument, which is now in fair adjustment, is used for photographing the sun in monochromatic light. The numerous photographs shown gave an idea of the efficiency of the instrument, and they are now being daily secured, weather permitting. Composite pictures in "K" light were shown, the "limb" and "disc" of the sun being taken on one plate. Many of the photographs showed rapid solar changes, one enormous prominence 192,000 miles in length increasing to 216,000 miles in five hours, its height changing from 55,000 miles to 60,000 miles simultaneously.

In a paper on the unsymmetrical distribution of rainfall about the path of a barometric depression, Dr. H. R. Mill showed that, for the British Isles, the area of heavy rainfall, in nine cases out of ten, lay on the left of the cyclone's path, and in advance of the centre. This relationship suggests that a more definite basis for forecasting heavy rains becomes available if it be possible to ascertain previously the path of the cyclone's centre.

Miss Hardcastle read Miss F. E. Cave's paper, which contained some further results she has obtained relative to

the application to meteorology of the theory of correlation. The two stations taken were Wilmington (North Carolina) and Halifax (Nova Scotia), distant from one another about 1000 miles. Allowing different intervals between the corresponding barometric observations, the magnitude of the correlation was found to vary with these intervals, being greatest when Halifax is taken one day later than Wilmington. It was suggested that for selected places further apart the discovery of correlations of sufficient magnitude might be of use in the practical work of prediction.

Major B. Baden-Powell described briefly the development of the aëroplane, and gave an account of the experiments that he has been recently carrying on. Chief among these were his gliding experiments made at the Crystal Palace, in which he is seeking to find out how a man-carrying machine behaves while travelling in the air.

After a paper by Prof. D'Arcy W. Thompson on Plato's theory of the planets, the business of the subsection came to a conclusion, the following papers being taken as read:— Report of Committee on Underground Temperatures; Dr. F. Hirtel, Zur Flugfrage; Rev. J. M. Bacon, upper air currents and their relation to the audibility of sound; Prof. Lemström (Helsingfors), on the effect of electric air-currents; J. Hopkinson, the rainfall of the midland and eastern counties of England, and the rainfall of England, 1861–1900.

WILLIAM J. S. LOCKYER.

ZOOLOGY AT THE BRITISH ASSOCIATION.

THE meetings of Section D were held in the new Sedgwick Museum of Geology. On Thursday morning, August 18, Mr. W. Bateson, F.R.S., delivered to a large audience his presidential address (see NATURE, August 25), the vote of thanks for which was moved by Prof. Poulton and seconded by Prof. Max Weber. In the afternoon Prof. F. W. Keeble gave an address, illustrated with diagrams and lantern slides, on the coloration of marine Crustacea, embodying results of the researches carried on by Dr. Gamble and himself during the last seven years. He described the prawn-like *Hippolyte varians* which lives among the seaweeds around our coasts, and matches their colour with marvellous precision. Its colours range through green, yellow, and brown to red. When given a choice between different coloured weeds, this animal invariably picks out for its abiding place that weed which is in harmony with its own coloration, a faculty to be ascribed not to the possession of a colour sense by the animal, but rather to an extreme sensitiveness to light. Only in one position, namely, on weed of its own colour, is it in a position of light equilibrium, and then it rests. The coloration of the animal is produced by the manipulation of its three colour pigments, red, yellow, and blue. The common shrimp and prawn were shown to possess the same mechanism, although they make little use of it. Transparent young Hippolytes placed on weed of a certain colour develop the pigment necessary to approximate the animals to that colour in forty-eight hours or less; older animals take almost a week for the same process, and adults a fortnight, but even then the result is imperfect. Though the adults have lost, to a large extent, this power of sympathetic colour change, the pigments react rapidly to changes of light. This reaction is most marked not when the intensity of light changes, but when the background on which the animal rests is changed from white to black, *i.e.* from one which scatters to one which absorbs light. In the daytime the pigments are expanded; at night they are contracted, except the blue, so that the animal has then a transparent azure colour. This is a true periodic change; it has become a habit, and endures for days even though the animals be kept in darkness.

Prof. W. B. Scott, of Princeton, U.S.A., then delivered an address (with lantern illustrations) on the Miocene ungulates of Patagonia The animals described were collected by the Princeton Expedition from the Santa Cruz beds, the Miocene age of which seems to be now established. Prof. Scott pointed out that while these South American ungulates are singularly different (especially in the structure of the periotic region) from those of the northern hemisphere, it is not unlikely that they have a common origin, as Ameghino has described a number of genera from pre-Patagonian formations which, though incompletely known, appear to be referable to the Condylarthra—the parent stock of the northern ungulates. Very probably an early Eocene or late Mesozoic migration carried the Condylarthra into South America, and there, in almost complete isolation, they gradually gave rise to the various peculiar orders of the Noto-Ungulata. The possibility of such a migration is shown by the discovery of an armadillo in the Middle Eocene of North America.

The section was occupied practically the whole of Friday, August 19, with papers and discussions on heredity, Prof. Hickson, F.R.S., in the chair.

The first paper was by Miss E. R. Saunders on heredity in stocks. She said that since the re-discovery of Mendel's work, experimental evidence of the purity of the germ cells has been found in a rapidly increasing number of examples. Much of this evidence has been derived from cases like those studied by Mendel where the differentiating characters are related to each other as dominant and recessive. In such cases the individuals of the (F_1) first generation (DR) show the dominant character, and those of the second (F_2) generation the two parental characters in the ratios 3 D : 1 R or 1 D : 1 R, according as they result from DR×DR or DR×R. In other cases the results are complicated by reversion, gametic coupling of distinct characters, &c., and they require careful analysis, and several generations may be required to elucidate them. As a surface character hoariness is dominant, glabrousness recessive. Experiments in the form DR×DR or DR×R, where D is the white-flowered form of *Matthiola incana* and R a glabrous ten-week strain, give normal Mendelian ratios in F_2. In other cases the result, as regards hoariness and glabrousness, is more complex, owing to the different behaviour of various glabrous strains, which, as far as can be seen, differ only in *flower colour*. As to flower colour, various combinations of colours give reversionary purple in the first generation (F_1). Purple F_1 may also be produced by two white parents if they belong to strains differentiated by the leaf surface. Such purple cross-breeds may give a simple Mendelian result in F_2, or a variety of new colour forms may appear, this latter being commonly seen when cream is one of the parental colours. For example, in a cross of a glabrous white with a glabrous cream, at least nine colour forms were produced in F_2. Whether the appearance of these new forms indicates disintegration or simply re-combination of preexisting characters is uncertain. Creams breed pure at once. Some whites are pure, others are heterozygotes with cream. The number of extracted recessive types resulting from a given union and their specific behaviours are not yet known.

Mr. A. D. Darbishire gave some account of his experiments on the breeding of mice. The Japanese waltzing mice show the well known restless and spinning movements; they have a piebald yellow and white coat and pink eyes. When an albino is crossed with a Japanese waltzing mouse the majority of the offspring are on first inspection indistinguishable from the common house mouse, and they invariably (in all the 300 cases bred) have black eyes. Hybrids never exhibit waltzing movements, and they are never albinos. When such hybrids are bred together they produce offspring which, considered from the point of view of colour, fall into three categories:—(1) those (half the number) with black eyes and coloured coat, and therefore resembling their parents; (2) those (one-fourth) with pink eyes and coloured coat, therefore presenting the same features of eye- and coat-colour as Japanese waltzers; (3) those (one-fourth) with pink eye and uncoloured coat, *i.e.* albinos. About one-quarter of these hybrids waltz, but the rest are normal in their progression, and the waltzing habit may be associated with any of the three colour categories. The albinos (group three) breed true, the pink-eyed mice with coloured coats breed nearly true, and the black-eyed mice with coloured coats produce, when paired together, albinos, pink-eyed mice with coloured coats, and black-eyed mice with coloured coats (proportions of each not yet determined). Some of the facts seem to confirm the Mendelian interpretation, while others may be described in terms of either Galton's or Pearson's formulæ of ancestral inheritance.

Mr. C. C. Hurst described some experiments on heredity in rabbits. An inbred pair of albino Angoras was crossed

reciprocally with an inbred pair of Belgian hares (F_1), and the hybrid progeny were bred with one another for two generations (F_2 and F_3). In F_1 the Angora coat was always recessive to the normal coat, and the albino character recessive to the normal character, while in F_2 and F_3 both these features followed the ordinary Mendelian rules. As to coat colour, in F_1 the first cross of brown and albino gave offspring all of which had wild grey coats. In F_2 the hybrid greys bred together gave a ratio of 9 grey : 3 black : 4 albino, which, when worked out in detail, is in accordance with the Mendelian expectation. Experiments on F_3 proved that the black factor was not introduced by the original brown parent, but by the albino, which, though gametically pure as regards simple albinism, was at the same time carrying the distinct factor for black coat colour.

Prof. Weldon, in opening the discussion, referred to one of Mendel's experiments in which he took a pea of a race producing only seeds with green cotyledons and crossed it with one of another race producing only seeds with yellow cotyledons. The resulting seeds produced plants a quarter of which bore green seeds only, a quarter yellow seeds only, and each of these sets was said to breed true. The remaining half produced seeds with the hybrid properties of their immediate cross-bred parents. Considering how reversion has been found by Mr. Galton in other cases, we might regard the hybrids which made up half the segregation generation as reverting directly to their parents, and the remaining half as reverting to the various green-seeded or yellow-seeded ancestors in various proportions, so that every generation of ancestry was represented to a greater or less extent, the nearer ancestors more frequently, the remoter more rarely. In Mr. Bateson's translation Mendel says that the yellow-seeded individuals reproduce the character of the yellow-seeded "parent form," but we do not know whether Mendel meant the race or one individual of the race. Mr. Bateson and others have adopted the view that, so far as colour is concerned, the green-seeded and the apparently true-breeding yellow-seeded forms were not merely like, but identical with the pure individuals of the green- or yellow-seeded races used in making the original cross. The view attributed to Mendel paid attention to the last two only of the pure-bred ancestors, while that of Galton and others considered that all the ancestors contributed in various proportions to the characters of the subsequent generations. The description of the seed colours is not accurate enough to enable one to decide between these two hypotheses. Because each human being, his parents and grandparents, have seven cervical vertebræ, we have no right to say that we are exactly like our fathers, and that our grandfathers have no share in determining our characters. Again, each of the species included as *Lychnis dioica* has a hairy and glabrous form, the plants resulting from a cross of which are hairy, and the offspring of such hybrids are hairy or glabrous in Mendelian proportions. But we are not told how hairy either plant is. Prof. Weldon counted the hairs on pure-bred hairy plants, and found them to vary from about a dozen to 1300 per sq. cm. of leaf surface. Now if one with 1300 hairs per sq. cm. were crossed with a glabrous plant, and if the offspring had on an average 500 hairs per sq. cm., were they "hairy" like their hairy parent or completely intermediate between the two parents? Questions of this kind required finer methods of observation and description. Again, the frequent existence of reversions to the characters of fairly remote ancestors was inconsistent with the idea that the characters of hybrids might be regarded as due to the combination of "pure" determinants derived from their immediate parents. It had been said that the numerical conclusions drawn from the Mendelian hypothesis agreed so closely with the observed distribution of the descendants of hybrid individuals that these alone justified the conception of gametic purity. It was easy with a small series of results to devise several hypotheses which would fit the results. For example, crossing albino and yellow mice of known ancestry, Cuénot obtained 81 albino, 34 yellow, 20 black, and 10 grey mice, and the remarkable modification of Mendel's theory which he had put forward to describe this result led him to predict the numbers 76, 38, 19, and 19. This was not so good as Prof. Pearson's prediction—82·5, 31, 20·5, 17. In conclusion, he argued that until further experiments and more careful descriptions of results were available, it was better to use the purely descriptive statements of Galton and Pearson than to invoke the cumbrous and undemonstrable gametic mechanism on which Mendel's hypothesis rested.

In the afternoon of August 19 Mr. Punnett, on behalf of Mr. Bateson, described the effects of crossing in fowls, and Prof. Minot added some observations on his experiments upon guinea-pigs.

Mr. Bateson then replied in some detail to Prof. Weldon's criticisms, and maintained that by the Mendelian hypothesis alone was it possible to draw together the vast number of observed facts which had seemed utterly incoherent. The Ancestrians, however, asserted that the laws based on ancestry could cope with the same facts. Prof. Weldon had passed very lightly over the critical fact which finally settled the question—the purity of the characters of the segregated types. None of the various schemes of the Ancestrians had contemplated such purity, and all were totally unable to deal with it. The last attempt to explain away the fact of purity of type was that enunciated to-day by Prof. Weldon, who regarded it as "reversion." But if the "reversion" were so complete as to include even the purity of the parental type, such reversion was Mendelian segregation by another name. The second fact with which the Ancestrians could not deal was the condition of those hybrids or heterozygotes which, though again and again crossed back with pure types, had always the same gametic constitution undiluted. He illustrated this from the work of Mr. R. H. Lock on maize, in which it was shown that, using mongrel materials, as regards yellow and white grains, the inheritance was of a normal Mendelian order. Sweet peas provided further illustrations of the applicability of Mendelian principles to complex cases. It was shown that, in one example, at least eight kinds of purple individuals occur in the second generation, each having distinct powers of transmission, though outwardly indistinguishable. Only minute experiment could distinguish these fundamental differences, which the biometrical system entirely disregarded. The evidence also included one significant case in which sterility of the anthers behaved as a Mendelian character, and made it possible to discriminate two types of extracted whites almost certainly dissimilar in their powers of transmitting colour-factors. Prof. Weldon had asked whether the extracted types showed parental characters unchanged. Frequently the extracted types were identical with the pure, but the question must be answered case by case, according to the special sort of segregation which took place in each case. The Mendelian theory had begun to coordinate the facts of heredity, until then utterly incoherent and contradictory. The advance made in five years had been enormous, and he had no doubt of the result.

Prof. Karl Pearson said that the great revolution which Mr. Francis Galton introduced into biological study was purely a difference of method. The introduction of methods of precision had nothing to do with Mendelism or ancestral law. He had seen the Mendelians produce figures without making any attempt to show that the figures were consonant with the theory they were supposed to illustrate. He believed he had elaborated the most complete Mendelian system ever yet worked out, but this led to general principles which were singularly like those proposed by Galton from observation. He asked from the Mendelians some definite theory which could be worked out, and for further work, for the controversy could only be settled by investigation, not by disputation.

After some remarks by Prof. Hubrecht and Rev. T. R. R. Stebbing, who said that interest in this important inquiry was greatly quickened by the controversy, and hoped it would continue, as from it the world could only gain the light, Prof. Hickson (from the chair) closed the discussion by saying that the subject in dispute was of the greatest importance, and the debate had been of much value to those biologists who were still "sitting on the fence."

In the zoological laboratory there were numerous exhibits of the specimens used in these various experiments on heredity.

At the invitation of His Grace the Duke of Bedford, a party of twenty-five zoologists visited Woburn Abbey on Saturday morning, August 20. The party was met by two representatives of the Duke of Bedford, and driven over the estate to see the splendid collection of animals there maintained in such excellent condition. Numerous species of

deer, the nilgai, gnu, eland, buffaloes and European bison, giraffes, and a fine series of Prjevalsky's horse were greatly admired. Mr. R. Lydekker (the leader of the party) and Prof. Ewart pointed out the interesting features of the rarer forms. The party was afterwards entertained to lunch, and conducted through the picture galleries of the abbey.

On Monday morning, August 22, Dr. C. W. Andrews gave an address on Egyptian Eocene vertebrates and their relationships, particularly with regard to the geographical distribution of allied forms.

Prof. Keibel, of Freiburg, exhibited some "Normentafeln" of the development of Vertebrata, and also some original drawings of embryos of apes. He stated that although there is a close resemblance between these and human embryos in a similar stage (as Selenka has shown), there are found on further examination various differences—apart from the tail—not only between human and Simian embryos, but also between those of different species of apes, so that the species may be determined without difficulty in embryos from the fourth to the fifth weeks.

Then followed communications by Mr. A. E. Shipley, F.R.S. (on behalf of Dr. Elliot Smith), on Looss's researches on *Ankylostoma duodenale* (miner's worm); by Prof. G. N. Calkins on *Cytoryctes variolae*, Guarnieri, the organism of small-pox; and by Dr. J. A. Murray on the biological significance of certain aspects of the general pathology of cancer (for abstracts see NATURE, September 22, p. 519).

Dr. T. H. Bryce demonstrated a series of slides illustrating the histogenesis of the blood of the larva of Lepidosiren.

Mr. J. W. Jenkinson gave an account of the origin of the cleavage centrosomes in the egg of Axolotl. The middle piece of the spermatozoon, after forming the centre of the sperm-sphere and sperm-aster, completely disappears. At a later stage a centrosome is formed from the sperm-nucleus, and this divides to give rise to the cleavage centrosomes. A watery substance collects in vacuoles in the centre of the sperm-sphere, which suggests that the sperm introduces into the ovum a hygroscopic substance.

Four papers from the Irish Fisheries Laboratory were then read by Mr. Tattersall.

Messrs. E. W. L. Holt and W. M. Tattersall described some new and rare Schizopoda from the Atlantic slope on the west of Ireland, Mr. Tattersall some Isopoda, and Mr. G. P. Farran some Copepoda from the same region. Many of the Isopoda and Copepoda collected appear to be identical with, or closely allied to, Norwegian forms. Mr. Tattersall also gave a brief account of a new species of Dolichoglossus. It was found in Ballmakill Harbour, co. Galway, in coarse sand and mud at extreme low water spring tides, eight to twelve inches below the surface, in tubes of sand cemented by mucus. A nearly complete specimen measured 12·5 cm. Its chief points of interest are two proboscis pores, complete and continuous lumen of stomochord, and the great size of the pericardium.

The proceedings on Tuesday morning, August 23, were opened by Prof. Graham Kerr's account of the work of the late Mr. J. S. Budgett on the development of Polypterus. A series of lantern slides, most of which had been prepared from Mr. Budgett's drawings, showed that as regards external characters the development was very like that of an amphibian. There is a pair of true external gills and a pair of cement organs. Dr. Harmer and Prof. Bashford Dean spoke in appreciative terms of Mr. Budgett's work.

Mr. E. J. Bles contributed some notes on the development of *Phyllomedusa hypochondrialis*, Cope. The material described was obtained by Mr. Budgett in South America. Just before hatching paired cement organs are present as vestigial structures, but soon disappear without having become functional. This indicates that Phyllomedusa is probably descended from a form which, like our European Hyla, was hatched as a heavily yolked larva which hung from its cement organ until the yolk was absorbed. The amount of yolk in the egg of Phyllomedusa (which is now large) has probably only comparatively recently increased. There is also a glandular frontal organ in Phyllomedusa probably of use in assisting the embryo to escape from the egg-membranes. The thyroid gland in Phyllomedusa differs from that of other tadpoles, and is more like the early thyroid of Ammocœtes, as it reaches along the whole length of the floor of the buccal cavity. The subnotochordal rod is also conspicuous. The pectoral lymph-hearts in this, as in other tadpoles, appear not at the metamorphosis, but when the tadpole has still a solid intestine and the yolk has almost disappeared from all the other tissues. The wall of the lymph-heart appears to be derived from an outgrowth of the posterior cardinal vein, and before the valves are formed the lumen of the lymph-heart contains blood corpuscles.

Prof. C. S. Minot then communicated three papers. In the first he presented the theory of cellular rejuvenation, which he claimed must be defined as the increase of the nuclear substance in proportion to the amount of the protoplasm. This increase occurs during the period of segmentation of the ovum, is the immediate result of impregnation, and results in the production of rejuvenated cells, *i.e.* cells with a very small amount of protoplasm around their nuclei. These cells and their descendants then enter upon a career of cellular senescence. In an experiment with telegony Prof. Minot used females of a known race the virgin does of which were allowed to breed with a male of entirely different strain, about half the offspring having the paternal colour. The same does were afterwards allowed to breed with bucks of their own race, and in no case was there any trace of the colour of the telegonous father in the offspring. Prof. Minot gave an account of the Harvard embryological collection, which comprises more than 800 series of sections of vertebrate embryos, and pointed out its value in aiding research.

Dr. G. H. F. Nuttall, F.R.S., gave a paper on the precipitin tests in the study of animal relationships. He briefly described the methods of testing by means of precipitating antisera, and pointed out two practical applications of the test—in legal medicine for the identification of blood stains, and in the study of animal relationships. For example, this method has demonstrated a close relationship between Hominidæ and Simiidæ, a more distant one between these and Cercopithecidæ, a slight bond connecting all of these with the New World monkeys. The lemurs do not appear to be connected with the Primates any more than do other mammals. The test appears to connect the Cetacea with the Ungulata, and the Reptilia with the Aves.

In reply to a question by Prof. Poulton, Dr. Nuttall stated that tests of the blood of Echidna do not indicate any relationship between this animal and other mammals.

Prof. E. B. Poulton, F.R.S., gave a paper on the mimetic resemblance of Diptera to Hymenoptera, to which Lord Avebury, Mr. Bateson, and Mr. O. Latter added further observations.

In the afternoon of August 23 three addresses dealing with the evolution of the horse were delivered by Profs. Osborn, Ewart, and Ridgeway (for abstracts see NATURE, September 22, p. 520).

On Wednesday morning, August 24, Mr. J. W. Jenkinson gave an account of the effects produced by growing frog-embryos in salt and other solutions. The object of the experiments was to discover whether the distortion of development produced by growing the eggs of the frog in a 0·625 per cent. solution of sodium chloride is due to the physical (increased osmotic pressure) or chemical properties of the solution or both. The monstrosity consists of (1) failure of the blastopore to close, so that a large persistent yolk-plug is produced, and (2) the failure, total or partial, of the medullary folds to close. Solutions of chlorides or bromides of barium, calcium, &c., cause death of the egg at an early stage, possibly due to the formation of insoluble carbonates in the cells. When kept in chlorides or bromides of potassium, lithium, &c., the egg loses its power of elongating in the direction of the long axis of the embryo, but differentiation of the germ-layers and organs proceeds; ultimately degeneration and disintegration of the tissues set in. In sodium or magnesium chlorides or nitrates the embryo is able to elongate, but development is abnormal. In solutions of urea or sodium sulphate development is nearly or quite normal, especially in the latter solution, in which the tadpoles will live for weeks. Mr. Jenkinson thinks the various phenomena are to be attributed to the poisonous properties of the substances employed.

Prof. M. M. Hartog showed lantern slides of magnetic models of cellular fields of force. He remarked that there is in the dividing cell a dumb-bell-shaped structure recalling the figure of the "field of force" manifested by sprinkling

a sheet of paper, overlying two poles of a magnet, with magnetic dust. He showed photographs of various "fields" obtained by a combination of electromagnets, and pointed out that all the cellular phenomena could be reproduced by the action of a polar or dual force such as statical electricity or magnetism, and that the apparent anomalies were due to the peculiar conditions of the protoplasm in which the field was formed. He also showed some beautiful sections of the embryos of Rhynchelmis, lent by Prof. Vejdowsky, of Prague, in which the dumb-bell-shaped figure is of exceptional size.

GEOGRAPHY AT THE BRITISH ASSOCIATION.

As the exploration of the higher mountain areas has been mainly the work of university men, it was very appropriate that Mr. Douglas Freshfield, one of the pioneers of Alpine exploration, should be president of the geographical section at Cambridge. No one was better qualified than he to deal with mountains and mankind, which formed the subject of his address, which has already appeared in NATURE (September 1).

Several other communications dealt with the "culminating area" of the globe, as Hermann Wagner calls it. Mr. Maurice de Déchy contributed a full account of the glaciers of the Caucasus, which at one time were supposed to be of very small dimensions. He gave statistics of the altitude of the snow-level in different parts of the system, showing how it rose towards the Caspian, and of the dimensions of the principal glaciers, including the depth to which their tongues descended below the snow-level. He then surveyed the variations of ice movements during the past half century, and pointed out how they corresponded with those which have been observed in the Alps. Finally, he referred to the evidences of the former great extension of the glaciers. Mr. Charles Rabot, secretary of the Paris Geographical Society and of the French Glacial Commission, discussed the importance of glacier-bursts in shaping the topography of glaciated areas. These bursts are due to the creation and subsequent sudden discharge of a reservoir of water, by a glacier dam due to the ice stopping the exit from a valley and the consequent accumulation of water, or to water gathering above, below, or in the glacier itself. The violence of the outburst is proportional to the volume of the water and the slope of the ground. In 1878 the Märjelensee discharged 7,700,000 cubic metres in nine hours, and the Gietroz outburst of 1818 attained a volume of 530,000,000 cubic feet. Twenty-five such outbursts are known to have taken place in the Alps, and they have been reported from all glaciated mountain areas. Their effects are necessarily confined to modifying the contours of the valley, by enormous erosion above, and by the deposition of vast masses of waste below. In discussing glacial phenomena, sufficient importance has probably not been given to these torrential outbursts, which must have been commoner in Pleistocene times. Mr. A. W. Andrews showed a number of excellent maps and views of passes of the Alps in order to prove that in teaching a well chosen set of lantern slides could be used to bring out their characteristic natural features, and to indicate their relation to routes, &c.

There was no tale of startling adventure recounted, but a number of excellent travel papers was read. Mr. Bruce's account of the Scottish National Antarctic Expedition, while barren in hair-breadth escapes, was one of steady scientific investigation under very difficult conditions in perhaps the most interesting area of the Antarctic. Notable though the discovery of the northern Atlantic margin of Antarctica and the depths of the ocean to the north are, the oceanographic, biological, and more particularly the meteorological work of the expedition are likely to yield results of the greatest value. It is a matter of congratulation that Mr. Mossman, probably one of the best living meteorological observers, remains in the south with the cooperation of the Argentine Government, for there the study of meteorological conditions is more important than elsewhere in high southern latitudes in view of the dangers attending the rounding of Cape Horn, and the importance of an investigation of the centres of atmospheric activity controlling its meteorology.

The papers dealing with distant lands described the low-lying Malabar coasts, the savanna lands of northern Nigeria, the fertile Cyrenaica, and the puna of the Andine plateau. Mr. R. S. Pepper gave a comprehensive account of the climate, products, and peoples of the Malabar coast, illustrated by excellent views. He pointed out the great progress which had been made during the past half century, and insisted on the economic value of the region. Major J. A. Burdon, Resident of the Sokoto Province, described the Fulani Emirates of northern Nigeria in a communication which it would be difficult to over-rate. The impressive contrasts between the conditions in this laterite plateau dissected by broad flat valleys, leaving monotonous table-topped hills covered with open brush, and the dense forests of southern Nigeria were admirably shown, and the resulting effects traced—Paganism and degenerate peoples in the forest belt, Islam and a well developed social organisation in the north. The effects of the nomad Fulani conquest of the region were traced, and form an interesting contribution of the evidence which goes to prove that a definite type of social organisation is connected with nomadic pastoral peoples all the world over, and that a fairly constant series of events follows the thorough conquest of a settled people by such nomadic tribes. The present British administration is fortunately inspired by the scientific spirit of constructive action based on existing institutions.

In 1903 Mr. Arthur Hill made a journey to Lake Titicaca. The uniformity of the vegetation at altitudes from 12,500 to 16,500 feet was striking; the plants growing in rosettes have long tap-roots by which they reach the warmer soil at some distance below the surface, and their leaves are linear and hairy, and suited to the dry air subjected to temperature variations of as much as 70° F. within a few hours.

Mr. D. G. Hogarth spent nearly a week in Cyrenaica in April, 1904, and was able to note certain geographical facts which explain some of the peculiarities of Cyrenaic history. He pointed out that changes of coastal level must have taken place since ancient times. This point is of considerable importance, as Mr. R. S. Günther showed by a series of maps and photographs of the Neapolitan region. In a paper descriptive of these he summarised the results of his investigations on the Bay of Naples,[1] where he found a mediæval land level 12 to 23 feet below the present one, and a Græco-Roman land level some 16 feet above the existing level, and therefore in places 40 feet above the mediæval one. Round Genoa the coasts were also lower in the thirteenth and fourteenth centuries, and the Nile delta has been shown to be higher in classical times. The old shore lines are not horizontal, and Mr. Günther considers that land oscillations have been the cause of the changes of level. In the discussion which followed Messrs. R. D. Oldham and J. Y. Buchanan both pointed out other changes which had been observed in the level of the Mediterranean. A special committee to investigate the evidence was appointed by the general committee. The two afternoon lectures arranged by this section had reference to the Mediterranean basin; and Dr. Tempest Anderson's views and description of the Lipari Islands reminded his hearers of the obvious unstable condition of part of it at the present day. Mr. Silva White's admirable account of the Nile Valley emphasised its organic unity, its physical and political insularity, which has resulted in the political control of Egypt since the time of Alexander the Great by the Power possessing command of the sea. He also showed some views, and gave an eloquent description of the desert barrier which surrounds it.

Coming to our own country, the papers dealt with problems within the sphere of influence of Cambridge. Mr. H. Yule Oldham, reader in geography at Cambridge, discussed the changes in the fen district since the seventeenth century, when the tides came up the Ouse and nearly reached Cambridge. By the cutting of the new Bedford River and the building of the sluice at Denver, the tidal waters were diverted up the new river, and this permitted the drainage of the fens. The old course of the Ouse was indicated in modern maps by the irregular boundary between Cambridgeshire and Norfolk, which followed it. Mr. R. H. Yapp dealt with the vegetation of the fen region, and by a series of excellent slides showed the characteristic forms found in different edaphic conditions. The Rev. Alfred Hunt claimed the hamlet of

[1] The full report is published in the *Geographical Journal* for August and September, 1903; and in *Archaeologia*, lviii.

Burnham, in the parish of Thornton Curtis, in north Lincolnshire, four miles from the Humber, where entrenchments have been found, as the site of the battle of Brunanburh, when, under Athelstane, the south of England obtained the dominance over the north.

Dr. Mill exhibited and described a map showing the names of the physical features of England and Wales to which the Royal Geographical Society's council had given its imprimatur. Mr. Whitaker protested against the use made of the term weald, the new name given to Ashdown Forest, and other points. It is to be hoped that after a thorough discussion by all interested a general agreement will be come to as to the use of topographical terms. The majority of those on the map will be accepted by all.

Three papers dealt with map-making. The Rev. H. S. Cronin described what he believed to be the way in which Ptolemy constructed his map of Asia Minor, and pointed out how wrong conclusions were certain to arise from treating it as if it were a modern map, or his geography as modern geography. Mr. C. R. Beazley contributed an account of the Portolani of the early fourteenth century, the first true maps of the Mediterranean. Major C. F. Close discussed the methods of topographical surveying suitable for different countries, choosing the United Kingdom, India, the Gold Coast, where "long traverses" are necessary owing to the dense forest making the cost of triangulation prohibitive, South Africa, already triangulated and ready for plane tabling, which can be carried out in the open country under very favourable conditions, and Canada, for which a scheme has recently been drawn up by Major Hills. In Canada, in very special circumstances, photographic surveying has been carried out, but Major Close considered that ordinary methods under ordinary conditions were better as regards accuracy, rapidity, and cost. This was queried in the subsequent discussion. Sir David Gill dealt with the condition of the South African survey, which owes so much to him.

FIG. 1.—A Roll Wave leaping the Outfall of the Grünnbach Conduit.

The report by Dr. Cornish of the committee on terrestrial surface waves and wave-like surfaces was read. It contained a description of roll waves, a term used to describe waves resembling a bore travelling down stream more rapidly than the current in such open paved conduits as the lower courses of the Guntenbach and Grünnbach, which flow into the Lake of Thun (see Fig. 1). The phenomenon has been noticed on the Tees. The committee was re-appointed.

The geographical section combined with the zoological one to recommend the appointment of a committee to carry on physical and biological investigations in the western Indian Ocean under the leadership of Mr. Stanley Gardiner. This was duly appointed, and a grant of 150*l.* assigned to it.

Another important committee was nominated on the joint recommendation of geologists and geographers to collect information and report on the meaning and distribution of local terms given to topographical and geological features.

CONFERENCE OF DELEGATES OF LOCAL SCIENTIFIC SOCIETIES.

TWENTY years have passed since the local scientific societies of this country first had the opportunity of coming into official relation with the British Association. Although it is believed that this relationship has been, in various ways, of much benefit to many of the societies, it must be admitted that the results, viewed as a whole, have hardly equalled the expectations which were originally entertained when the scheme of affiliation was projected. This view was prominently brought forward at the conference of delegates from the corresponding societies recently held at Cambridge.

The chairman of the conference, Principal E. H. Griffiths, F.R.S., of Cardiff, pointed out the desirability of binding together all the scientific societies of this kingdom, so that they could move, in matters of national importance, as one body. He pictured them, at present, as a scattered heap of iron filings, waiting for the British Association to act as a magnet in their midst, so as to "transform the confused assemblage into a field of symmetry and beauty."

The work of the local societies may be said, broadly speaking, to be of two kinds, *educational* and *technical*, the latter including observational and investigational work. Of these branches, the chairman was disposed, in the present state of things, to regard the former as the more important. "The work is educational not only in arousing intelligent interest in the facts of natural science and quickening in the individual the power of observation, but also in promoting the missionary spirit which will enable the members to excite the interest and sympathy of their neighbours."

In order to extend the influence of the British Association, Principal Griffiths suggested some relaxation in the rules which now regulate the admission of societies. At present no society can be brought into union unless it publishes the results of original investigations. But, said he, "it is very doubtful if publication *is* the best test of merit"; and he added that if we exclude those societies which "refrain from adding to the mass of literature under which there is danger of our being smothered, it is possible that we are excluding the very bodies whose sympathy and interest we should most wish to encourage."

Principal Griffiths was accordingly led to advocate the recognition of two classes of corresponding societies, one to be called affiliated societies, conforming to the existing regulations, the other to be called associated societies, including any local society which has existed for a period of, say, three years, and numbers not fewer than fifty members. "Surely," said the chairman, "we desire to throw our doors as wide open as possible, surely we wish to give every encouragement to all scientific societies, but more especially to those working under difficulties, to strengthen the hands of their promoters, and to ask their aid and assistance in our deliberations. Moreover, it is precisely those societies with narrow means, and whose members are possibly drawn from working classes, that can be of the greatest use to us. They are missionaries situated where we most want them, and preaching to the unconverted. This yearly meeting of single delegates from a few of the leading societies, although an admirable nucleus, is not sufficient to produce crystallisation of the scientific interests in solution in the population of this kingdom."

As a means of inter-communication between the societies, and with the view of uniting them "in common action for

the attainment of some purpose of national or scientific importance," Principal Griffiths advocated the publication of a *Journal of Corresponding Societies*, towards the expenses of which the various societies should contribute according to the respective numbers of their members.

The chairman's views were received with much favour by the delegates and others attending the meeting. Sir Norman Lockyer referred to his presidential address of last year, in which he suggested that the organisation of the corresponding societies might become a potent and valuable machine for influencing public opinion on matters relating to science throughout the country. He regarded the corresponding societies as having before them an important and undeveloped field of work. With regard to the Corresponding Societies Committee, he advocated more frequent meetings and a closer union with the central organisation of the British Association. Mr. W. Whitaker agreed with the chairman that the time was come when it seemed desirable to reconsider, and possibly revise, the old conditions regulating the affiliation of local societies. He considered that the maintenance of a good museum might be as much a ground for union as the publication of a volume of proceedings. The Rev. W. Stallworthy advised the appointment of a small number of competent members as inspectors, who should visit the various local societies and report upon their work to the authorities at headquarters. Prof. Ewing advocated the admission of the smaller societies in outlying districts, where publication was not to be regarded as the test of usefulness. Dr. G. Abbott supported the views of the chairman, and enlarged on the advantage of uniting societies in local groups. Many societies in the south-east of England had been strengthened by such a union. He thought that the British Association should get into touch with as many societies as possible, and that no barrier should be raised, such as that of publication. The Rev. T. R. R. Stebbing deprecated publication being used as a test of the usefulness of a society. If the paper were important, it ought to go to a central society, and not be published locally; if it were unimportant, it were better not published at all.

Ultimately a committee was appointed to consider the present relation between the British Association and the local scientific societies, and to make suggestions to the council with a view to the greater utilisation of this relationship, and the extension of affiliation to societies now excluded.

The subject of museums, which has often been discussed at the annual conference of delegates, was brought forward by the Rev. W. Johnson, of York, who read a paper on the utilisation of local museums, with special reference to schools. He believed that provincial museums have often failed in developing the scientific habit in visitors, because they have given too much prominence to rarities, whereas the beginner needs illustrations of common objects, such as he is likely to find in his own study in the field. A large amount of material now lies buried in our museums needing judicious display and description to render it available to the young student. Mr. Johnson held that every museum should have attached to it a demonstration room, fitted with lanterns and other lecture-room appliances, and he considered that demonstrations by competent persons might well be paid for by the State, in consideration of their value in assisting the higher science teaching in our schools. The excellent work of Mr. Crowther, the curator at Leeds, in giving demonstrations to children from the local schools, was referred to with warm approval. Mr. Johnson recommended that during the winter-holidays museum-lectures should be given on elementary meteorology, explaining the nature and use of the various instruments which are used at most museums for obtaining weather records.

In discussing the paper, Mr. Rudler referred to the difficulties incidental to museum demonstrations, and advocated the delivery of the lecturette in a separate room, followed by adjournment to the museum. The interest of the delegates in the museum question centred in the point of contact between the local museum and the local society, and he referred to some of the ways in which the society might assist the museum, such as the frequent display of fresh specimens of wild flowers with instructive labels. Whilst admitting the importance of taking children to the museum, he held that it was equally desirable to take the museum to the children, and he consequently favoured the practice of circulating educational cabinets of specimens among the local schools.

At the second meeting of the delegates, Mr. J. Hopkinson, of the Hertfordshire Natural History Society, brought forward a very practical subject relating to the publications of scientific bodies. He denounced the insufficiency of the title given in certain papers, and the absence of an index, a table of contents, or a list of plates in the publications of many societies. The date of publication of each part or number of a volume of proceedings should always be given, and in the case of reprints of papers, the original pagination should be preserved, whilst the date and volume of the publication from which they are extracted should invariably be stated. Dr. Tempest Anderson, who presided at the second meeting of the delegates, spoke strongly in favour of securing uniformity in the size of the publications of scientific societies.

In the discussion on the aid which local societies could give to the work of the committees of various sections of the British Association, Dr. H. R. Mill, as a delegate from Section A, pleaded for increased interest in meteorology, and urged the local societies to take regular and systematic observations. Mr. Whitaker, on behalf of Section C, solicited the aid of the societies in seeking the derivation and precise significance of local terms relating to geological and geographical subjects—an appeal which was supported by Dr. Herbertson, representing Section E. The Rev. T. R. R. Stebbing, speaking for Section D, suggested, as additional work for local societies, the study of overland lines of migration of birds, and the collection of slugs from all parts of the British Isles. Miss Sargent solicited information with regard to certain points in the growth of British orchids. The conference was not favoured with suggestions from any of the other sections.

EOCENE WHALES.

A MOST important contribution to our knowledge of the extent and affinities of that group of Eocene marine mammals known as Archæoceti has recently been made by Prof. E. Fraas, of Stuttgart, in an illustrated memoir entitled "Neue Zeuglodonten aus dem unteren Mitteleocän vom Mokattam bei Cairo," published in Koken's *Geologische und Palaeontologische Abhandlungen.* The Archæoceti, or zeuglodonts, which have hitherto been definitely known only by various species of the typical genus Zeuglodon, have been regarded by many zoologists as the direct ancestors of the modern whales and dolphins, and if this view be accepted, it has for some time been evident (although this was not the opinion of the late Sir William Flower) that the toothed whales, at any rate, are probably the descendants of carnivorous mammals, as it seemed impossible that the zeuglodonts could be derived from a herbivorous type.

The carnivorous descent of the zeuglodonts is now fully demonstrated by Prof. Fraas, who describes two new generic representatives of the group—Protocetus and Mesocetus—from the well known Middle Eocene nummulitic rocks of the Mokattam range near Cairo. Of the former genus the author figures a nearly complete skull, together with many of the bones of the skeleton. In both genera the teeth are of the typical mammalian number, and divisible into incisors, canines, premolars, and molars, the latter, in Protocetus at any rate, being quite unlike the corresponding teeth of Zeuglodon, and approximating to those of the primitive Eocene Carnivora of the group Creodontia. The skull, moreover, although much more elongated than in any of the land forms, presents all the distinctive characteristics of the latter group, and there can be little hesitation in accepting Prof. Fraas's view that Protocetus and Mesocetus form connecting links between the terrestrial creodont carnivores on the one hand and the marine zeuglodonts on the other. They are, in fact, terrestrial animals in course of modification into purely aquatic ones. Prof. Fraas does not, however, by any means stop at this, but proceeds to argue that the Archæoceti are entirely unconnected with either the whalebone or the toothed whales, and merely form a marine group of Creodontia which died out without leaving any descendants. As he rightly observes,

we have evidence that members of several distinct groups of reptiles—the ichthyosaurs, the plesiosaurs, the marine crocodiles, and the mosasaurs—were independently modified for a marine existence, and there is no reason why a similar state of affairs should not have occurred among mammals.

This is doubtless true; but it has to be borne in mind that, so far as we can see, the new discoveries in no wise affect the alleged relationship of Zeuglodon to the Cetacea, which, if well founded previously, apparently still remains so. Moreover, if we remember rightly, Dr. Elliot Smith, in a recent paper on the brain of the Archæoceti, has pointed out very definite cetacean resemblances, which it would be difficult to explain as due solely to parallelism. Again, if we remove the Archæoceti from the cetacean line, there are no possible ancestors for the whales to which we can point, and, in the present comparatively advanced position of the palæontological record, it would be strange indeed if the past history of the Cetacea (with the exception of forms belonging to the existing groups) were an absolute and complete blank.

While according therefore to Prof. Fraas full credit for having brought the zeuglodonts into phylogenetic relationship with the creodont carnivores, we may be permitted, perhaps, to reserve our judgment as to whether he has succeeded in demonstrating the absence of relationship between the former group and modern whales.

R. L.

FORTHCOMING BOOKS OF SCIENCE.

MR. GEORGE ALLEN directs attention to:—"The Glamour of the Earth," by G. A. B. Dewar, illustrated; "A Volume on Bird Life," by E. Selous, illustrated; and "Recent Discoveries and Excavations in the Forum, 1898 to 1904," by St. Clair Baddeley, illustrated.

Mr. Edward Arnold announces:—"The Becquerel Rays and the Properties of Radio-active Substances," by the Hon. R. J. Strutt; "The Chemical Synthesis of Vital Products and the Inter-relations between Organic Compounds," by Prof. R. Meldola, F.R.S.; "Experimental Researches with the Electric Furnace," by Prof. H. Moissan, translated by Dr. A. T. de Mouilpied; "Physical Chemistry in Biology and Medicine," by Prof. B. Moore; "Astronomical Discovery," by Prof. H. H. Turner, F.R.S.; "The Theory of Optics," by Prof. A. Schuster, F.R.S.; "Preliminary Practical Mathematics," by S. G. Starling and F. C. Clarke; "The Evolution Theory," by Prof. A. Weismann, translated by Prof. J. A. Thomson, two volumes, illustrated; "Nature Study in the House, Garden, and Field," by Prof. L. C. Miall, F.R.S.; "Lectures on Diseases of Children," by Dr. R. Hutchison; "A Manual of Pharmacology for Students," by Dr. W. E. Dixon; "Recent Advances in Chemical Physiology," by Drs. A. P. Beddard, L. Hill, F.R.S., J. J. R. Macleod, B. Moore, and M. S. Pembrey; "Exercises in Arithmetic," oral and written, by C. M. Taylor, part iii.; "The Elements of Trigonometry," by Dr. R. Lachlan and W. C. Fletcher; "A Second Geometry Book," by J. G. Hamilton and F. Kettle; and new editions of "Electrical Traction," by Prof. E. Wilson; and "Human Embryology and Morphology," by Dr. A. Keith, illustrated.

Messrs. Baillière, Tindall and Cox's list includes:—"Manual of Anatomy" (University series), by Dr. A. M. Buchanan; "Malignant Diseases of the Larynx," by P. de Santi; "Psychiatry," by Prof. Bianchi, translated by Dr. J. H. MacDonald; "Appendicitis," by H. W. Allingham; "Guide to the Examination of the Throat, Nose, and Ear," by Dr. W. Lamb; "After-Treatment of Section Cases," by Dr. W. J. S. McKay; "Aids to Pathology," by Dr. W. d'Este Emery; "Aids to Sanitary Law," by Dr. H. G. Critchley; "Coroner's Duties," by R. H. Wellington; "Ship Surgeons' Pocket-book," by W. E. Dawson; "Surface Anatomy," by J. G. Morehead; "Artistic Anatomy of Animals," by Prof. E. Cuyer, translated by G. Haywood; "Diseases of Foot of the Horse," by H. C. Reeks; "Veterinary Ophthalmology," by Captain H. T. Pease; and new editions of "Handbook of Diseases of the Ear," by R. Lake; "Diagnosis and Modern Treatment of Pulmonary Tuberculosis, with Special Reference to the Early Recognition and Permanent Arrest of the Disease," by Dr. A. Latham; "After-treatment of Surgical Operations," by Dr. P. L. Mummery; "Manual of Veterinary Hygiene," by Lieut.-Colonel F. Smith; "The Nutrition of the Infant," by Dr. R. Vincent; "The Röntgen Rays in Medical Work," by Dr. D. Walsh; and "Handbook of Surgical Pathology," by Dr. W. J. Walsham.

The list of Messrs. W. Blackwood and Sons contains:—"Philosophy as Scientia Scientiarum," by Dr. R. Flint; and new editions of "The Ethics of Naturalism, a Criticism," by Prof. W. R. Sorley; and "The Forester, a Practical Treatise on Planting," by Dr. J. Nisbet, two vols., illustrated.

In the list of Messrs. Burns and Oates, Ltd., we notice:—"Stars without Stripes, being a Grand Review of the Planetary System held by his Sovereign the Sun, with a Foreword," by A. M. Clerke.

Messrs. Cassell and Co., Ltd., promise:—"Serums, Vaccines, and Toxines, in Treatment and Diagnosis," by Dr. W. C. Bosanquet; and "The Student's Handbook of Surgical Operations," by Sir F. Treves, Bart., K.C.V.O., abridged from the new edition of "The Manual of Operative Surgery," illustrated.

The following are in preparation at the Clarendon Press:—"The Ancient Races of the Thebaid, being an Anthropometrical Survey of the Inhabitants of Upper Egypt from the Earliest Prehistoric Times to the Mohammedan Conquest of Egypt," by Dr. A. Thomson and D. Randall-MacIver; Suess's "Das Antlitz der Erde," authorised English translation, by Dr. H. Sollas, edited by Prof. W. J. Sollas, F.R.S., with preface written by Prof. Suess for the English translation; "Index Kewensis Plantarum Phanerogamarum. Supplementum secundum, nomina et synonyma omnium generum et specierum ab initio anni 1896 ad finem anni 1900 complectens"; Goebel's "Organography of Plants," authorised English translation, by Prof. I. Bayley Balfour, F.R.S., vol. ii., "Special Organography"; "A Geometrical Political Economy: being an Elementary Treatise on the Method of Explaining some of the Theories of Pure Economic Science, by means of Diagrams," by H. Cunynghame, C.B.; "India," by Sir T. Holdich, K.C.I.E.; and "The Farther East," by A. Little.

Messrs. T. and T. Clark announce:—A new series, "The Library of Ancient Inscriptions," in which will appear "Babylonian and Assyrian Laws, Contracts, and Letters," by the Rev. C. H. W. Johns; "History of the Discovery and Decipherment of the Ancient Inscriptions," by Prof. C. F. Kent and Dr. G. A. Reisner; "Babylonian and Assyrian Epics, Penitential Psalms, Proverbs, and Religious Texts," by Prof. F. Delitzsch; "Egyptian Religious, Magical, Medical, and Scientific Texts, Legal and Business Documents," by F. L. Griffith; "Assyrian Historical Inscriptions," by Prof. M. Jastrow; "Inscriptions of Palestine, Syria, and Arabia," by Prof. C. C. Torrey; "Egyptian Tales, Proverbs, Poems, and Belles-Lettres," by Prof. Maspero; "Egyptian Historical and Biographical Inscriptions," by Prof. W. Max Müller. They also promise "By Nile and Euphrates: a Record of Discovery and Adventure," by H. V. Geere.

Mr. W. B. Clive's list contains:—"A Higher Text-book of Magnetism and Electricity," by Dr. R. W. Stewart; "Technical Electricity," by Prof. Davidge and R. W. Hutchinson; "Preliminary Geometry (part i., the Junior Geometry), for the Preliminary Cambridge Local," by W. P. Workman; "Tutorial Geometry," by W. P. Workman; "School Magnetism and Electricity," a school course by Dr. R. H. Jude; "Properties of Matter"; "Practical Physics"; "First Stage Theoretical Organic Chemistry," by R. A. Lyster; "First Stage Physiology"; "First Stage Human Physiology"; "First Stage Applied Mechanics"; "Deakin's Algebra," scholarship edition; "Scholarship Geometry"; "Scholarship Graphs"; "Scholarship Elementary Science," section i.; "Scholarship Elementary Chemistry"; "Scholarship Elementary Astronomy"; "Scholarship Elementary Biology"; "Deakin's Algebra," certificate edition, by Rupert Deakin; "Deakin's Euclid," certificate edition, Books i., ii., iii., iv. (1–10), vi. (1–4), by R. Deakin; "Graphs," the graphic representation of algebraic functions; General Elementary Science, part i., "Physiography," part ii., "Biology"; part i. "School and Home Hygiene," by R. A. Lyster; and new editions

of "New Matriculation Chemistry"; "Tutorial Chemistry," part i.; "First Stage Building Construction," by B. Cunningham; "First Stage Magnetism and Electricity," by Dr. R. H. Jude.

Messrs. Archibald Constable and Co., Ltd., announce:—"Wanderings in the Great Forests of Borneo, Travels and Researches of a Naturalist in Sarawak," by Dr. O. Beccari, revised and edited by Dr. F. H. H. Guilleman, illustrated; "Agricultural and Pastoral Prospects in South Africa," by Colonel O. Thomas; "The Conception of Immortality," by Prof. W. Royce, being the Ingersol lecture; "Science and Immortality," by Prof. W. Osler, F.R.S.; "New Methods of Treatment," by Dr. Laumonier, translated and edited from the second edition by Dr. H. W. Syers; "The Surgery of the Diseases of the Appendix Vermiformis and their Complications," by W. H. Battle and Dr. E. M. Corner; "Clinical Causes of Cancer of the Breast," by C. H. Leaf; "Leprosy and Fish Eating," by Dr. J. Hutchinson, F.R.S.; "Clinical and Pathological Observations on Acute Abdominal Diseases," by Dr. E. M. Corner; "Reinforced Concrete," by C. F. Marsh, illustrated; "Smoke Prevention and Fuel Economy," by W. H. Booth and J. B. Kershaw, illustrated; "Small Dust Destructors for Institutional and Trade Refuse," by W. F. Goodrich, illustrated; "The Microscope," by Prof. A. E. Wright, illustrated; "Electric Furnaces and their Industrial Application," by J. Wright, illustrated; and a new edition of "Farthest North," by F. Nansen.

Messrs. J. M. Dent and Co. will issue:—"Forestry," by Prof. Schwappach, translated by F. Storey.

Messrs. Duckworth and Co. announce:—"Fetichism in West Africa," by the Rev. Dr. R. H. Nassau, illustrated; and a new edition of "A Glossary of Botanic Terms," by B. D. Jackson.

Mr. W. Engelmann (Leipzig) gives notice of:—"Einführung in die medizinische Optik," by Dr. A. Gleichen, illustrated; "Handbuch der Heidekultur," by Dr. P. Graebner, illustrated; "Conspectus Floræ Græcæ," by E. v. Halácsy, vol. iii., fasc. ii.; "Handbuch der Blütenbiologie," by Dr. P. Knuth, iii. Band, 2 Teil; "Grundlinien einer Psychologie der Hysterie," by Dr. Hellpach; "Experimenteller Beitrag zur Physiologie der Spinalganglien und zur Lehre von den trophischen Nerven. Zu gleich ein Beitrag zur Pathogenese der Tabes dorsalis," by Dr. Köster; "Grundzüge der Kristallographie," by Prof. C. M. Viola, illustrated; "Kants Rassentheorie und ihre bleibende Bedeutung," by Dr. T. Elsenhans; and "Lehrbuch des gesamten Tiefbaus," by Prof. K. Esselborn, illustrated.

Messrs. J. Finch and Co., Ltd., give notice of:—"The *Ipsissima Verba* Library," being the principal ideas and facts of physical, philosophical, and social sciences in the words of their original masters:—"Philosophy," by Dr. E. Reich; "Economics," by A. Milnes; and "Natural Science," by Prof. E. Ray Lankester, F.R.S.

Mr. Gustav Fischer (Jena) promises:—"Ergebnisse, Wissenschaftliche, der deutschen Tiefsee-Expedition auf dem Dampfer *Valdivia*, 1898–9," edited by Prof. C. Chun:—vol. iv., Hexactinellida, by Prof. F. E. Schulze, illustrated; vol. vi., Brachyura, by Dr. F. Doflein, illustrated; and "Handbuch der pathogenen Mikroorganismen," vol. iv., illustrated.

Messrs. R. Friedlander und Sohn (Berlin) give notice of:—"Die Käfer der Balkanhalbinsel mit Berücksichtigung Klein-Asiens und Kretas," by V. Apfelbeck, vol. ii.; "Die Vögel der paläarktischen Fauna," by E. Hartert, Heft. iii.; "Analytische Übersicht der paläarktischen Lepidopterenfamilien," by C. v. Hormuzaki, illustrated; "Abbildungen der Grundformen deutscher Orchideen," by Kränzlin Müller, coloured plates with text; "Résultats du Voyage du S.Y. *Belgica*, 1897–99, sous le Commandement de A. de Gerlache de Gomery," in ten volumes; "Résultats des Campagnes scientifiques accomplies par Albert Ier, Prince de Monaco"; "Tierreich":—Lief. 21, Amphipoda, i., by T. R. R. Stebbing; Lief. 22, Heliconiidæ, by H. Stichel and H. Riffarth; "Catalogus Mammalium tam viventium quam fossilium," Quinquennale Supplementum Anno 1904, by E. L. Trouessart, fasc. ii.

The list of Messrs. Charles Griffin and Co., Ltd., is as follows:—"A Text-book of Physics," by Profs. J. H. Poynting, F.R.S., and J. J. Thomson, F.R.S., vol. iii., "Heat," illustrated; "Light and Magnetism and Electricity"; "Constructional Steel Work," by A. W. Farnsworth, illustrated; "Oil Fuel," by S. H. North, illustrated; "Smoke Abatement," by W. Nicholsun, illustrated; "Analysis of Mine Air," being translations, with additions, by the late Sir C. Le Neve Foster, F.R.S., of pamphlets by M. Poussigne and Dr. Brunck, to which is added original papers by Dr. J. S. Haldane, F.R.S., illustrated; "Electricity Control," a treatise on electricity switchgear and systems of transmission, by L. Andrews, illustrated; "Spinning and Twisting of Long Vegetable Fibres (Flax, Hemp, Jute, Tow, and Ramie)," by H. R. Carter, illustrated; "The Synthetic Dyestuffs and the Intermediate Products from which they are Derived," by Drs. J. C. Cain and J. F. Thorpe, illustrated; "Inks: their Composition and Manufacture," by C. A. Mitchell and T. C. Hepworth, illustrated; "A Text-book of Human Physiology, including Histology and Microscopical Anatomy, with Special Reference to the Requirements of Practical Medicine," by Dr. L. Landois, translated and edited by Drs. A. P. Brubaker and A. A. Eshner, illustrated; and new editions of "Chemistry for Engineers and Manufacturers," by B. Blount and A. G. Bloxam—vol. i., Chemistry of Engineering, Building and Metallurgy; vol. ii., the Chemistry of Manufacturing Processes, illustrated; "Getting Gold: a Gold-mining Handbook for Practical Men," by J. C. F. Johnson, illustrated; "The Chemistry of Gas Manufacture: a Handbook on the Production and Purification of Illuminating Gas," by W. J. A. Butterfield, vol. i., illustrated; and "Calcareous Cements: their Nature, Manufacture, and Uses," by G. R. Redgrave and C. Spackman, illustrated.

Messrs. Gurney and Jackson have in preparation an illustrated book on "British Mammals," by Captain Barrett Hamilton, based to some extent on the work of the late Prof. T. Bell.

Mr. W. Heinemann's list contains:—"The World's History, a Survey of Man's Record," edited by Dr. H. F. Helmolt—Western Europe since 1880, the Atlantic Ocean, Eastern Europe, the Slavs, and the Teuton and Latin Races; also "In the Unknown Pamirs: Vakhan and Garan," by O. Olufsen, illustrated; and "Publications of an American Archæological Expedition to Syria in 1899–1900."

Messrs. T. C. and E. C. Jack promise:—"The Edinburgh Stereoscopic Atlas of Anatomy," edited by D. Waterston; "Moths and Butterflies of the United States East of the Rocky Mountains," by S. F. Denton, two vols.; "Spanish-Colonial Architecture in Mexico," by S. Baxter, ten vols., illustrated; "Round the World," a series of geographical readers; and "Nature-study Readers."

Mr. John Lane gives notice of:—"Africa from South to North through Marotseland," by Major A. St. H. Gibbons, two vols., illustrated; "Birds by Land and Sea," by J. M. Boraston, illustrated; in the series of "Handbooks of Practical Gardening":—"The Book of the Lily," by W. Goldring; "The Book of Topiary," by C. H. Curtis and W. Gibson; "The Book of Rarer Vegetables," by G. Wythes and H. Roberts; "The Book of the Iris," by R. I. Lynch; and "The Book of the Scented Garden," by F. W. Burbridge.

The following is the list of Messrs. Crosby Lockwood and Son:—"Marine Engines and Boilers, their Design and Construction," based on the work of Dr. G. Bauer, translated by E. M. Donkin and S. B. Donkin, edited by L. S. Robertson; "The Mechanical Handling of Materials," by G. F. Zimmer, illustrated; "Engineering Tools, a Practical Treatise, including Instruments of Measurement," by J. Horner, illustrated; "The Cultivation and Preparation of Para Rubber," by W. H. Johnson; "Building Materials, a Practical Handbook on their Properties and Uses," by C. Healy; and a new edition of "Concrete, its Nature and Uses," by G. L. Sutcliffe.

Messrs. Longmans and Co. announce:—"The Mammals of Great Britain and Ireland," by J. G. Millais, in three volumes, illustrated, vol. i.; in "Text-books of Physical Chemistry," "Electro-chemistry," part i., General Theory, by Prof. R. A. Lehfeldt, including a chapter on the relation of chemical constitution to conductivity, by T. S. Moore; part ii., Applications to Electrolysis, Primary and Secondary Batteries, &c.; "Spectroscopy," by E. C. C. Baly; "Chemical Dynamics, and Reactions," by Dr. J. W. Mellor; also a "Text-book of Medical Practice," by various

contributors, edited by Dr. W. Bain, illustrated; "Machine Tools and Workshop Practice," by A. Parr, illustrated; "Laboratory Studies for Brewing Students, a Systematic Course of Practical Work in the Scientific Principles Underlying the Processes of Malting and Brewing," by A. J. Brown, illustrated; "Petrol Motors and Motor Cars, a Handbook for Engineers, Designers, and Draughtsmen," by T. H. White, illustrated; "A Complete Class Book of Naval Architecture, Practical, Laying Off, Theoretical," by W. J. Lovett, illustrated; "An Introduction to the Geology of Cape Colony," by A. W. Rogers; "A Gardener's Year," by H. Rider Haggard, illustrated; "Life and Energy, an Attempt at a New Definition of Life with Applications to Morals and Religion," by W. Hibbert; "The Principles of Education," by T. Raymont; "A Handbook to Agra and the Taj, Sikandra, Fatepursikri, and the Neighbourhood," by E. B. Havell, illustrated; and a new edition of "Engineer's Valuing Assistant, being a Practical Treatise on the Valuation of Collieries and other Mines," by H. D. Hoskold.

Messrs. Sampson Low and Co., Ltd., promise:—"Japan, the Place and the People," by G. W. Browne, illustrated; and new editions of "Manual of First Aid," by Dr. J. A. Austin; and "Analysis Tables for Chemical Students," by R. L. Taylor.

Messrs. Luzac and Co. have in the press a translation of Baron Max von Oppenheim's "Raheh and the Lake Chad Country."

In the list of Messrs. Macmillan and Co., Ltd., we notice:—"The Native Tribes of South-east Australia," by Dr. A. W. Howitt, illustrated; "Tribes of the Malay Peninsula," by W. W. Skeat, two vols., illustrated; "The Origin and Development of Moral Ideas," by Dr. E. Westermarck, two vols.; "Scientific Fact and Metaphysical Reality," by R. B. Arnold; "Miscellaneous Essays" and "Philosophical Fragments," each by Prof. H. Sidgwick; "The Cambridge Natural History," edited by Dr. S. F. Harmer, F.R.S., and A. E. Shipley, F.R.S., illustrated:—vol. vii., Balanoglossus, &c., by Dr. S. F. Harmer, F.R.S., Ascidians and Amphioxus, by Prof. W. A. Herdman, F.R.S., Fishes, by Dr. T. W. Bridge and G. A. Boulenger, F.R.S.; vol. i., Protozoa, by Prof. M. Hartog, Sponges, by Prof. W. J. Sollas, F.R.S., Jelly-fish, Sea-Anemones, &c., by Prof. S. J. Hickson, F.R.S., Star-fish, Sea-Urchins, &c., by Prof. E. W. MacBride; vol. iv., Spiders, Mites, &c., by C. Warburton, Scorpions, Trilobites, &c., by Dr. M. Laurie, Pycnogonids, by Prof. D'Arcy W. Thompson, C.B., Linguatulida and Tardigrada, by A. E. Shipley, F.R.S., Crustacea, by Prof. W. F. R. Weldon, F.R.S.; and new editions of "The Scenery of England and the Causes to which it is Due," by the Right Hon. Lord Avebury, F.R.S., illustrated; "A Treatise on Chemistry," by Sir H. E. Roscoe, F.R.S., and Prof. C. Schorlemmer, F.R.S., vol. i., the Non-metallic Elements, revised by Drs. H. G. Colman and A. Harden; and "A Handbook of Metallurgy," by Prof. C. Schnabel, translated and edited by Prof. H. Louis, two vols., illustrated.

In Mr. Murray's list are to be found:—"Recent Development in Biological Science," by W. B. Hardy, F.R.S.; "Bacteriology and the Public Health," by Dr. G. Newman; "The Culture of Fruit Trees in Pots," by J. Brace, illustrated; "River, Road, and Rail, some Engineering Reminiscences of Undertakings in Various Parts of the World, including the St. Gothard Tunnel and the Zambesi Falls Bridge," by F. Fox, illustrated; "Hints on the Horse, for Artist and Buyer," by Captain C. N. Gonne, R.A., illustrated; "The Moon, a Summary of the Existing Knowledge of our Satellite, with a Complete Photographic Atlas," by Prof. W. H. Pickering, illustrated; "Artillery and Explosives, Essays and Lectures Written and Delivered at Various Times," by Sir A. Noble, K.C.B., F.R.S., illustrated; in the "Progressive Science" Series:—"Earthquakes, in the Light of the New Seismology," by Major C. E. Dutton, illustrated; and "Heredity," by Prof. J. A. Thomson, illustrated; also "Growth and Spread of Culture," by Prof. E. B. Tylor, F.R.S., illustrated; "A Second Course of Practical Science," by J. H. Leonard and W. H. Salmon; "A Primer of Botany," by Prof. J. B. Farmer, F.R.S.; "The Vegetable Garden, or the Edible Vegetables, Salads, and Herbs Cultivated in Europe and America," by W. Robinson; and a new edition of "Marine Boilers, their Construction and Working, Dealing more Especially with Tubulous Boilers," based on the first edition of the work by M. L. E. Bertin, brought up to date, edited by L. S. Robertson.

Messrs. J. Nisbet and Co., Ltd., promise:—"A Tropical Dependency, being some Account of Nigeria, its Progress, and its Peoples," by Lady Lugard, illustrated.

Mr. D. Nutt announces:—"Folk-lore of the Musquakie Indians of North America and Catalogue of Musquakie Beadwork, and other Objects in the Collection of the Folklore Society," by M. A. Owen, illustrated.

Messrs. G. P. Putnam's Sons' announcements include:—"The Heart of the Orient: Saunterings through Georgia, Armenia, Persia, Turkomania, and Turkestan, to the Vale of Paradise," by M. M. Shoemaker, illustrated; "Strabismus, or Squint, Latent and Fixed, a Supplement to 'Errors of Refraction,'" by Dr. F. Valk; "Field Book of Wild Birds and their Music, being a Description of the Songs and Colouring of Wild Birds intended to Assist in the Identification of Species Common in the Eastern United States," by F. S. Mathews, illustrated; "An Introduction to Vertebrate Embryology Based on the Study of the Frog and the Chick," by Dr. A. M. Reese; "Bog Trotting for Orchids," by G. G. Niles, illustrated; "The Mystic Mid-Region, the Deserts of the South-west," by A. J. Burdick, illustrated; "The Trees of North-eastern America," with introduction by N. L. Britton; and new editions of "Landscape Gardening," by S. Parsons, jun.; and "The Shrubs of North-eastern America," by C. S. Newhall, two vols. in one, illustrated.

The Walter Scott Publishing Co., Ltd., give notice of:—"A Study of Recent Earthquakes," by Dr. C. Davison; "Science and Hypothesis," by Prof. H. Poincaré, translated by W. J. Greenstreet; and a new edition of "Electricity in Modern Life," by G. W. de Tunzelmann, illustrated.

The announcements of Messrs. Swan Sonnenschein and Co., Ltd., include:—"Physiological Psychology," by Prof. W. Wundt, a translation of the fifth and wholly rewritten (1902–3) German edition by Prof. E. B. Tichener, in three vols., vol. i., illustrated; an abridged edition of Erdmann's "History of Philosophy," based on the fifth German edition, revised by Dr. B. Erdmann, translated and edited by W. S. Hough; "A Philosophical Introduction to Ethics," by W. B. B. Gibson; "Thoughts and Things: a Genetic Study of Logical Process," by Prof. M. Baldwin; "Student's Text-book of Zoology," by A. Sedgwick, F.R.S., vol. ii., illustrated; and new editions of "Handbook of Systematic Botany," by Dr. E. Warming, translated and edited by Prof. M. C. Potter, illustrated; "Introduction to the Study of Organic Chemistry," by J. Wade, illustrated; and "Sanatoria for Consumptives in Various Parts of the World," by Dr. F. R. Walters, illustrated.

Mr. E. Stanford announces:—"The Sea Fishing Industry of England and Wales, a Popular Account of the Sea Fisheries and Fishing Ports of those Countries," by F. G. Aflalo, illustrated; "Stanford's Compendium of Geography and Travel" (supplementary volume), "Glossary of Geographical and Topographical Terms, and of Words of Frequent Occurrence in the Composition of such Terms and of Place Names," by A. Knox; "Stanford's Geological Atlas of Great Britain (based on Reynold's Geological Atlas), with Plates of Characteristic Fossils, Preceded by a Description of the Geological Structure of Great Britain and its Counties, and of the Features Observable along the Principal Lines of Railway," by H. B. Woodward, F.R.S., illustrated; and a new edition of "Stanford's Compendium of Geography and Travel"—"Africa, vol. ii., South Africa," by Dr. A. H. Keane, illustrated.

Messrs. W. Thacker and Co. promise:—"The Exploration of Tibet," by G. Sandberg; "The Birds of Calcutta," by F. Finn; "Indian Electricity Act, 1903," by J. W. Meares; and new editions of "Game, Shore, and Water Birds of India," by Colonel Lemessurier; and "Astronomy without a Telescope," by E. W. Maunder.

The University of Chicago Press (Chicago) will publish:—"Studies in General Physiology," by Dr. J. Loeb, two vols.; and "Lectures on the Calculus of Variations," by Prof. O. Bolza.

Mr. Fisher Unwin announces:—"Travel, Exploration and Climbing in Siberia," by S. Turner, illustrated; "The Land of the Horn," by W. S. Barclay, illustrated;

"Through Town and Jungle: Fourteen Thousand Miles Awheel among the Temples and People of the Indian Plain," by W. H. and F. B. Workman, illustrated; "British Bird Life," by W. P. Westell, illustrated; and "Gardening for the Million," by A. Pink.

Messrs. Whittaker and Co.'s announcements are as follow:—"Insulation of Dynamo Electric Machinery," by H. W. Turner and H. M. Hobart; "Armature Construction," by H. M. Hobart; "Steam Turbines," by H. M. Hobart and T. Stevens; "Concrete-Steel," by W. Noble Twelvetrees; "Practical Wireless Telegraphy," by Prof. Mazzotto, translated from the Italian by S. Bottone; "Percentage Tables for Elementary Analysis," by L. F. Guttmann; and new editions of "The Alternating Current Circuit and Motor," by W. P. Maycock; "Electricity in its Application to Telegraphy," by T. E. Herbert; "Central Station Electricity Supply," by A. Gay and C. H. Yeaman; "The Management of Accumulators," by Sir D. Salomons; and "The Optics of Photography and Photographic Lenses," by J. T. Taylor, revised by P. F. Everitt.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Mr. George H. Carpenter, of the Science and Art Museum, Dublin, has been appointed professor of zoology in the Royal College of Science for Ireland.

At the inaugural ceremony in connection with the University of Leeds on Thursday, October 6, the following honorary degrees, among others, will be conferred:—D.Sc., Lord Rosse, Lord Kelvin, Sir Isaac Lowthian Bell, Sir James Kitson, M.P., Sir William Henry Broadbent, Sir Arthur W. Rücker, Dr. Thorpe, C.B., Dr. C. G. Wheelhouse, Mr. Jonathan Hutchinson, Mr. J. P. Teal, Dr. H. Jackson, Prof. Miall, Dr. Tempest Anderson, and Prof. A. W. Mayo Robson.

The inaugural lecture of the new session of the London School of Economics and Political Science will be given by the director, Mr. H. J. Mackinder, on Monday, October 3, on "The Need of Scientific Method in Affairs." The arrangements for the session include courses of lectures on all branches of economics, sociology, and cognate subjects of decided value in the development of a scientific spirit in commerce and industry. Among the lecturers are Mr. A. L. Bowley, Dr. E. Cannan, Mr. H. S. Foxwell, Prof. A. C. Haddon, Mr. A. W. Pollard, and Dr. E. A. Westermarck.

The Department of Agriculture and Technical Instruction for Ireland proposes to establish for the year 1904–5 a limited number of commercial scholarships, tenable for one year only (value 100*l*. each), at such schools as the department may approve; also one scholarship for persons engaged in the woollen industry, and one for those engaged in the leather and tanning industries. These scholarships will be tenable at some higher institution, to be approved by the department, in which these industries are taught. They will be of the value of 80*l*. each, and may be renewable for second and third years at the discretion of the department. Candidates for the scholarships must apply for forms, which should be returned to the department duly filled in not later than October 5.

It is announced in the *British Medical Journal* that Lord Strathcona and Mount Royal, the Chancellor of McGill University, Montreal, has presented the sum of 10,000*l*. to the medical faculty. This is in addition to a gift of 20,000*l*. which Lord Strathcona made to the medical faculty about two and a half years ago. The whole of that sum was expended in alterations and extensions of the buildings of the faculty; these were so extensive that they practically amounted to rebuilding. Two new lecture rooms, and three laboratories for chemistry, physics, and hygiene respectively were erected, and other alterations and additions made which greatly increased the working power of the faculty. These buildings, which were opened by the Prince of Wales about two years ago, cost some 750*l*. more than was expected. The further sum now given by Lord Strathcona is intended to cover the deficit and to assist the general work of the medical school.

At University College, London, on October 3, Prof. Norman Collie will give a public introductory lecture to the faculty of medicine on "The Bearing of Chemistry on Medicine." On October 18 Sir William Ramsay will commence a course on the chemical aspects of the recent discoveries connected with radio-active matter. A course of lectures on spectroscopy and spectrum photography, by Mr. E. C. C. Baly, will be given twice during the session, beginning in November and February.

A list of courses of lectures and practical work at Herold's Institute—the London Technical School of Leather Manufacture—has been received. The school is a monotechnic equipped with every appliance requisite for the practical manufacture, currying, dyeing, and finishing of all kinds of leather. Students are urged to go through courses of study of two or three years' duration, and every possible facility is afforded to those who desire to carry out original researches.

The syllabus of classes at the Sir John Cass Technical Institute, Aldgate, shows that much care has been devoted to the organisation of the work of the institute, which is now an educational centre for industrial classes, men and women, of east London. The institute has now completed its first two sessions, and a fairly definite line has been taken in the science teaching, which is chiefly concerned with physics, chemistry, and metallurgy, whilst these departments are correlated to the department of arts and crafts in respect to the teaching of art metal work, jewelry, and enamelling. Metallurgy is one of the more special departments of the institute, and we notice that a course is announced on metallography.

At St. Thomas's Hospital Medical School the entrance scholarship in natural science, of the value of 150*l*., has been awarded to Mr. Ernest W. Withey, and the university scholarship, of the value of 50*l*., to Mr. Charles E. Whitehead, of Caius College, Cambridge.

SOCIETIES AND ACADEMIES.

London.

Royal Society, July 26.—"On the Production of a Specific Gastrotoxic Serum.—Preliminary Communication." By Dr. Charles **Bolton.** Communicated by Prof. Sidney Martin, F.R.S.

This communication deals with the production of a gastrotoxic serum by the injection of the mucous membrane of the stomach (1) of the guinea-pig into the rabbit, (2) of the rabbit into the rabbit, and (3) of the guinea-pig into the guinea-pig.

In each case the blood of the injected animal becomes toxic; in the first case for the guinea-pig, in the second case for the guinea-pig, and in the third case for the rabbit.

The lesions produced by injection of the serum are in all three cases the same. They consist of circumscribed areas of necrosis in the mucous membrane of the stomach associated with hæmorrhage, the latter being secondary to the necrosis, and to some extent also of hæmolytic origin. At a later stage definite ulcers of the stomach are produced, and in this process of ulceration the gastric juice is considered to play a prominent part. The remaining portions of the alimentary canal are found to be normal. The gastrotoxic serum does not produce any visible change in the stomach cells which are exposed to its action *in vitro*.

An inquiry into the nature of the gastrotoxin has shown that it consists of an "immune body," which is newly formed in the blood and resists the action of heat, and a "complement" which is contained in the normal blood and is destroyed by heat.

The specificity of the gastrotoxin was tested by mixing various cells (such as liver, blood) with it previous to its injection in order to determine whether guinea-pig's stomach cells alone, or whether any other cells, could extract the "immune body." As the result of this, it was found that guinea-pig's stomach cells alone in the first two cases were able completely to extract the "immune body" and thus

render the serum inactive. It was, however, found, on immunisation of a rabbit against guinea-pig's stomach cells washed quite free from blood, that the hæmolytic power of the rabbit's serum for guinea-pig's red blood corpuscles was much increased, and therefore that the gastric cells possess receptors to some extent in common with red blood corpuscles. The gastrotoxin is thus shown to consist of two factors:—(1) gastrotoxic, (2) hæmolytic.

The hæmolytic factor is by no means the more important, because the lesions produced were in the hitherto observed cases limited to the stomach, the hæmolytic factor could be extracted from the serum leaving the gastrotoxic factor, and in many cases no evidence of hæmolysis could be found on microscopic examination of the lesions.

In the case of the gastrotoxic serum produced by injection of the stomach cells of the rabbit into the rabbit, it was found that although the rabbit's stomach cells possessed an affinity for the gastrotoxin, yet they completely failed to extract the "immune body" when exposed to the action of the serum *in vitro*. It is therefore concluded that probably this phenomenon, together with absence of autolysis, may be explained by the presence of an "anti-immune body" which is concomitantly formed by the rabbit to protect itself from the effects of the poison which it is manufacturing.

This opens up a hitherto unexplored field in the pathology of human gastric ulcer.

Paris.

Academy of Sciences, September 19.—M. Mascart in the chair.—On the production of sugar in the kidney of a dog to which phloridzin has been administered: R. **Lépine** and M. **Boulud.** It is shown that the sugar obtained in experiments in glass does not give an exact measure of the sugar actually present in the blood in the veins.—On the depth of field and focal length of photographic objectives: J. **Thovert.** Regarding the object of photography as the reproduction of an object as seen by the eye, the limit of angular definition of a photographic image should be about 1/3000. It is shown that this ideal cannot be attained for lenses of short focal length.—On the chemical composition and formula of adrenalin: Gabriel **Bertrand.** Three formulæ have been proposed for adrenalin, the active substance in the extract of suprarenal capsules. Starting with 118 kilograms of the fresh organs, from 4000 horses, 125 grams of crystallised adrenalin were obtained, and this was submitted to an elaborate fractional precipitation. The figures obtained by combustion analyses of the various fractions were very concordant, and show that crystallised adrenalin extracted from the suprarenal capsules of the horse is a distinct substance and not a mixture. The molecular weight was fixed by the lowering of the freezing point of glacial acetic acid, and the formula of the substance fixed as $C_9H_{13}NO_3$, this agreeing with the views of Aldrich.—The nomenclature of the rosanilines: Jules **Schmidlin.**—Tetraoxycyclohexane-rosanilines: a new class of colourless derivatives: Jules **Schmidlin.** The formation of this new class of compounds depends on a simple hydrolysis which rosaniline salts undergo in acid solution. The conclusion is drawn from these experiments that the salts of rosanilines contain four double linkages of the fatty type.—Ultramicroscopic observations on solutions of pure glycogen: Wilhelm **Biltz** and Madame Z. **Gatin-Gruzewska.** Two sets of experiments are described. The first set, agreeing with the results of Raehlmann, show that an aqueous solution of glycogen contains particles of different diameters, varying with the condition of the solutions. In the second set, the effect on the size of the particles by precipitation with gradually increasing quantities of precipitants was studied.

New South Wales.

Royal Society, August 3.—Mr. C. O. Burge, president, in the chair.—On Eucalyptus kinos, their value for tinctures, and the non-gelatinisation of the product of certain species: H. G. **Smith.** In this paper, which is the second of the series dealing with Eucalyptus kinos, the author shows that the tannins in the exudations from the various Eucalypts vary largely in character, and that while some kinos gelatinise in tinctures, others do not. There is a remarkable regularity in the action of kinos from allied species, and the marked differences in the tannins themselves appear to be the reason why they act so differently as regards gelatinisation. There are three tannins at least in Eucalyptus kinos, and all are determinable by reagents.—On some hydrographical data in relation to ocean currents: H. A. **Lenehan.** A paper dealing with ocean drifts, principally in the southern hemisphere. It contains a tabulated statement of 182 records, the most important of which travelled a distance of 11,350 miles between June 19, 1901, and March 5, 1904, at a daily rate of 11½ miles. There are also eleven other drifts more than 3000 miles long. Two charts accompany the paper, showing the positions where the records were cast adrift and the places where found.

Göttingen.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part iv. for 1904, contains the following memoirs communicated to the society:—

July 9.—W. **Nernst**: On the formation of nitrogen dioxide at high temperatures. H. **Gerdien**: Measurements of atmospheric electricity during two balloon ascents. Wilhelm **Biltz**: Ultra-microscopic observations, i. The precipitation of sulphur from thiosulphuric acid and of selenium from selenious acid.

June 25.—H. **Minkowski**: On the closest possible parallelopipedal piling of congruent solids.

July 23.—Eduard **Riecke**: Researches on the phenomena of discharge in Geissler tubes, i. On the exhaustion of Geissler tubes by the electric current.

THURSDAY, OCTOBER 6, 1904.

THE NORTH POLAR SEAS.

The Norwegian North Polar Expedition, 1893–1896. *Scientific Results.* Edited by Fridtjof Nansen. Vol. iv. Published by the Fridtjof Nansen Fund for the Advancement of Science. Pp. 232; 32 plates. (London: Longmans, Green and Co., 1904.) Price 21*s.* net.

THE present volume, in continuation of those previously published,[1] contains three articles, which may be noticed in sequence, although the contribution by Dr. Nansen constitutes the principal portion of the work.

In article xi. H. H. Gran deals with "Diatomaceæ from the Ice-floes and Plankton of the Arctic Ocean." It is pointed out that the plankton samples collected on previous expeditions to the Polar seas contained a considerable quantity of algæ, especially diatoms; whereas the samples brought home by Nansen indicate that the deep Polar Sea is deficient both in species and specimens. When found in quantity, they were principally oceanic diatoms; but the author remarks that it is difficult to understand how all the crustaceans (*Calanus finmarchichus*, &c.) that swarm in the upper portions of the Polar Sea can find means of sustaining life. The samples of diatoms taken upon the drift-ice, partly upon the ice-floes and at their edge, partly from channels in the ice, are of greater botanical interest. Most of them must have lived and multiplied on the ice; others, including a few fresh-water forms, were probably transported casually on to the ice. At present little is known concerning the distribution of ice-diatoms, but the samples examined indicate that those of North Siberia and East Greenland are directly connected with one another; and the study of these organisms appears likely to prove of value in determining the drift of the ice.

In article xii. Johan Kiær describes "The Lower Silurian at Khabarova." Fossiliferous calcareous slates were discovered by Nansen in 1893 on the south side of Yugor Strait, near Khabarova, south-west of the Yalmal peninsula. The fossils, though badly preserved, could be identified as belonging to the brachiopods *Leptaena sericea*, Orthis and Strophomena; and to the trilobites Asaphus, Megalaspis, and Remopleurides. They indicate the zone of *Asaphus platyurus*, which belongs to the middle part of the Ordovician.

In article xiii. Nansen contributes an elaborate essay on "The Bathymetrical Features of the North Polar Seas, with a Discussion of the Continental Shelves and Previous Oscillations of the Shore-line." This work, illustrated by 29 maps and profiles, embodies the more important observations and conclusions of the great explorer; and it will be of considerable interest to geologists, as well as to geographers, as some aspects of the subject have been vigorously discussed by Prof. Hull, Dr. J. W. Spencer, Mr. Hudleston, and Sir Archibald Geikie.

[1] Notices of previous volumes appeared in NATURE for June 14, 1900, p. 146; June 13, 1901, p. 151; and December 4, 1902, p. 97.

As pointed out by the author, the general idea prevailing before the expedition was that the North Polar ocean, between Siberia and North America, was a shallow sea, with a comparatively rapid deposition of sediments carried into it by the Siberian and American rivers, or brought from the coasts by drifting ice. The expedition has shown that the sea occupies a basin with depths approaching 4000 metres, and that at present there is no rapid deposition in it of sediments. Even the dust carried by the winds, or otherwise derived from the atmosphere by precipitation, settles on the floating ice, giving it a dirty brown appearance, and is transported to more southern latitudes, where the ice melts. Proof has likewise been obtained that Franz Josef Land is a group of comparatively small islands, and that probably no extensive land-masses exist to the north of the New Siberian Islands. The deep basin appears to be separated from the Norwegian sea by a shallow suboceanic ridge extending from Spitsbergen to Greenland.

As the *Fram* was heavily laden, Nansen had not encumbered her with the equipment necessary for sounding in very deep water. In the course of his drift across the North Polar basin he soon discovered that his arrangements for sounding were insufficient, and new line had to be made from one of the ship's thick steel-wire cables. Eventually, after much arduous labour, a fairly good sounding line, 4450 metres long, was constructed. According to the soundings thus made, and to those known from other expeditions, a chart has been prepared to show the bathymetrical conditions of the northern seas, but much naturally remains to be done to delineate in detail their submarine contours. The most striking feature in this region is the broad and shallow continental shelf extending northwards from the Eurasian continent, and on which are situated Bear Island, Spitsbergen, Franz Josef Archipelago, and Novaya Zemlya. Continued as it is along the American borders, it forms the most extensive submarine shelf. Davis Strait, with the deep Baffin Bay, and the Norwegian sea with the deep depression of the North Polar basin, form, with their many branches (*e.g.* the Barents Sea), enormous fjords penetrating this platform. Soundings show that its depths are, on the whole, very uniform.

The Siberian continental shelf is regarded as a submerged tract that was originally sculptured with furrows which were the continuations of the sounds, fjords, and valleys of the borderland. These depressions may have been filled up by ground moraines during the Glacial epoch, and also by the deposition of glacial sediments outside the margin of the Siberian ice-sheet, as well as by comparatively recent silting up by deposits from the rivers and shores. Floating ice also assisted in the process.

After describing the American Arctic continental shelf, the author discusses the features of the Barents, Murman, and Kara seas, in which he infers evidence of sculpturing by subaërial agents, fluviatile and glacial. It is interesting to read (p. 28) that "the possibility exists that there has

been no oscillation of sea level, but that the channels may have been excavated by glaciers to their present position below the sea surface"; and, although the author does not regard this possibility as of much weight, we may recall attention to the interesting suggestion (quoted in NATURE, July 7, p. 218) made by Mr. G. K. Gilbert, from his observations on Alaska, that glaciers, under certain conditions, may excavate beneath sea-level.

The continental shelf of the Norwegian coast is somewhat irregular, the depth of the edge below sea-level differing much between 80m. and 300m., and it is only at a few places that it is as deep as 360m. (200 fms.). The great valleys and fjords of the land are often continued as submarine valleys or fjords across the submerged continental shelf, and at some points they open out at its edge, forming distinct incisions in the continental slope; but they are not as a rule traceable beyond the 400 metres line, and seldom even so far.

The Norwegian submarine channel at the southern end of Norway is regarded as part of the bed of the ancient "Baltic River," which drained the Baltic basin and southern Scandinavian tracts. It is pointed out that Prof. Amund Helland attributed this channel to the erosion of the Scandinavian glacier during the Great Ice Age, and the author, while admitting the influence of that glacier, considers that the present relative depth is due to the adjacent areas having been to a great extent filled up with glacial drift.

After dealing briefly with the regions of the Færoës and Iceland, and with the continental shelves of Britain, France, and North America, the author summarises his views on the general subject of the origin of continental shelves. He discusses also various explanations that have been given.

Regarding the continental shelves as having been shaped prior to the submerged valleys, and considering the great extent of these shelves, and the improbability of regular and extended vertical movements of the lithosphere, the author in 1901 had concluded that they must be due to oscillations of the hydrosphere. He now considers that the general level of the sea must have remained near its present position, despite many oscillations of the land, during the later geological periods. The eroded parts of the continental shelves must have been developed when the shelves were near to sea-level, owing their features partly to conjoint action of subaërial erosion and marine denudation, partly to deposition of terrigenous waste, and even locally to organic agents.

Attention is directed to the extensive coast platforms that occur in part a little below sea-level and extend above it, evidencing small oscillations of the shore-line. The Norwegian coast platform has a surface formed chiefly by solid rocks, and the depressions in it are not filled up to any great extent by waste or glacial drift. This platform was in the author's opinion formed by marine denudation after the fjords and channels now traversing it were cut; but the sculpturing may have been facilitated by the clearing away of débris by glacial action. He believes that marine denudation is most potent when coasts are being slowly submerged; but that the Norwegian platform can hardly have been formed during one period of submergence. These platforms were formed in comparatively recent times, whereas the continental shelves were to a great extent developed during Pliocene and Pleistocene times.

With regard to the oscillations of the land, the author leaves the explanation in a somewhat vague state, observing in conclusion that

"whatever the causes of the oscillations of the shore-line may have been, the above facts seem to prove that, after each disturbance in the relation between land and sea, the earth's crust has a remarkably strong tendency to return to a certain position of perfect equilibrium, which is probably determined by the buoyancy of the crust floating on the underlying magma."

H. B. W.

FOREST ENGINEERING.

A Manual of Forest Engineering for India. By C. G. Rogers. Vol. i., pp. xx+321, price 6*s*. Vol. ii., pp. xix+267, price 6*s*. Vol. iii., pp. xii+392, price 7*s*. 6*d*. (Calcutta: Office of the Superintendent of Government Printing, India.)

THE manual under notice was written by order of the Indian Government. The work covers the syllabus of the course of study at the Imperial Forest School of Dehra Dun, but, in addition to this, there is much useful information included, giving the book a wider scope than the necessarily limited one of a syllabus of systematic instruction. The manual has been divided into eight parts. The separate parts deal with the following subjects:—(1) building materials; (2) building construction; (3) road making; (4) bridges; (5) transport of timber; (6) wells; (7) construction of embankments and water channels, river training works; (8) demarcation of forests.

In part i. we have a vast amount of information of the most useful kind on such materials as stone, bricks, tiles, lime, and timber. The source, strength, durability, preparation, and preservation of those various materials have been fully dealt with, each under its own heading. The last section of this part is devoted to carpentry and joinery, which, although not coming strictly under the heading of building materials, fit very well into this place as the most convenient for reference. Part ii., which is devoted to building construction, includes much eminently sound and useful information concerning foundations, walls, arches, floors, stairs, roofs, &c. All the best authorities have been consulted, and no suggestion or recommendation has been made which cannot be easily and successfully put into practice by the forester with such materials as he may find ready to hand and most suitable for his purpose, situated as he often is in out-of-the-way parts of the world, where not only the advice of a specially trained engineer, but also manufactured building materials are unobtainable. These two parts complete the first volume of the manual.

Parts iii. and iv., which deal respectively with road making and bridges, form vol. ii.; here again the parts have been subdivided into sections. The various problems and practical operations are dealt with in a very explicit and satisfactory manner. In this volume, as well as in the others, many useful figures and illustrations are given which supplement and enhance the value of the text. Parts v. to viii. are included in the third and last volume of the manual. As the author points out, this volume deals with those subjects which are of special interest to the forest manager. In dealing with the transport of timber, the author has given a complete account of the different methods of transport by roads, slides, forest tramways, wire-rope ways, and water. Each method has its own particular advantage, according to circumstances, which vary from place to place, but, with this volume as a guide, the forester need have no difficulty in selecting the method best suited to his own local conditions.

As the title indicates, the manual is intended for the use of forest officers in India, to whom it cannot fail to be of the greatest service and value. Great care has been taken to make the work as accurate and up to date as possible, and with this end in view the author sent proofs of the different parts of the manual to the Inspector-General of Forests to the Government of India and all conservators of forests for circulation among such forest officers as they might select for the purpose of recording any suggestions which they had to make; hence before publication the book was subjected to a thorough, practical, and critical examination, which renders it a standard authority and trustworthy source of reference.

While not replacing any of the standard works on civil engineering, the manual fills a big gap in the literature, and it is written in such a way that even those who have not had a special training in engineering may understand and appreciate its use. This work merits, and will no doubt attain, a wide circulation outside India. As a work of reference it should be in the hands of all whose profession brings them in contact with such engineering operations as do not require the skill of a highly trained expert.

There is a marked absence of technical terms, and where the use of these is unavoidable the author takes good care to make their meaning thoroughly clear. The illustrations form a very valuable feature of the manual, and greatly increase its practical utility. In most cases a detailed description has been appended, so that each figure may be clearly understood without any further reference to the text. The majority of these illustrations were drawn specially for the manual, a fact which adds much to their value. For the few illustrations which have been borrowed from other sources ample acknowledgment is made.

It will thus be seen that the manual embraces a wide range of subjects, all of which are pretty intimately associated with forestry. The third volume is of special interest to the forest manager, while vols. i. and ii. cannot fail to be also of great utility and value to those concerned in agriculture, horticulture, and planting in all their branches.

It has been the endeavour of the author, as he informs us in the preface, to make the manual a book of reference for the practical man as well as a text-book for the use of students. With this end in view, the information given on each subject has been made as complete and compact in itself as possible, thus obviating the necessity of cross references. In adapting the work to serve this double purpose, the author has exhibited a great amount of skill in the selection, treatment, and arrangement of the information given under the various headings.

NATURAL HISTORY OF COMMON ANIMALS.

The Natural History of Some Common Animals. (Cambridge Biological Series.) By Oswald H. Latter. Pp. x + 331. (Cambridge: University Press.) Price 5s. net.

THIS is an excellent book, written by a man who is equally in his element whether he writes as an outdoor naturalist or as a laboratory student. This combination is by no means a common one, and it is just the combination that is wanted for a book of this kind.

The common animals chosen are earthworms and leeches, the crayfish, the cockroach and its allies, dragonflies, wasps, the fresh-water mussel, snails and slugs, frogs, toads and newts, and some common internal parasites of domestic animals. The treatment of the "earthworm" is first rate. Its structure is well described, and always as the structure of a live animal, the function of each part being never lost sight of. For instance, the use of the setæ in locomotion is made clear, and the simple experiment of putting the earthworm on a polished horizontal surface is suggested. The familiar phenomenon of earthworms appearing on the surface of the soil after heavy rain is explained, and, no less successfully, what is less familiar, their method of coping with bacteria.

The "crayfish" seems to be the least successful of the papers. Only twenty-two pages are allowed to it, and of these five and a half are devoted to a discussion of the function of the otocysts. There is no lack of interest in the five and a half pages, but much that has been omitted might have claimed precedence. There is little about the appendages, from the swimmerets to the eye-stalks—a field rich in interest to the evolutionist. When the work of the scaphognathite is described, a parenthetic explanation, not easy to understand without previous knowledge, of what the scaphognathite is has to be inserted.

With insects Mr. Latter is thoroughly at home. He has made a great many observations of his own, and he has read the literature of his subject, so that he is able to give the best of what has been discovered. The result of reading his account of the wasp and its mode of life is that one wishes to read more. He has much to say about its sting, its "homing" faculty, its parasites. He enters equally into the life of the fresh-water mussel and its young glochidia sticking to fish and trailing after them. In the maw of a fresh-water mussel were found, among other things, a number of rotifers, a very interesting fact, especially

to one who has long tried to discover what preys on these small succulent creatures. Those that are bigger of build prey upon the smaller, and a large infusorian will swallow a small rotifer, but the fresh-water mussel is a giant who devours great and small impartially.

The paper on snails and slugs is good throughout, and might with advantage have been extended beyond the thirty pages allotted to it. The want of space is due to the attempt to make the book useful to the systematist and the collector, as well as to the observer and student of the lives of animals. No less than eleven pages are devoted to the definitions of the different species of British land and fresh-water gastropods, and, after all, they are too brief to be of much use to the collector. Why, then, insert them at all? In the same way no less than eight pages are expended on the specific characters of dragonflies. Where, as in the case of the British Amphibia, there are but few species, the descriptions are fuller and well suited to what I take to be the aim and purpose of the book, viz. to help and encourage the genuine student and observer as distinguished from the mere collector. Altogether the book is an admirable one. Though the waste of space which has been pointed out is to be regretted, it does not interfere with the excellence of the rest. The illustrations, fifty-four in number, are good.

F. W. H.

OUR BOOK SHELF.

The Purification of Sewage. By S. Barwise, M.D., B.Sc. Pp. xiv+220. (London: Crosby Lockwood and Son, 1904.) Price 10*s.* 6*d.* net.

THE author has in the present edition attempted to bring the information available upon this important subject up to the present state of knowledge and practice, and he has added to the former edition an appendix in which the processes in common use for the chemical examination of sewage and sewage effluents are briefly described. The work bears evidence that it has been written by one who is in touch with the practical side of the recent methods of sewage purification; the text also indicates considerable acquaintance with the advances which have been made in the treatment of sewage in various centres of population in this country.

The matters dealt with briefly but usefully include:—the nature, varieties, and chemical nature of sewage; pollution of rivers by sewage; and the treatment of sewage by land, by precipitation, and by the "septic tank," followed by either the intermittent or the percolating bacteria bed. These processes are illustrated by good reproductions of photographs, and by sectional and diagrammatic drawings. The appendix on chemical processes of analysis is also illustrated, but the directions are such as can only be usefully followed by one who has received a training in chemical analysis.

The book will undoubtedly be of use to those who are responsible for directing and advising on the treatment of sewage. The information furnished, as a whole, is reasonably accurate and up-to-date, but there are portions of the book in which the author appears to show lack of information of published results. Thus his statement on p. 125 of the relative advantages of intermittent and percolating beds leaves out of consideration the very potent aëration of the intermittent bed by the process of gaseous diffusion, since results published by the London County Council show that even at the bottom of a twelve-foot bed a fair proportion of oxygen was present in the interstitial air; he also appears to hold the opinion that such a bed has a serious tendency to become choked, which is not noticed in properly worked beds; and he speaks of four feet being "the maximum efficient depth" for such a bed, when he should know that a 12-foot bed has been worked with entirely satisfactory results. In these and in other respects the intermittent bed appears at an unfair disadvantage with the percolating bed. It should be understood that these two methods of subjecting sewage to aërobic purification are at present under trial, and as a verdict is still scarcely obtainable, a cautious statement of their relative merits is desirable.

Physiologie des Menschen. By Dr. Luigi Luciani. Ins Deutsche übertragen und bearbeitet. By Dr. Baglioni and Dr. Winterstein. Erste und zweite Lieferungen. Pp. vii+322. (Jena: Fischer, 1904.) Price 4 marks each.

THIS translation into German of Luciani's text-book of physiology aims at occupying an intermediate position between the student's text-book and the larger handbooks, being more complete than the former and less encyclopædic than the latter. The translators have brought the book up to date by additions summarising more recent work.

The present first two parts of the work, which is expected to extend to twelve parts, deal with general or cellular physiology, the physiology of the blood and circulation, and the physicochemical phenomena of respiration.

Very interesting and complete accounts are given of the mechanism of the heart beat, and of the physiology of the cardiac muscle and nerves, to our knowledge of which the author himself has added much. The detailed description of practical methods has been wisely printed in smaller type.

Useful summaries of the chief sources of the literature of physiology are given at the close of each section.

A special feature of the work lies in the excellence of the historical introductions to the sections dealt with. The account of the discovery of the circulation is exceptionally complete and interesting.

So far as one can judge from the two parts already published, the difficult task of the collection of facts and their fusion into an interesting whole has been carried out with admirable skill, and the text-book promises to form a most useful and philosophic presentation of the chief facts of physiology. The author and translators are to be congratulated on the production of a work which is distinguished not only by its mastery of detail, but by its eminently readable character and attractive literary form. The appearance of the later parts will be looked forward to with much interest.

Kritische Nachträge zur Flora der Nordwestdeutschen Tiefebene. By Dr. F. Buchenau. Pp. vi+74. (Leipzig: W. Engelmann, 1904.) Price 1*s.* 6*d.*

THE "Flora der Nordwestdeutschen Tiefebene" was published in 1894, and was well received. Since that time the author has personally, and with the help of other botanists, collected a number of new localities for plants enumerated in the flora, and new plants have been discovered. As the publishers could not at present undertake a second edition, Dr. Buchenau has prepared this small pamphlet, which forms an appendix. It contains a full numbered list of all the species of the area, but diagnostic characters are given only for new species or varieties, and the additions and eliminations are tabulated at the end of the book.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Radio-activity and London Clay.

I venture to think your readers may be interested in the following results.

The recent tube operations in London have brought to the surface specimens of the London Clay from different districts. Samples of this clay taken from such different points as Hyde Park Corner, Brompton Road, and Haverstock Hill have been tested in the physical laboratory of the South-western Polytechnic for the presence of a radio-active gas by Mr. H. Cottam, and he has been unable to detect with his apparatus any marked quantity of active gas from the clays.

With the same apparatus he has detected quite easily the radio-active gas from the water of a deep well, belonging to Messrs. Eastman, Latimer Road, W., which goes below the clay to the greensand. We have come to the conclusion that the London Clay forms a floor through which the radio-active gas does not penetrate; or it may be said that the radio-active substance only travels when the water with which it is associated can travel. This is an argument in support of Prof. J. J. Thomson's view, that the radio-active gas, which he found in deep well waters, arises from the splitting up of a trace of soluble radium salt which comes up with the water. S. Skinner.

South-western Polytechnic, Chelsea.

Cecil's Gas Engine.

The earliest practical gas engine appears to be unknown to the leading writers on internal combustion engines. I think that it may be a matter of interest to those who are antiquarians in their subject—as Maxwell used to say—to know that a working gas engine was shown in Cambridge in the year 1820. It was the invention of the Rev. W. Cecil, fellow of Magdalen College, Cambridge. A full account of his engine is given in vol. i., p. 217, of the *Proceedings* of the Philosophical Society of Cambridge (paper read November 27, 1820). The paper is long, and contains excellent matter; a new form of parallel motion is described, and what the author calls "ardent spirit" and turpentine, and vapour of oil, are suggested as possible substitutes for the gas employed by the inventor of the engine. F. J. Jervis-Smith.

Trinity College, Oxford, September 29.

The Iris and the Colour Sense.

Mr. Vincent Napier's communication in your issue of September 1 on "Adaptive Colours of Eyes" moves me to record an observation which I have never seen formulated. It is that persons who exhibit a fondness, in dress, for striking colours, or display exceptional taste in colour combination, have eyes of a pronounced and positive colour. One naturally notices this chiefly in women, but I believe it holds good for men also. In the matter of harmonious costuming, perhaps it would not be too much to say that many women dress conformably to the tint of the iris.

New York, September 17. W. P. G.

Electrolytic Oxidation.

I notice with interest that in your issue of September 22 (p. 511) a brief account is given of a memoir published by Paterno and Pannain in the *Gazzetta* on the electrolysis of alkaline aqueous solutions of potassium cyanide. The chief result of their work appears to be the production of potassium cyanate. In the summer of 1899 a friend and I were working in the same direction. From the commencement of our experiments, on both aqueous and semi-alcoholic solutions of potassium cyanide, we were struck by the almost entire absence of oxygen in the electrolytic gases. The aqueous solutions became strongly alkaline and ammoniacal. The semi-alcoholic solutions became strongly alkaline, but not ammoniacal. Acetamide was, however, detected in a distillate, the presence of which may explain the absence of free ammonia. The alcoholic solutions also yielded, on evaporation, white crystals, which proved to be potassium carbonate.

We therefore assumed, without direct proof, that oxygen had been absorbed by the potassium cyanide to form potassium cyanate. This assumption, which now receives confirmation, was based on the detection of its hydrolytic products, which we considered to have been formed according to the following equation:—

$$KCNO + 2H_2O = KHCO_3 + NH_3.$$

It is possible that continued electrolysis would have led to the production of potassium formate from the bicarbonate (*Berichte*, xxxvii., 2836), if this change had not, to some extent, already occurred.

We obtained evidence of the formation of more complex bodies, but have been unable, up to the present, to prosecute further experiments. Herbert A. Kittle.

Leatherhead, Surrey, September 26.

DEVELOPMENTS OF THREE-COLOUR PHOTOGRAPHIC PROCESSES.[1]

I.

In reviewing the recent progress of the various processes, direct and indirect, of the reproduction of colours by photography, it is obvious that there is no very remarkable advancement to report. The ultimate aim of those who do fundamental work at this subject is to formulate a method that shall automatically reproduce the colours of the original, just as by means of a camera and lens the form of the original is automatically drawn in true perspective. The realisation of this desideratum does not seem at hand. There is no method of producing colour prints known that does not need so much control in the working of it or alteration of its results, that it would be incorrect to regard the final products as simple photographs. The skill and sometimes the taste of the operator, and the nature of the appliances that he makes use of, have an important effect upon the work. This fact may lead to the idea that photographic methods of colour reproduction are of little use. But by the aid of photography results may be obtained that were impossible before, either in their character or in the economy of their production. Photography in portraiture is not considered useless because the negative goes through the hands of the retoucher.

Of the direct methods of heliochromy, the interference method that was practically worked out by Lippmann remains nothing more than an interesting illustration of certain physical phenomena. The many restrictions that limit its applications and the difficulties that beset its practice are such that it can never be expected to develop into a practical process. After a dozen years or so, Lippmann photographs are still regarded as curiosities, and are interesting only as examples of the method. None appear to have been made for the sake of the subject. The restrictions as to size and the angle under which they must be viewed, the need for getting rid of reflections from the surface of the film, the slowness of their production, and, above all, the uncertainty of the colours produced and the fact that they change with any alteration in the condition of the film, render the process useful to the physicist rather than the photographer.

The only other method of direct colour photography that appears at all likely to develop into a practically

[1] "The Water-Colour Drawings of J. M. W. Turner, R.A., in the National Gallery." By T. A. Cook. Pp. vi+86 and 58 plates. (London: Cassell and Co., Ltd., 1904.) Price 3 guineas net.
"Three-Colour Photography." By A. F. von Hubl. Translated by H. O. Klein. Pp. 148. (London: A. W. Penrose, Ltd., 1904.)
"Photography in Colours." By R. C. Bayley. 2nd edition. Pp. 151. (London: Iliffe, Ltd., 1904.) Price 1s. net.

useful process, that is, a method in which the coloured image that falls upon the prepared surface produces on it its own colours at once, is that suggested about twenty-five years ago by Charles Cros. The receiving surface is coated with a red, a yellow, and a blue dye of suitable tint, each of which fades quickly when exposed to white light. As it is the light that is absorbed that causes the fading and not the reflected light, on exposure to light of any given colour the only dye or dyes that remain unbleached are those that reflect the same colour as the incident light: a red light, for example, causes the yellow and blue dyes to fade, but not the red, and this colour therefore remains in those parts upon which it impinges. The primary difficulty is to prevent further change in the resulting picture, for the very essence of the process consists in the fugitive nature of the dyes employed. This principle of work has recently engaged the attention of several investigators, but no satisfactory method has yet been arrived at.

All practical methods of colour photography, that is, methods that are practised for the sake of the results that they furnish, are indirect. The light from the coloured object does not produce colour at all. By dividing the light into three suitable parts or colours each may be photographed separately so as to give a record of the distribution of its own colour, and by the use of these records a compound print may be made with three suitable colours. Three colours are used for the same reasons that led to the theory that the normal eye can distinguish only three colours—the three colour sensations—all the vast variety of tints being due to the excitation of one or more of these simultaneously and in due proportions. Although it has been proved that three colours are sufficient, four, and even five, have occasionally been used to overcome the difficulties of the simpler method. But none of these methods must be confused with the procedure in chromolithography, in which a dozen or more colours may be used, their choice being chiefly, if not entirely, empirical.

If any two or all three of the colour sensations are excited to the same extent, the same colour effect will be produced whatever the character of the light that causes the excitation. Therefore, the fact that two colours are not distinguishable from each other by the naked eye is no proof that they are really the same; spectroscopic analysis of the two coloured lights may reveal a great difference between them. In reproducing colour by photography, therefore, it is not necessary (and not often possible) to reproduce the original colours; it is sufficient to produce a colour that the eye cannot distinguish from the original, that is, one that affects to the same extent each of the three sensations. It was by the application of this principle that Ives worked out the essential conditions for his chromoscope. It has been stated that Ives's actual apparatus does not illustrate this principle as completely as has been claimed, but whether this is so or not does not affect the principle itself nor the usefulness of it.

The conditions obtaining in Ives's chromoscope, and in the method of making coloured transparencies (or lantern slides) which Sanger-Shepherd has made a commercial success, are the two simplest illustrations of three-colour photography. In the first case the three lights are added, for each is transmitted to the eye independently of the others, while in the second case the colours are superposed and the light that passes is only that which is absorbed by neither of the three. In the first case the result is the sum of the transmitted lights, while in the second it is the sum of the absorptions that has to be considered. Practically speaking, though not quite actually, the colours used in the second case have to be complementary to those in the first case. The first thing to be done is to settle on the three fundamental colours. Ives and others have sought to follow the three-colour sensation spectrum curves founded on the Young-Helmholtz theory of colour, as drawn by Clerk-Maxwell and later by Sir William Abney. Colonel A. F. von Hübl, in his "Three-Colour Photography," just published in English (translated by Mr. H. O. Klein), arranges a diagram in which the normal spectrum forms a circle with purple between the violet and red, white being at the centre of the circle, and the remainder of the space being filled with whitish tints of the periphery colours. He says that an infinite number of systems of three theoretically correct fundamental colours may be selected by taking any three that are 120° distant from each other. But as blue is the darkest colour it must be one of the three fundamentals, and, of course, red and green follow. Hübl asserts that Ives's curves are entirely different from those which the theory of Helmholtz requires, and are based on Maxwell's colour-mixing experiments, in which three spectrum colours were assumed as fundamentals. Hübl, by means of a similar diagram, but with black (total absorption) at the centre, finds the three fundamental colours for superposition. "Three narrow-banded colours, situated in the colour circle at 120° from each other, form a suitable colour system for trichromatic printing, and a great number of such theoretically possible systems can be ascertained." But here again we are limited to one system. As "yellow cannot be produced by pigment mixtures . . . this colour must form one of the fundamental colours." "The yellow must be absolutely correct and must not be of a reddish tint," or any neutral pure yellow would be missing in the print. Both methods, therefore, in both cases give no choice for a perfect system, and the practical results as obtained by those who have worked them out on these rather different plans are very similar.

But it is not simply a matter of dividing the light into three suitable parts. The object of the division is to get a photographic record of each, and as no photographic plate yet made has a sensitiveness to various colours proportional to their brilliancy to the eye (or rather will give densities by exposure and development proportional to these brilliancies), the colour screens or filters that divide the light into the selected fundamental parts have to compensate for the deficiencies of the plates used. Now, this compensation can only be done by reducing the light that produces an excessive effect; it therefore always leads to the necessity for a lengthened exposure. Practically, a lengthened exposure means a more costly procedure, if only because, for the same capital outlay in apparatus and accommodation, less work can be done in a given time. But, even disregarding such considerations as these, ordinary plates are so little sensitive to red that it would be hardly possible to get a photograph on them of the red image, because the very protracted exposure would give the opportunity for all sorts of interfering circumstances to produce their characteristic errors. The sensitising of the plates to be used for the green and red elements becomes, therefore, an essential part of the procedure. About two years ago, Dr. Miethe, of Berlin, showed some results of three-colour work that attracted considerable attention, the superiority of which was partly due to the use of ethyl red, a cyanine derivative, instead of the cyanine invariably used until then. Plates treated with this sensitiser give with the prismatic spectrum an almost even density from nearly C to the violet, the deficient sensitiveness in the green that most sensitisers (including cyanine itself) give being hardly appreciable. Last year a still better sensitiser was introduced, namely, "orthochrome T," and a few months ago this was found to be surpassed by

"pinachrome," both these being cyanine derivatives. Dr. E. König, who has investigated the comparative merits of these three sensitisers, states that if the sensitiveness conferred by ethyl red to red light is regarded as 100, "orthochrome T" gives a sensitiveness of 160 to 180, and "pinachrome" 450 to 500. But the density that the best of these sensitisers gives on development in the red and green of the spectrum is not proportional to the luminosity of these colours, therefore the exposure for these colours has to be longer than for the blue, but only about three times as long.

Theoretically perfect colour screens or filters are therefore useless, because a perfect plate, so far as the interpretation of colour is concerned, has not yet been produced. The colour screens and plates must be tested together, and for this purpose it is necessary to have recourse to the spectroscope, making photographs, of course, under the various conditions. But spectroscopic results are so liable to deceive observers who are not thoroughly accustomed to such work that less discriminative methods of testing are generally preferred. The colour sensitometric methods that Sir William Abney has done so much to perfect are often employed for this purpose. A series of small pieces of suitably coloured material are arranged in such a manner that when the plate is exposed through its screen and this sensitometer a definite and easily recognisable result will be obtained if the plate and screen are mutually correct. Or the colours may be arranged on a rotating disc concentrically with a grey produced by the mixture of definite proportions of black and white, so that the colour and the grey will give an equal density in a photograph of it taken in the camera through the screen on the plate. Colonel Hübl, in the volume above referred to, gives a colour chart that consists of small patches of nine pigments, with the results that should be obtained when this is photographed, using the given plate and each of the three colour screens in turn. To facilitate the use of the chart, an extra copy is provided in a pocket on the cover of the book. A grey scale of different shades, made on platinum printing paper, is exposed and developed with the colour chart, and the three prints should show this grey scale alike, when the differences due to the colour screens should be as shown in the three prints supplied.

Chapman Jones.

(*To be continued.*)

REFLEXIONS IN WATER.[1]

THERE are few studies more fascinating than that of the reflexions formed naturally in the sea, and in rivers and lakes. In the first place, this study is naturally pursued in the open air; further, the effects observed are often of surprising beauty; and lastly, most, if not all, of the phenomena observed can be explained in accordance with a few simple principles, so that it is possible for almost anyone possessing a trained faculty of observation to add to our knowledge in this direction. In writing a book on reflexions in water, Sir Montagu Pollock has entered an almost untrodden region within the borders of both art and science; with the exception of some passages in the works of Mr. Ruskin, it would be difficult to refer to any other work dealing with the same subject. It is no small accomplishment to produce a book in which so many intricate effects are traced to their causes, using language

Fig. 1.—*Old Harbour Side, Scarborough.* From "Light and Water."

[1] "Light and Water: a Study of Reflexion and Colour in River, Lake, and Sea." By Sir Montagu Pollock, Bart. Pp. xii+115; with 39 plates and 28 explanatory figures. (London: George Bell and Sons, 1903.) Price 10*s.* 6*d.* net.

of the simplest, and yet sacrificing nothing in the way of accuracy and clearness; and, although the book was written to aid artists in their study of nature, it will none the less be welcomed by men of science and those amongst the general public who attach importance to accurate observation.

There are some artists who make no secret of their disdain for scientific methods as an aid to their work; but even these, on reading Sir Montagu Pollock's book, will be forced to admit their indebtedness. Some sort of scientific method is indispensable for accurate observation of reflexions in water. Even reflexions in still water differ from what would be expected by an untrained observer; the reflected image is indeed generally a counterpart of the object, but it not uncommonly presents an entirely different aspect. Many striking instances of this are discussed and explained in the first chapter; one of the most remarkable is afforded by the reflexion of a rainbow in a lake, which is really the image of a bow quite distinct from the one seen directly. When we come to the study of reflexions in rippled water, further complications arise; in the second chapter, the reader is led on from the most simple and elementary facts to appreciate and understand complicated effects such as are reproduced in the accompanying illustration (Fig. 1). In such cases some amount of scientific training is absolutely necessary to one who would give a faithful pictorial representation of nature; for the appearance presented changes every instant, and without the aid of some sort of clue one can scarcely avoid obtaining inharmonious effects. But even in still water, where there is no incessant change to distract the attention, there are yet many opportunities for the artist to go wrong; without a very accurate knowledge of fundamental principles, it would be impossible, for instance, to deduce the nature of the reflexions shown in Fig. 2 from the actual appearance of the objects reflected. Notice, for instance, that while the reflected image of the spire of the distant church is seen, the body of the church and the dark hill behind it are not present in the reflexion; there is even no image to be seen of the shore between the church and the water.

The third and fourth chapters are devoted to a study of the colours in still and rippled water. This part of the subject is exceedingly complicated, and it is difficult to make any general statement which will help us to predict the exact colours to be seen under given conditions. The observed colour of the water is due, partly to light reflected from the surface of the water; partly to light scattered by minute particles floating on the surface; partly to the inherent colour of the water, modified, maybe, by the presence of fine suspended particles; partly to the colour of the stones, sand, or mud at the bottom of the water; and, lastly, the whole effect is complicated by "contrast," which may modify greatly the various colours observed. For instance, standing on one of the cliffs of Sark, and looking out over the sea, the latter often appears of a vivid green, dappled here and there with patches of intense purple. Careful observation shows that the purple patches mark the

FIG. 2.—Sils Baseglia, Upper Engadine. From "Light and Water."

sites of submerged beds of sea-weed; but the weed is not itself purple, but of a dark olive-green colour, so that the colour of the patches is not easily explained. The most probable explanation appears to be as follows:—The sea-water is itself blue, *i.e.*, it is relatively opaque to red and partly opaque to yellow light. Yellow light is most copiously reflected from the sandy bottom of the sea, so that, on the whole, the greater part of the light reflected from the bottom of the sea which reaches our eyes is green. The beds of sea-weed merely act as general absorbers, and would give rise to dark patches were

it not for the effect of contrast; it is well known that a grey object lying on a vividly green ground appears to be of a reddish or purplish hue. It may here be remarked that this phenomenon yet awaits explanation; it was at one time thought that the eye insensibly travelled over the green expanse, the green colour sensation became fatigued, and faint white light afterwards provoked the complementary sensation. It has been found, however, that the same colour phenomena are observed when the illumination is instantaneous, so that this theory falls to the ground.

Finally, it may be stated that Sir Montagu Pollock's book is throughout of absorbing interest; the excellence of the illustrations can be inferred from an inspection of those used to illustrate this short notice, and the printing is everything that could be desired.

Edwin Edser.

NOTES.

We understand that the second International Wireless Telegraph Conference, which was to have been held in Berlin on October 6, has been postponed until next spring. It will be remembered that the Wireless Telegraph Act which was passed at the end of last session was rushed through the House partly that the Government representatives might have a better basis for making agreements at this conference. It is stated that a considerable number of applications for licences under this Act have been received by the Postmaster-General. Some of these applications come from the submarine cable companies.

The funeral of Prof. Niels Finsen at Copenhagen on September 29 was attended in person by King Christian, King George of Greece, Queen Alexandra, and all the other Royalties now in Copenhagen, as well as by the Danish Ministers of State, members of the Diplomatic Corps, the president of the Danish Parliament, the Burgomasters of Copenhagen and the chief provincial towns, and numerous representatives of foreign scientific institutions, universities, and societies. King Edward was represented by the British Minister, Sir W. E. Goschen. A number of Danish medical men have issued an appeal for the erection of a monument to Prof. Finsen by voluntary contributions.

A new association, the Institute of Hygiene, has been formed having for its object the dissemination of knowledge on the subject of personal and domestic hygiene. It aims to be self-supporting, and in order to accomplish this has organised a permanent exhibition of hygienic products and appliances, *e.g.* foods, clothing, filters, stoves, &c., open free to the general public, and a special section devoted to drugs and medical and surgical appliances to which medical men alone are admitted. The revenue gained from the rents paid by exhibitors will be devoted to educational work, which will take the form of local lectures, with examinations and certificates. The exhibition, which was formally opened by Sir Joseph Fayrer on September 30, is housed at 34 Devonshire Street, W.

A visit by a party of French physicians and surgeons is about to be paid to London. The party is to arrive on October 10, and will comprise some 150 gentlemen. A committee, of which Sir William Broadbent is president and Sir Thomas Barlow treasurer, has been organised to make arrangements for their reception and entertainment, Dr. Dawson Williams and Dr. Jobson Horne being the honorary secretaries. They will be entertained at a banquet at the Hotel Cecil on October 12.

Prof. Koch has retired from the post of director of the Institute for Infectious Diseases at Berlin owing to the increasing demands which other bacteriological work make upon his time and energies. The Berlin correspondent of the *Times* states that in the course of the winter Prof. Koch will proceed to German East Africa in order to continue those studies of tropical and other diseases which he had not completed during his recent visit to Rhodesia. In particular he will continue to investigate the part played by ticks in conveying the infection of various cattle diseases.

A conference on agricultural education will be held in the Shire Hall, Gloucester, on Saturday, October 15, under the presidency of Sir John Dorington, M.P. At the morning session Lord Onslow will deliver an address, and the other speakers will include Sir W. Hart Dyke, Prof. T. H. Middleton, and Lord Monteagle. At the afternoon session Sir T. Dyke-Acland, Sir John Cockburn, Mr. A. D. Hall, and others will address the conference.

The deaths are announced of Prof. E. von Martens, vice-director of the Berlin Zoological Museum, and Dr. P. van der Vliet, formerly professor of physics at the University of St. Petersburg.

The Physico-Mathematical Society of Kazan has awarded the Lobatchewsky prize to Prof. D. Hilbert, of Göttingen, for his book on "Die Grundlagen der Geometrie" and other researches. The Lobatchewsky gold medal has been conferred on Prof. Poincaré, and Profs. Mansion, Laisant, and Peano have been elected honorary members of the society.

The twenty-fifth annual "Fungus Foray" of the Essex Field Club will be held on Saturday, October 15, at High Beach, Epping Forest. The referees will be Dr. M. C. Cooke and Mr. George Massee, of the Kew Herbarium. Mr. Massee will read a paper on some diseases of trees. Any botanists wishing to attend should communicate with the secretary, Buckhurst Hill, Essex.

Prof. Fehr, of Geneva, editor of *L'Enseignement mathématique*, is circulating among mathematicians an inquiry form containing a number of questions relating to their manner of working. These questions refer to such points as when and where the mathematician answering them acquired his taste for mathematics, whether his researches are suggested by the study of mathematical literature or the ideas come to him spontaneously, whether he publishes his ideas immediately or leaves them for a time, whether he observes regular rules in his living, whether he finds the morning or evening best for work, and so forth. The answers are to be analysed by Prof. Th. Flournoy and Dr. E. Claparède, both experienced psychologists.

The system of "normal piling" which forms the basis of Prof. Osborne Reynolds's "Theory of the Universe," is discussed by the late Prof. J. D. Everett in the *Philosophical Magazine* for July. In the review of Prof. Reynolds's work, which appeared in Nature, attention was directed to the fact that the arrangement of spheres consistent with minimum volume is not unique. Prof. Everett's paper states that every system of maximum compactness consists of parallel tiers in triangular arrangement, but each tier can be fitted over the one below in two ways. When two tiers have been placed the piling will be normal if the spheres of the third tier are *not* vertically above those of the first; but another arrangement, giving rise to what Prof. Everett called *antinormal* piling, may be obtained by placing the third tier in the spaces above the first.

Among recent contributions to aëronautics, considerable interest attaches to Mr. A. F. Zahm's paper on atmospheric friction, published in the *Bulletin* of the Philosophical Society of Washington, xiv., pp. 247–276. It is commonly assumed by experimenters that skin friction in ordinary gliding models is a negligible quantity, but Mr. Zahm finds that the frictional resistance is not improbably as great for air as for water in proportion to their densities, and, indeed, that it constitutes one of the chief obstacles to bodies and aërosurfaces gliding at high speeds. By plotting the relations between velocity and resistance on logarithmic squared paper, the author found for plane surfaces that the frictional resistance varied as the power of the velocity with index 1·85. Prof. M. Smoluchowski-Smolan, in his paper in the *Philosophical Magazine* for June on the principles of aërodynamics, discusses the equations of motion of a compressible fluid when account is taken of thermodynamical effects, and he applies the principle of dynamical similarity to certain physical problems. The *Scientific American* for September 10 contains two illustrations of gliding machines. The idea of attaching a machine to a bicycle in order to attain the requisite speed has doubtless frequently suggested itself to experimenters, and Mr. S. V. Winslow contributes a photograph of a "bicycle aëroplane," which he alleges "has proven perfectly successful so far as balancing is concerned." The figure of Prof. Botts's circular aëroplane, furnished with vertical screws in the centre, reminds one of the illustrations in the well known "Histoire des Ballons" of Tissandier, and it may be safe to predict that a small model of this pattern would constitute a pretty toy, and would sail well through a room.

In the *Journal* of the Royal Microscopical Society for August, a simple direct proof of Abbe's theorems on the microscopic resolution of gratings is given by the late Prof. J. D. Everett, F.R.S.

In the *Physical Review* for July Mr. N. A. Dubois describes a simple method of employing allotropic silver for the preparation of conducting fibres for quadrant electrometers and other similar apparatus. The author finds that dried films of allotropic silver, although poor conductors, become very good conductors on being treated with gaseous hydrochloric acid, and that the method can be applied to the most delicate apparatus in a few minutes without risk of injury.

Messrs. E. L. Nichols and E. Merritt describe some interesting studies on fluorescence in the *Physical Review*, xix., 1 (July). The authors found that eosin, naphthalin roth, fluorescein, quinine sulphate, chlorophyll, canary glass, green and white fluorspars, and other substances exhibited the same types of fluorescence, the spectrum consisting of a single band near the infra edge of the corresponding absorption band. The position of the maximum and the distribution of intensity was independent of the wave-length or composition of the exciting light. Fluorescence near the red or violet ends was traceable further towards the opposite end than is the case with bands near the middle of the spectrum, because of the increased luminosity in these directions. In no case did Stokes's law hold. Fluorescent substances having absorption bands of shorter wave-length than that with which fluorescence was associated were excited by light in that band, but the same was not the case when the wave-length was longer. Finally, where more than one fluorescence band existed, it was considered probable that each was due to a different fluorescent material, as no case of multiple fluorescence occurred where only one fluorescent substance was present.

The first two numbers (July and August) of a new magazine—*Le Radium, La Radioactivité et les Radiations*—received from MM. Masson and Co., Paris, contain many useful and interesting articles on radio-activity and allied subjects. These articles are not original contributions, but are readable and well illustrated accounts of very recent original work. Several deal with recent attempts to use radio-active bodies for therapeutic purposes. There are in addition reviews of recent papers, notices of new books, and a correspondence column. While such a magazine may not be essential to those who are able to keep in touch with the recognised scientific journals, it will probably be found useful by many interested in the subject.

The meteorological observations and results relating to the Bremen Observatory for 1903 have been published by Dr. Paul Bergholz. The volume forms one of the series of the *Deutsches meteorologisches Jahrbuch*; it therefore follows that the work leaves nothing to be desired. The tables show the actual readings at three hours daily, with monthly and yearly means, and daily means for each hour. In addition, there are phenological and other observations for Bremen, and rainfall summaries for several stations in connection with the observatory.

We have received the report on rainfall registration in Mysore for 1903, by Mr. J. Cook, director of meteorology in that province. The number of Government stations is 194. In addition to the tables, the report includes useful maps showing average monthly, yearly, and geographical rainfall for thirty-four years (1870–1903). During 1903 some heavy falls in twenty-four hours are recorded:—11 inches in the district of Shimoga, in July; 11·5 inches in Kolar, in November; 12·65 inches in Kadur, in July. Mr. Cook states that a station which escapes inspection even for a single year is most likely to be defective in some particular; a yearly inspection would obviously entail a large amount of expense in travelling, and its necessity would seem to point to want of interest by the observers in their work.

We have received a copy of a second edition of Mr. Conway Belfield's "Handbook of the Federated Malay States," which has just been published. The book has been thoroughly revised, and the statistics brought down to the end of the year 1902.

Prof. J. Cvijić contributes to the *Mitteilungen* of the Vienna Geographical Society an important paper summarising the results of recent research on the glacial phenomena of the Balkan peninsula, and correlating them with the results of similar investigation in the Alps and Carpathians.

We have received the third *Bulletin* of the International Council for the Study of the Sea, containing the observations made during the cruises of the different vessels in February, 1904; also No. 14 of the council's *Publications de Circonstance*, on surface temperature observations in the North Sea, by Dr. Evan Everdingen and Dr. C. H. Wind.

A series of gazetteers of the States is being published by the U.S. Geological Survey. During the last few weeks gazetteers of Virginia, Maryland, Delaware, and Texas have appeared, each giving a general description and an account of special features. Another valuable publication of the same department is a third edition of the *Bulletin* on the "Boundaries of the United States and of the Several States and Territories."

The Central Meteorological Observatory of Japan has issued the first of a new series of *Bulletins*, in which it is

intended to publish the results of researches on meteorology and allied sciences made by members of the staff of the observatory. The present *Bulletin* contains valuable papers on earth temperature at Tokio, the mean annual temperature of the surface of the sea in the Western Pacific Ocean, the epochs of the first ice in Japan for 1902, and evaporation in Japan.

A valuable contribution to the theory of oceanic currents is made by Prof. Otto Pettersson in a paper on the influence of ice-melting upon oceanic circulation, published in the September number of the *Geographical Journal*. Prof. Pettersson describes the results of some remarkable experimental work, and gives an account of recent theoretical inquiries by himself and others, applying the results to the elucidation of the complex circulation in the Norwegian Sea and the north polar basin. An interesting point is the suggestion that the problem of forecasting the monsoons of India may ultimately be solved by a systematic survey of the hydrographic conditions in the Indian Ocean.

The analyses given in the Jamaica *Bulletin* of the Department of Agriculture (August) testify to the purity of the native sugars, but where the sugar is required for preserving fruit the addition of an antiseptic is found to be necessary in order to prevent infection with Torula. Experiments are being made with calcium bisulphite.

More than a dozen fungi have been recorded as destructive parasites on vine-roots, and to these an addition has been made by Dr. Istvánffi, who describes in the third volume of the *Annals* of the Royal Hungarian Viticultural Institute how he has traced the cause of disease in several districts in Hungary to the ravages of the Gasteromycete, *Ithyphallus impudicus*.

The second part of "Plantæ Yucatanæ," forming vol. iii. of the botanical series of the Field Columbian Museum, Chicago, was issued in April, and deals with the Compositæ. The features of this work, which include only plants of the northern half of Yucatan, are the descriptive accounts, with occasional notes on native names and uses, by Dr. Millspaugh and the excellent drawings of flower and fruit executed by Mrs. Chase for each species.

The most striking features of the North American and Mexican deserts are discussed at some length in Schimper's "Plant Geography." In the *Botanical Gazette* (July) Dr. D. T. MacDougal gives an account of the expedition which he arranged to explore the delta of the Rio Colorado and that practically unknown portion of the Mexican desert which lies on both sides round the head of the Gulf of California. Amongst the xerophytes, which were found in the regions of extreme aridity, were many perennials containing latex and a large number of forms which secrete volatile oils or exude resinous gums; but plants with massive storage organs were absent, a fact which Dr. MacDougal attributes to the excessively small and even distribution of the rainfall throughout the year.

The two articles in the September number of the *Zoologist* are devoted to ornithology, Mr. F. M. Littler treating of the birds of Tasmania, while Sergeant H. Mackay, of the 2nd Highland Light Infantry, discusses those of Jersey. It is highly satisfactory to find a non-commissioned officer of His Majesty's Service studying the zoology of the district in which he happens to be quartered.

The report of the Indian Museum, Calcutta, for 1902–3, and that of the Albany Museum, Cape Colony, for 1903, are just to hand. Both institutions appear to be in a flourishing condition, although there are complaints from both of insufficient numbers on the staff to cope with the work. The registered additions to the Indian Museum during the period covered by the report numbered 2096 specimens, of which 326 were archæological and the remainder zoological. It is satisfactory to note that the Albany Museum is making strenuous efforts to secure a representative series of the large mammals of the Cape Colony and adjacent districts, its present deficiency in the smaller forms being a matter of little consequence, as these are in no present danger of extermination.

The prophylaxis of malaria was exhaustively discussed in the section of tropical diseases at the recent meeting of the British Medical Association (*Brit. Med. Journ.*, September 17, p. 629). Dr. Strachan, C.M.G., principal medical officer of Lagos, West Africa, emphasised the value of anti-mosquito measures and of the prophylactic use of quinine. Captain James and Lieut. Christophers, from their experience at Mian-Mir (see Nature, lxix. p. 467, and lxx. p. 230), doubted the universal applicability of anti-mosquito measures for the reduction of malaria. Prof. Ronald Ross, F.R.S., criticised the work and conclusions of the last named observers on the following grounds:—(1) it is doubtful if mosquito propagation at Mian-Mir was really suppressed to the extent claimed; (2) the tests employed for detecting reduction in the number of mosquitoes were not conclusive; (3) the figures given regarding the variations in the amount of malaria are inconclusive; (4) the whole experiment is open to the final criticisms (*a*) that it might not have been continued long enough, and (*b*) that the radius of operations might not have been large enough. He considered that all that the experiments proved was that after operations (*i.e.* anti-mosquito measures) extending to a half-mile radius, lasting a year and a half, and apparently costing between two and three hundred pounds, no very large reduction in the number of mosquitoes or in the amount of malaria was apparent.

Messrs. Charles Griffin and Co. have just published the sixth edition, revised and enlarged, of Mr. Andrew Jamieson's "Elementary Manual of Applied Mechanics."

Mr. Balfour's presidential address delivered before the British Association at the recent meeting at Cambridge, and printed in Nature of August 18, has been published in pamphlet form by Messrs. Longmans, Green and Co. The price of the pamphlet is one shilling net.

A cheap edition of Lord Avebury's book on the "Scenery of England" has been published by Messrs. Macmillan and Co., Ltd. The book contains nearly two hundred illustrations—many of them full-page and all instructive—and in its new form it should be the means of creating wide interest in the scientific significance of scenery.

The first volume of *Technics*—a magazine for technical students—is full of useful articles and notes on many aspects of technology. There are descriptions of institutions where the work of higher scientific and technical education is being developed, articles on the education of engineers, educational systems, designs, materials and manufactures of various kinds, photography, bacteriology, and many other departments of pure and applied science. The magazine is well illustrated, and should be of real service to technical education in this country. The publishers are Messrs. George Newnes, Ltd.

Mr. Edward Arnold announces an illustrated work on "English Estate Forestry," by A. C. Forbes.

The list of announcements of the Cambridge University Press includes:—"Mathematical and Physical Papers by the late Prof. Sir G. G. Stokes, Bart., F.R.S.," vol. v.;

"The Collected Mathematical Papers of Prof. J. J. Sylvester, F.R.S.," vol. ii.; "The Dynamical Theory of Gases," by J. H. Jeans; "The Analytical Theory of Light," by J. Walker; "A Treatise on Analytical Dynamics," by E. T. Whittaker; "Alternating Current Theory," by A. Russell, in two vols.; "The Study of Chemical Composition," by I. Freund; "The Fauna and Geography of the Maldive and Laccadive Archipelagoes: being the Account of the Work carried on and of the Collections made by an Expedition during the years 1899 and 1900 under the leadership of J. S. Gardiner," vol. ii., part iv., illustrated; "Reports of the Anthropological Expedition to Torres Straits by the members of the Expedition," edited by Dr. A. C. Haddon, F.R.S.; "Studies from the Anthropological Laboratory in the University of Cambridge," by W. L. H. Duckworth, vol. i.; "On two Orders of Arachnida: Opiliones, especially the Suborder Cyphophthalmi and Ricinulei, namely the family Cryptostemmatoidæ," by Drs. H. J. Hansen and W. Sørensen, illustrated; "Immunity in Infectious Diseases," by Prof. Metchnikoff, authorised English translation by F. G. Binnie, illustrated; "Morphology and Anthropology," by W. L. H. Duckworth; "The Origin and Influence of the Thorough-bred Horse," by Prof. W. Ridgeway; "Fossil Plants: a Manual for Students of Botany and Geology," by A. C. Seward, F.R.S., vol. ii.; "Trees: a Handbook for Students of Forest Botany," by Prof. H. M. Ward, F.R.S., in six volumes, vols. ii. to vi.; "The Morphology of Plants," by J. C. Willis; and "The Journal of Agricultural Science," edited by Prof. T. H. Middleton, T. B. Wood, R. H. Biffen, and A. D. Hall.

MESSRS. JOHN WILEY AND SONS (New York) and Messrs. Chapman and Hall, Ltd. (London), have in preparation:—"An Elementary Treatise on the Differential Calculus, Founded on the Method of Rates," by W. W. Johnson; "A Treatise on Concrete, Plain and Reinforced," by F. W. Taylor and S. E. Thompson; "Elements of General Drafting for Mechanical Engineers," by C. E. Coolidge and H. F. Freeman; "Conversations on Chemistry," by W. Ostwald, translated by E. C. Ramsay, part i.; "Machine Shop Tools and Methods," by W. S. Leonard; "Ordinary Foundations, including the Coffer-dam Process for Piers, with numerous Practical Examples from Actual Works," by C. E. Fowler; "The Textile Fibres, their Physical, Microscopical, and Chemical Properties," by J. M. Matthews; "Manual of the Chemical Analysis of Rocks," by H. S. Washington; "Untechnical Addresses on Technical Subjects," by J. Douglas; "Techno-Chemical Analysis," by G. Lunge, translated by A. I. Cohn; "Application of some General Reactions to Investigations in Organic Chemistry," by Prof. Lassar-Cohn, translated by J. B. Tingle; "Notes on Assaying and Metallurgical Laboratory Experiments," by R. W. Lodge; "Elements of Mechanism," by P. Schwamb and A. L. Merrill; "An Introduction to Projective Geometry and its Applications, an Analytic and Synthetic Treatment," by A. Emch; and "Manual of Serum Diagnosis," by O. Rostoski, translated by C. Bolduan.

OUR ASTRONOMICAL COLUMN.

THE SOUTH TEMPERATE SPOTS ON JUPITER.—In a letter to No. 348 of the *Observatory*, Mr. Denning directs attention to the need for further observations of the white spots which encroach on the south side of the south temperate belt of Jupiter.

On August 9 he saw two brilliant spots in this locality, having the longitudes 254°.1 and 290°.1 respectively, and has little doubt that these are identical with those he observed in 1903 and previously.

As Mr. Denning has suggested that the movements of these objects may cause the observed irregularities in the velocity of the great red spot—the velocity of which is a little less—it is important that they should be frequently observed, and the results of the observations published.

The spots lose about 16°.4 per month relatively to Crommelin's System ii., and their positions for the next few months will be as follows:—

		I. Long.		II. Long.
1904 Oct. 15	...	218°.4	...	254°.0
Nov. 15	...	202.0	...	237.6
Dec. 15	...	185.6	...	221.2
1905 Jan. 15	...	169.2	...	204.8
Feb. 15	...	152.8	...	188.4

Mr. Denning will be pleased to receive records of new or old observations of these objects.

A RAPIDLY MOVING SOLAR PROMINENCE.—A fairly large prominence having a great velocity was observed by Mr. J. B. Coit, of Boston University, on May 23. Whilst setting the slit of his spectroscope on Hα he noticed a cloud-like arch, made up of radial filaments, stretching from P = 89° to P = 100°, the space below the arch being apparently quite blank. At 11h. 55m. the altitude of the prominence was 90″, and it quickly increased to 105″, after which it rapidly decreased until, at 11h. 58m., it was only 70″. By this time all semblance to the original structure was lost, and only a few cloudlets remained. At 12h. 1m. nothing could be seen above the limb, and the chromosphere between 89° and 100° was quite tranquil, except for a few small shreds at the places where the ends of the arch had rested. Subsequent observations with a 5-inch equatorial showed no trace of spots or bright faculæ on or near the limb in this region (*Popular Astronomy*, No. 7, vol. xii.).

PUBLICATIONS OF THE GRONINGEN ASTRONOMICAL LABORATORY.—Two numbers of these *Publications*, which are printed in English and edited by Prof. Kapteyn, have just been received. No. 12 is devoted to the results of an investigation by Dr. W. de Sitter of the systematic differences between the photographic and visual magnitudes of stars depending upon the galactic latitude. The investigation was carried out at the Cape Observatory, Dr. de Sitter taking the photographs and Mr. R. T. A. Innes making the visual observations.

The results show, among other things, that the colours of the stars near the galactic poles seem to be distributed at random, and, further, that no *average* colour exists for those in the galaxy, but rather that there are colour differences which vary irregularly with the galactic *longitude*. This interesting result calls for further investigation, and Dr. de Sitter suggests several methods which might be employed to elucidate the matter further.

No. 13 of the *Publications* contains a catalogue of the proper motions of 66 stars of the Hyades, derived from the comparison of thirty-four catalogues published between 1755 and 1900. This work was performed by Herr H. A. Weersma to facilitate the reduction of Prof. Duner's plates, which were taken for the purpose of determining the proper motions of the Hyades stars. The results are given in detail in the paper, which concludes with a general catalogue of the 66 stars, showing their magnitudes, their positions for 1900, and their proper motions.

THE GOODSELL OBSERVATORY EXPEDITION TO THE ROCKY MOUNTAINS.—A short general description of the results obtained by Dr. H. C. Wilson and Prof. Payne during their sojourn at Midvale (Mont.), which is situated at an altitude of about 4800 feet in the Rocky Mountains, is given in No. 7, vol. xii., of *Popular Astronomy*.

The expedition was undertaken in order to photograph some of Herschel's suspected nebulous regions under exceptionally good atmospheric conditions. The heavy dews, caused by a difference of 40 or 50 degrees between the day and night temperatures, and the smoke from neighbouring forest fires somewhat interfered with the carrying out of the entire programme, but on the whole the photographs obtained were very successful. A full description of the work accomplished, the observing conditions, &c., is promised for a later publication.

Anthropology at the British Association.

The address of the president, Mr. Henry Balfour, dealt with the subject of evolution in the material arts as illustrated by the work of the late Lieut.-General Pitt Rivers, and has been already printed in full in Nature (September 1).

Evolution in the Material Arts.

The remainder of the programme on August 18 was appropriately reserved for communications which illustrated the application of the theory of evolution to special problems of art and technology, as follows :—

Prof. Oscar Montelius gave a demonstration of the evolution of the lotus ornament, which, though it brought forward no new points, gave a well illustrated survey of the work of Goodyear and others, and analysed the complicated results of the interaction of naturalistic and conventional treatments of the same original motive. The discussion which followed was mainly directed to secure recognition for other plant-motives, such as the fleur-de-lys, iris, papyrus, as being partly responsible for certain variations of the "lotus-ornament," and the inevitable skirmish followed the mention of the "Ionic capital."

Prof. Flinders Petrie's note on the entomology of scarabs distinguished five principal types of scarab-backs, designed in imitation of five genera of beetles, Scarabæus, Catharsius, Copris, Gymnopleurus, and Hypselogenia, and showed how the characteristic forms of the head, elytra, and legs of these genera have given rise to a large number of conventional variants. The use of other beetles besides the true Scarabæus, for magical purposes, is well attested both by the medical papyri and by the modern folk-lore of Egypt.

Prof. Flinders Petrie's description of his excavations at Ehnasya (Herakleopolis Magna), in Egypt, was chiefly noteworthy for his comparative study of the forms of the Roman lamps and terra-cotta figurines, which were obtained in large enough numbers to afford an intelligible series. Here, also, a very few principal types have degenerated into numerous conventional and unintelligible variations, which have often influenced each other and given rise to fresh types based on misinterpretation of the blurred forms. In this instance it is noteworthy that the older and purer forms can be proved to have survived alongside even the most corrupt; as if the latter, though well established, pursued a separate course, and failed to supplant their archetypes.

Another point of some interest in this connection is Prof. Petrie's discovery, near Ehnasya, of a modern Coptic cemetery which preserves, in its tomb-façades and enclosures, many architectural features which are characteristic of ancient Egyptian burial-places.

Mr. R. T. Günther read on August 22 a study of the *cimaruta*, a common Neapolitan charm representing in silver a sprig of rue with magical symbols appended. He brought together a large number of examples, and supplied full details of the successive developments which the originally naturalistic model has undergone, as well as of the significance of the emblems which have been added to the rue-plant to increase its prophylactic powers.

Physical Deterioration and Anthropometric Surveys.

The session of August 19 was devoted to a systematic discussion of the alleged physical deterioration of the people of these islands, with special reference to the recent report of the Privy Council Committee, and to the scheme proposed by the association's committee on anthropometric investigation for the organisation of an anthropometric bureau to collect and analyse more adequate data than those which are at present available.

The report of the committee on anthropometric investigation was read by the secretary, Mr. J. Gray. Some progress has been made in the determination of the necessary standards of measurement, and the chairman and secretary of the committee have given evidence before the Privy Council's Committee as to the data which already existed, and as to the best means of securing an adequate, continuous, and homogeneous series in future. The committee recommends a small permanent anthropometric bureau, organised as a committee of the Privy Council, with an honorary consultative body, a director and deputy director (trained, one in anthropology, the other in statistical method), and an adequate body of surveyors, male and female, who would visit schools, factories, and other institutions, and secure representative sets of measurements. An appendix to the report takes account of the surveys already in progress in Scottish schools and lunatic asylums, in London hospitals, in Dorsetshire, and among the gipsies of the Scottish border.

Prof. D. J. Cunningham, F.R.S., who is chairman of the anthropometric committee, accepted the general conclusion of the "epoch making" report of the Privy Council Committee, that there was no serious physical deterioration in the nation at large, but held strongly that without proper environment and nurture, and particularly without proper air and food, it was impossible to maintain in the coming generation the mean national standard of physique to which a people tends naturally to approximate, so far as outward circumstances permit. Slow evolutionary changes in this physical standard are taking place, but except in regard to the teeth, which are degenerating rapidly, they may be neglected in practice. The recent improvement in the physique of women of the upper and middle classes is due to healthier conditions and habits, and illustrates their effects. In spite, however, of the labours of the British Association's Anthropometric Committee in 1878–83, the evidence on which all inferences have been based hitherto is fragmentary, ill coordinated, and quite inadequate, and a systematic survey such as is now proposed would put the whole matter on a quite different footing. The cost would be slight, and the national advantage incalculable.

Dr. F. C. Shrubsall followed with a comparison of the physical characters of hospital patients with those of healthy individuals from the same areas, with suggestions as to the influence of selection by disease on the constitution of city populations. Blondes are found to suffer more than brunettes from rheumatic disorders, and less from tuberculosis, nervous disorders, and cancer. Blondes also suffer more from disease in childhood, and their numbers and proportion consequently diminish until the age of twenty to twenty-five, when the pulmonary tuberculosis of the brunettes begins rapidly to redress the balance. In cities, the most overcrowded and most unhealthy areas are consequently the most brunette, and also have the highest infant mortality through the extinction of blonde children by disease. Dr. Shrubsall's paper was well illustrated with original tables and maps, and was evidently followed with close attention.

Mr. J. Gray then explained in detail the working of an anthropometric survey, and the valuable results which may be expected from it in anthropological science, and in practical economy and hygiene. Civilisation has brought so many new influences to bear on the more advanced races of mankind that more accurate and copious observations are required to detect in their inception deep-seated changes in the relation of man to his environment, the effects of which may be controlled if recognised in time.

The president of the association, who occupied the chair in the section throughout the session, opened the discussion by the inquiry, what is the precise nature and effect of the set of circumstances which we describe as "town life"? the most important of the temporary and obvious causes of physical deterioration, as opposed to the permanent and insidious causes indicated by Dr. Cunningham. Mere want of indoor ventilation, for example, does not produce deterioration, *e.g.* in the one-room cottages of the gigantic Lowlanders of Scotland; and both sanitation and quality of food are, on the whole, better in the towns than in the country. Among the causes which might produce permanent changes in the national physique, three seemed particularly noteworthy. Since marriage is later, and families are smaller, in the middle classes than in the lower, facilities for "rising," such as are given by modern education, cannot but diminish the proportion in the next generation of the offspring of the more efficient in this. Town life, too, by encouraging a brunette population, is altering the inherited characteristics of the nation at the expense of the traits which we owe to our blonde ancestry. Further, town life, by attracting the more energetic elements in the rural population, is throwing

upon the less efficient remainder the greater part of the burden of continuing the race. Town life, however, does not seem to be among the factors which it is possible to eliminate by legislation, and it is permanently selective agencies such as this which affect the actual quality of a race.

Sir John Gorst considered it proved that a large proportion of the nation lives in conditions unfavourable to normal development, and that the race is being propagated in undue proportion by the lowest and least fit. The general death-rate decreases, for instance, but not the death-rate for infants. Legislation might fairly prohibit marriage between the immature or the mentally unfit; but the main cause of the relative increase in the low-class birth-rate is, as the Royal Commission in New South Wales has shown, the luxurious reluctance of the well-to-do to take their share in bringing up the next generation. Meanwhile, in so far as it controls any part of a child's lifetime, as it does by compulsory education, the State is so far responsible for securing it sufficient air and food. There are many ways of securing these and of coercing neglectful parents, and local authorities might well be given permission to experiment in the manner suggested by the medical faculty of Scotland in regard to the Scottish Education Bill.

Prof. Rudolfo Livi, director of the Italian Military Survey, described its methods, and replied to Dr. Cunningham's criticisms of military measurements. Conscript statistics, however, yield more representative data than those of a voluntary army, and the Italian survey establishes clearly the correlation between prosperity and enlightenment and immunity from disease. In England, probably the mitigation of extreme social conditions favoured a relatively high physique.

Mr. E. W. Brabrook, secretary of the British Association Committee of 1878–83, urged the importance of uniformity of measurements, and assured the anthropometric committee of the cooperation of existing surveys.

Major McCulloch described the survey, recently ordered, of children in army schools, and discussed practical difficulties of uniform measurements. Prof. A. Macalister insisted on the necessity for large numbers of observations. Statistical conclusions from inadequate data are fallacious.

Mrs. Watt Smyth recommended the inclusion of simple anthropometric observations in the ordinary routine of school registration as an aid to the teacher in following the development of the child. In Boston, U.S.A., such daily observation greatly diminished the risk of infectious disease. The valuable results thus attained would facilitate a full national survey.

Other papers on anthropological organisation occupied the afternoon of August 19. Mr. Edgar Thurston described the progress of the ethnographic survey in Madras, of which he has been the principal organiser, going into details as to method and cost, the nature of the evidence which it is possible to collect, both in anthropometry and in ethnography, the photographic record of racial types, and the difficulties of combined museum and field work such as are unavoidable with an infinitesimal staff working among ignorant and timid populations. He concluded with a summary of the ethnography of the area covered by the survey, and a criticism of the published measurements of the Indian Coronation contingent.

The report of the committee on anthropological teaching described the method of inquiry, and gave details of the position occupied by anthropology or its main subdivisions in some seventy-five universities and colleges in Europe, the United States, and elsewhere, with many interesting data as to the ways in which this comparatively new study has won recognition as an offshoot of this or that recognised subject, and as to the practical applications which are found to emerge wherever a more enlightened policy has permitted a museum or university to provide adequate teaching.

Mr. J. F. Tocher described in detail the recent anthropometric work in Scotland outlined in the morning's discussion, and also the distribution and variation of the surnames in east Aberdeenshire in 1696 and 1896. Migration accounts for the disappearance of many names; but the extinction calculated by Galton and Watson is found to be approximately correct, and likewise the rate of change on Karl Pearson's theory of contingency.

Anthropography.

The experiment was made on Monday morning (August 22) of a separate subsection for the discussion of papers on human anatomy and kindred subjects. The lecture room of the zoological department was kindly lent for this, and Prof. A. Macalister presided.

Dr. G. Elliot Smith made a communication on the persistence in the human brain of certain features usually supposed to be distinctive of apes, based on a large series of simple human brains, chiefly African. Simian characters are most conspicuous in the occipital region, because the visual area is as well developed in apes as in man; but though the structure is identical, the shape of this area in man is much distorted by increase of the cortical area in front of it. Simian resemblance is more often retained in the left occipital region than in the right, because in man the visual centre retracts more towards the mesial surface on the right side, and this asymmetry often influences the cranial form. Large "Affenspalten" may occur in various races, but are rarely symmetrical, except in Negro brains, which are distinctly more pithecoid. In discussion, Mr. Duckworth described similar simian features in Australian brains, with frequency of 50 per cent.; Prof. Grünbaum brought physiological evidence to corroborate the anatomical data; Prof. Windle and Prof. Macalister fully accepted Dr. Elliot Smith's conclusions.

Mr. Duckworth showed photographs of the brain of a fœtal gorilla suggesting the artificial nature of the cerebral fissures. Prof. Grünbaum suggested histological examination, and Prof. Macalister summarised the history of the recent study of these features.

Mr. R. B. Seymour Sewell described some variations in the astragalus observed in 1000 specimens, mainly Egyptian. Their angle of collum and corpus is intermediate between the European and the anthropoid; changes in the articular surfaces are determined by the adoption of certain postures, and by the progressive eversion of the foot. Accessory facets are occasionally present, and facets are occasionally fused or absent. The os trigonum is very variable. Prof. Windle criticised Pfitzner's view of the os trigonum.

Mr. P. P. Laidlaw described some varieties of the os calcis, based on the Cambridge collections, namely:—(1) variability of the processus trochlearis, which seems not to develop from a separate ossicle; (2) external plantar tubercle; (3) calcaneus secundarius of Gruber; (4) os sustentaculi proprium; (5) processus trochlearis of Kyrtl, shown to be pathological; (6) variation of facets due to ossicles and other factors; (7) European reduced projection of the heel due to backward extension of the fascia articularis posterior. In discussion, he gave the length of the Egyptian heel-bone as 3 per cent. more than that of the European.

Mr. F. G. Parsons's paper on facial expression discussed the anatomy of the facial muscles, and illustrated their effects from historic portraits. Prof. Windle attributed alteration of expression to habitual action of certain muscles, probably recorded in the subcutaneous tissues; on this fœtal evidence should be decisive. Mr. Parsons replied that subcutaneous thickening is already perceptible at the ninth month.

Mr. J. Gray proposed a new system of classifying the records in anthropometric identification. The Bertillon system with fixed subdivisions only identifies 61 per cent. on the first search. The system proposed substitutes progressive subclassification of the data of one measurement by the data of the next in order. Search is further simplified by the use of charts on which dimensions used as coordinates determine the position of a record-number. The discussion only emphasised the need of accurate measurement.

The committee on anthropometric investigations among the native troops of the Egyptian Army reported progress in coordinating Dr. Myers's data. The modern population of Kena province shows less variability in head length and breadth than the prehistoric population (at Nagada), but more in cephalic index. The greater variability of Theban mummies is explicable by racial admixture in a large city. The objections raised to inferences from conscript data seem to be invalid. The Coptic population is apparently more variable than the Mohammedan, apparently because variability increases the chance of survival, and so multiplies among the oppressed.

Dr. Myers's paper on the variability of ancient and modern peoples elaborated the last-named point in comparison with data from elsewhere. Ancient and modern peoples do not seriously differ in variability, provided the external conditions are similar, while favourable conditions tend to homogeneity, *i.e.* regression towards the mean; and *vice versâ*.

Mr. Duckworth discussed the methods of graphical representation of the various racial human types employed by Keane, Flinders Petrie, Thomson, and Strentz, and proposed the simile of a protoplasmic origin modified into processes representing the various morphological types.

Prof. A. Macalister exhibited a series of Amorite crania from excavations at Gezer, in Palestine. The people of the first two strata practised cremation, and so destroyed their skulls, but the third and fourth strata show burials in contracted posture, accompanied by food vessels.

Linguistics.

On the morning of August 22 Sir Richard Temple, Bart., explained a plan for a uniform scientific record of the languages of savages, which starts from the sentence as unit-expression of a complete meaning, and classifies words according to their function in the sentence. The forms assumed by words grow out of these functions, and are determined by sundry functional affixes. The sentence considered as the elementary component of a language indicates the outlines of a classification of languages, and the conditions under which languages and linguistic groups develop. The plan has been successfully applied to several savage tongues, as well as to Latin, English, and Hungarian, and claims consideration as leading to rapid and accurate analysis and acquisition of language.

General Ethnology.

Mr. A. W. Howitt read on Monday a paper on group-marriage in Australian tribes. Among the tribes round Lake Eyre, two forms of marriage occur. One follows upon betrothal of children by their mothers, and the other is the subsequent marriage of the woman to a younger brother of her husband. On ceremonial occasions this latter form of marriage is extended in the tribe by the allotment to each other of men and women who are already allotted to each other under one or other of the two marriages. This group-marriage also occurs in other tribes in south-east Australia, either in the form which it has in the Lake Eyre tribes or as a survival of custom. It is shown by the system of relationship in the Australian tribes to have been at one time common to all. In the Lake Eyre tribes there is female descent with group-marriage. In other tribes in which group-marriage is merely a survival, or is merely indicated by the terminology of relationship, there has been more or less an approach to a form of individual marriage accompanied by a change from female to male descent. Changes such as these are attended also by alteration of the social organisation of the tribes. In one direction there has been a segmentation of the tribe from a division of two intermarrying exogamous moieties of the tribal community to four such divisions, and finally into eight, with a change also in the line of descent. In the other direction there has been a partial or complete loss of this division of the community into four and eight segments. The tribe has become organised on a geographical basis into a number of local groups, and these localities have become exogamous and intermarrying. In these changes in the organisation of the tribes the line of descent has passed from the female to the male line. In the Lake Eyre tribes a group of totems is attached to each exogamous moiety. These remain in existence in the segmentation into four and eight groups. In those tribes where the organisation of the tribe has become local, the totem groups have either become more or less extinct or have changed in extreme cases into magial names without influence in marriage.

Mr. R. S. Lepper offered a discussion of the passing of the matriarchate as observed in southern India, but devoted the time allotted to him to an exhibit of photographs of more or less matriarchal peoples.

On Wednesday M. E. Demolins submitted, under the title "Classification Sociale," an elaborate analysis of types of human society, based upon that of Le Play, but designed to supersede it by a system based upon modern ethnological data. All human societies are either communistic, relying for social progress on the community rather than on the individual, or particularist, with the reverse tendency. The former dominates the east, and explains its immobility; the latter the west, and causes its progress. The communistic societies pass through the three stages of stability, instability, and chaos. In the third, communism is seen breaking down, as in ancient Greece and Italy, or in eastern Europe now. The particularist societies are in turn rudimentary, chaotic (*ébranlée*), and advanced; to the last, as illustrated in Greater Britain and the United States, belong the social types of the future. Within these main types social growth is conditioned by geographical considerations, which determine the dominant forms of human industry and the institutions which result. The paper, which was well illustrated by printed diagrams, gave rise to a lively discussion.

Dr. W. H. R. Rivers described the funeral ceremonies of the Todas. Among points not previously noted are:—(1) the laying of a cloth on the body by those who have married into the clan; (2) a purification-rite, in which a man in woman's ornaments touches the remains with a bow and arrow; (3) the Toda beliefs as to the incidents of the journey to the other world.

Mr. E. S. Hartland exhibited a votive offering from Korea, representing a tiger in roughly cast iron. The Korean mountains are infested by tigers, which were formerly worshipped, and every pass has its votive shrine; probably, therefore, this votive tiger belongs to some tiger-cult.

Mr. E. P. Martin's paper on the Fulahs of Nigeria, and Prof. Ridgeway's anthropological view of the origin of tragedy, were taken as read.

Ægean Archaeology.

The morning session of August 23 was devoted to the results of recent exploration in Crete, and the section adjourned to the New Theatre to secure accommodation for the more numerous audience.

The proceedings opened with a brief address from Dr. P. Kabbadias, Inspector-General of Antiquities in Athens, who discussed the reasons for the great rarity of Neolithic remains in Greek lands, and described the recent operations of the Greek Archæological Society in Thessaly. Dr. Kabbadias's appearance was received with the utmost cordiality, and expression was given by Sir John Evans, Sir Richard Jebb, and by two successive directors of the British School of Archæology in Athens to the general appreciation of his services to the cause of Greek antiquities and to the foreign students of all nationalities in Athens.

The report of the Cretan Exploration Committee summarised the course of the British excavations of 1904, and left the way clear for discussion of the results.

Dr. Arthur Evans, F.R.S., explained his preliminary scheme for the classification and approximate chronology of the periods of Minoan culture in Crete, from the close of the Neolithic to the early Iron age. To the period as a whole it is proposed definitely to attach the name *Minoan*, as indicating the probable duration of successive dynasties of priest-kings, the tradition of which has taken abiding form in the name of Minos. It is proposed to divide this Minoan era into three main periods, early, middle, and late, each with a first, second, and third subperiod. The use of the word *Mycenaean* should be confined to objects of the late and subsidiary outgrowth (*Late Minoan III.*), when the fine motives of the "last Palace Period" at Knossos (now *Late Minoan II.*) are already in the state of decadence observable at Tell-el-Amarna (about 1400 B.C.), and even in earlier objects associated with cartouches of Amenhotep III. and his Queen, in Egypt, Rhodes, Mycenæ, and elsewhere. The less decadent forerunners of this style, in the new-found cemetery at Knossos, are still later than the art of the "last Palace Period." The third late Minoan period may thus be roughly dated between 1500 B.C. and 1100 B.C.

Late Minoan II., which precedes it, is best illustrated, in the latest palace at Knossos, by the fine "Palace style," with its strong architectonic elements, and marked correspondence, in its latest stage, with the art of the Kefts

and "Peoples of the Isles of the Sea" on Egyptian monuments of the sixteenth century B.C.; and the royal tomb at Knossos contains alabaster vessels of early eighteenth dynasty date. But the "Palace style" must itself represent a considerable period of development, and its earlier phases must go back at least a century earlier. *Late Minoan II.* may thus extend from about 1700 B.C. to 1500 B.C., corresponding with the Mycenæan shaft graves, and at Knossos with the later Class B of the Palace archives in linear script.

Late Minoan I., an earlier stage of the later Palace, marked off by an extensive catastrophe, is clearly shown in the "Temple Repositories" as an age of ceramic transition with naturalistic art at its highest perfection, and Class A of the linear script. The elaborate lid with King Khyan's name, and a monument of thirteenth dynasty period, date this stratum between 1900 B.C. and 1700 B.C.

The *Middle Minoan* age is especially characterised by the polychrome style of vase-painting on a dark ground, and by the conventionalised pictographic script which precedes the linear. In *Middle Minoan III.* the polychrome is degenerate, and naturalism, in reliefs and on gems, is growing; and it is in *Middle Minoan II.* that the polychrome (formerly "Kamares") style reaches its acme. The beginning of this stage is approximately dated by Egyptian motives on the seal-stones, and by the sherds found by Prof. Petrie in the rubbish-heaps of Kahun, dating from the time of Usertesen II. of the twelfth dynasty (2300 B.C. acc. to Lepsius; Petrie and others say nearly 2700 B.C.). In any case the Cretan evidence excludes the recent theory which makes the twelfth dynasty border on the eighteenth. *Middle Minoan I.* is also represented among the Kahun sherds (which thus give a precise upper limit for *Middle Minoan II.*), and mounts back at least to the middle, and perhaps (on Petrie's chronology) to the beginning of the third millennium.

Beyond this lies the long *Early Minoan* cycle of nascent culture, with geometrical decoration and ornament, generally dark on a light ground, though the dark glaze slip itself goes back to the confines of the Neolithic. Raised decoration on the surface of the clay is also abundant, and the hand-polished, dark-faced Neolithic ware survives throughout. The painted decoration also betrays the influence of the earlier incised designs. A section opened below the pavement of the west court shows a distinct stratification of floor levels of this period, of which the earliest (sub-Neolithic) shows incipient light-ground technique, improved Neolithic fabrics, and the first spiral ornaments, carved or incised, the prototypes, probably Cycladic in origin, of the later painted spirals. Early Minoan seal-stones show adaptation of seventh dynasty motives, and vases of syenite, &c., betray intercourse with dynasties I. to IV., while imported black ware from the first dynasty layer at Abydos is indistinguishable from that of sub-Neolithic Knossos. Comparison of Neolithic with Minoan rates of accumulation of débris gives a probable antiquity for Knossos of 12,000 years in all.

Discussion was opened by Prof. Ridgeway, who agreed with the proposed chronology as far back as the beginning of the eighteenth dynasty, but was not satisfied in regard to the twelfth and beyond. The name "Mycenæan" was no longer appropriate in a generic sense, but the term "Minoan" was open to a similar objection when applied to a period so long and early. His chronological objections were supported in detail by Mr. J. Garstang. Lord Avebury, on the other hand, expressed himself prepared for even longer periods in prehistoric chronology, and Prof. Sayce agreed that the interval between dynasties XII. and XVIII., though archæologically a blank in Egypt, may have been a long one. Dr. Kabbadias and Mr. Hogarth discussed the relations in which Minoan culture stands to Hellenic, the former laying stress on the sociological differences, the latter on the continuity in artistic essentials.

Dr. Evans, in reply, agreed as to the large element of survival from Minoan to Hellenic time, but laid stress on the evidence for the introduction of a fresh ethnic element in the interval. Mr. Garstang's criticisms did not affect the proof that the respective stages of Minoan and Egyptian culture synchronised at the points indicated in his classification.

Other papers on Cretan archæology followed.

Mr. R. M. Dawkins described the painted vases of the Bronze age from Palaikastro, in eastern Crete, with special reference to the styles of decoration, to which Dr. Evans's Knossian classification is applicable at all important points.

Mr. R. C. Bosanquet reported progress in the British School's excavations at Heleia (Palaikastro) and Praisos; a late Mycenæan palace has been excavated, and the main street further explored, with the adjacent houses; more middle Minoan ossuaries have been opened, and also a very early burial-place near Kastri, and a later cemetery with larnax-burials. A steatite libation-table yielded an inscription of seventeen Minoan characters. Within the Minoan town a shattered Hellenic sanctuary contained a slab inscribed in letters of Roman date with an archaic Doric hymn in honour of Young Zeus. This identifies the site with the temple of Zeus Diktaios, and consequently the plain of Palaikastro with the classical place Heleia. At Praisos the west face of the Altar Hill has yielded fragments of architecture and inscriptions from a sanctuary on the summit, among them a fresh document of the Eteocretan language in Hellenic characters of the third or fourth century B.C.

Sir Richard Jebb gave a rendering of the hymn to Zeus, and discussed its allusions to the Curetes and their cult, adding a suggestion (based on Plato, *Laws* 624 A) as to the "nine-year" legend of Minoan legislation; and Prof. R. S. Conway discussed the linguistic character of the Eteocretan language in the light of the new inscription from Praisos, which confirms previous results, and indicates an Indo-European type.

Mr. R. C. Bosanquet described a find of copper ingots at Chalcis, in Eubœa, nineteen in number, and of a characteristic Bronze age form already known from Crete, Cyprus, and Sardinia. The source of supply was probably in Othrys, while Chalcis was the chief emporium. The bronze axe-heads frequently found hoarded in the Ægean (*e.g.* recently in Othrys itself) have shaft-holes too small for use, and may be currency. The memory survived in the Cretan expression "axe" for a fraction of a talent.

Prof. Oscar Montelius gave a well illustrated description of the geometric period in Greece, which succeeds the Mycenæan (late Minoan) in Hellas and the Ægean, though apparently not in Asia Minor. He rejects the view that the geometric style is derived from countries north of Greece, holding that its characteristic motives appear earlier in Greece than in the north. He regards it as a modified continuation of the Mycenæan style, not due merely to the migration of the Dorians (as it is well marked in Attica, which they did not conquer), but mainly to the expulsion of the Tyrrhenian or Pelasgian foreigners, to whom he attributes the Mycenæan culture. He dates the geometric period between the twelfth and the close of the eighth century, and divides it into the three stages marked by the Dipylon, Phaleron, and pre-Corinthian types of vases.

Other Archaeological Papers.

Prof. Valdemar Schmidt, of Copenhagen, summarised the latest discoveries in prehistoric science in Denmark. The musical properties of the famous Bronze age trumpets in the Copenhagen Museum have been re-discovered, and are utilised annually. An earlier period has been established in the Danish Stone age than those of the "kitchen-middens" and the dolmens; for a peat bog in W. Zeeland, near Mullerey Harbour, yields implements of early types which were dropped by the inhabitants of floating "raft-dwellings." Examination of the impressions of corn grains in prehistoric pottery has established the kinds of wheat and barley which were cultivated at different periods. Systematic archæological survey has established the true distribution of tumuli and other monuments. The tumuli follow lines which avoid swamps, converge on fords, and otherwise betray themselves as roads, and offer valuable clues for the location of settlements along them.

Miss Nina Layard's further excavations on a Palæolithic site in Ipswich determined a Palæolithic floor sloping to the margin of a former lake, all now buried 8 feet to 12 feet

in brickearth. Forty implements and numerous chipped fragments have been found, and the position of certain well wrought oval implements, in and under compact clay at the lowest levels, identifies them as missiles hurled at water-fowl on the lake. Teeth of elephant, rhinoceros, ox, and deer occur in coarse gravel below the implement layer, and plant-roots in the clay below that.

Prof. E. B. Poulton exhibited records of Palæolithic man from a new locality on the north-east coast of the Isle of Wight, including every stage from flake to finished implement.

The sixth report of the committee on the lake village at Glastonbury announced fresh excavation in 1904, under the joint superintendence of Mr. A. Bulleid and Mr. H. St. G. Gray. Eight mounds, containing two or more floors, were examined, and plans and photographs secured. Objects of amber, glass, and tin, and an adze of iron were found, as well as bronze, stone, and bone objects, and pottery. In one mound, peas were found in some quantity. Arrangements are in progress for the publication of the results of the whole excavation.

Mr. F. R. Coles and Dr. T. H. Bryce described an interment of the early Iron age found at Moredun, near Edinburgh, in 1903. A cist covered with flagstones contained fragmentary human remains of normal local type, with a fibula of La Tène type, a ring-brooch, and a circular open pinhead, indicating a date not later than the second century A.D. This is the first completely attested interment of early Iron age in Scotland.

Dr. T. H. Bryce discussed a phase of transition between the chambered cairns and closed cists in the south-west corner of Scotland. The clue is given by a cairn at Glecknabae, in Bute, which contained two "atypical" chambers set radially in the cairn and containing burnt bones, and a closed cist with unburnt interment. One of the chambers also contained an unburnt fragment. The pottery, which included both typical "chamber" pottery and also fragments of the "beaker" class, indicated a triple occupation of the site, and a late date for the reduced atypical chamber.

The report of the Roman sites committee described work in progress at Silchester and Caerwent, and Mr. T. Ashby summarised the season's progress on the latter site. The south gate has been found to be parallel to the gate on the other side, and an inscription dedicated to Mars bears the date August 23, 152 A.D.

Prof. Flinders Petrie's excavations at Ehnasya have been already mentioned in connection with his series of Roman lamps. Ehnasya is the Roman Herakleopolis Magna and the Egyptian Henensuten, about 70 miles south of Cairo and 10 miles from the Nile. It was the home of the ninth and tenth dynasties, of which hardly anything is known. It is found to contain temples of the eighteenth and twelfth dynasties, and under the latter a stratum of older houses and burials with scarabs of Antef V. This king has recently been assigned to dynasty XVI. or XVII., but is thus brought earlier than dynasty XII. Later buildings of dynasty XXIII. yielded a fine votive statuette, in gold, of the local ram-headed deity, Hershefia, dedicated by a vassal of King Piankhi; and houses of Roman date gave important evidence as to the stages by which Christianity first displaced the native animal-cults, and then itself absorbed the Isis and Horus worship as the Madonna-cult.

Mr. J. Garstang described his excavations in the Royal tomb of Negadeh, in Upper Egypt, which completed the work begun some years back by the French, and recovered another fragment of the "Tablet of Mena," to whom the tomb has been commonly attributed.

Mr. R. N. Hall's recent excavations at Great Zimbabwe show the ruins to be three times larger than was supposed, and distinguish clearly between (*a*) the original constructions (*e.g.* the eastern half of the "Elliptical Temple"), which are still of uncertain age and associated with numerous phalli, and (*b*) sundry additions which are shown by Arab pottery to be not older than about 1300 A.D., and do not contain phallic objects. Much useful work has been done on behalf of the Chartered Company to preserve existing structures, and to clear the ruins of surface deposits and other obstacles to study.

BOTANY AT THE BRITISH ASSOCIATION.

THE meeting of the botanical section at Cambridge may probably be regarded as the most successful of the whole series of meetings which have been held since botany was constituted a separate section of the British Association. A large number of distinguished foreign botanists were present, and there was a fully representative gathering of British botanists to meet them. By the kindness of Prof. H. Marshall Ward, F.R.S., the meetings were held in the rooms of the new botany school, which proved to be admirably suited for the purpose. Prof. Ward and the botanical staff are to be congratulated upon the excellent arrangements made for the lectures, lantern demonstrations, exhibition of apparatus and specimens, &c., which contributed so much to make the meeting a success.

The president (Mr. Francis Darwin, F.R.S.) in his address, which has already appeared in NATURE (September 8), dealt with the perception of the force of gravity by plants, and especially with the statolith theory of geotropism.

The general work of the section included, in addition to the more technical papers, the usual semi-popular lecture, and a series of three addresses of a general character on important topics.

The subject of the semi-popular lecture, which was delivered by Dr. D. H. Scott, F.R.S., was a new aspect of the Carboniferous flora. It was shown that Brongniart's conception of the Carboniferous period as the reign of Cryptogams can no longer be maintained. Recent work has all tended to show that a large number—perhaps the majority—of the so-called ferns of that period were not true ferns at all, but seed-bearing plants approaching the Cycadophyta. While their affinity with ferns is evident, these plants had already acquired spermatophytic methods of reproduction—hence the name Pteridospermeæ is proposed for them. If we further take into account the seed-plants previously known—notably the Cordaiteæ—and those Lycopods which produced organs analogous to seeds, we are led to the conclusion that quite half the vascular plants of the Carboniferous period had already assumed the seed-habit.

Ecology.

Prof. A. G. Tansley, in an address on the problems of ecology, defined ecology for his purpose as the study of those relations of plants to their environment dependent on geographical and topographical factors. It is very largely topographical aggregates, due to soil, water, and other conditions with which ecology has to do, and the study of these falls into two parts, descriptive and experimental. The problems to be solved may be indicated during the progress of an ordinary botanical survey, but it requires the establishment of experimental stations in regions characterised by definite and specialised floras in order that the detailed investigation of the functional relations of plants to their surroundings may be more completely carried out.

Dr. W. G. Smith, whose work in connection with the botanical surveys of the north of England is so well known, in referring to the ecological aspect of the British flora, pointed out that a general survey of the chief plant associations of Britain has so far revealed some broad principles of distribution in relation to soil and climate, and that when wider areas are investigated the chief plant associations may be more clearly defined as climatic, edaphic, or biological formations.

Mr. T. W. Woodhead gave an interesting account of his observations on the biology and distribution of woodland plants, and dealt with some of the principal factors, such as shade, soil, &c., which tend to modify the plant associations under trees.

Prof. A. Engler (Berlin) read a paper on the plants of the northern temperate zone in their transition to the high mountains of tropical Africa, in which he pointed out that the differences seen in most of the highland forms of plants of tropical Africa, as compared with their relatives of the northern temperate zone, are always in harmony with the different climatic conditions. The modifications observed may be regarded as adaptations, but only in the sense that the adaptation is a passive one caused by the physical con-

ditions of the climate, not an active one corresponding to the views of the Lamarckians.

Mr. Francis J. Lewis presented a paper on the inter-Glacial and post-Glacial beds of the Cross Fell district, in which he pointed out that the plant remains are of considerable interest as throwing light upon the duration and climatic conditions of the several Glacial and inter-Glacial periods. The plant remains of the post-Glacial peat also show that considerable fluctuations have taken place in climate since the close of the Glacial period.

Morphology (including Palaeobotany).

Dr. D. H. Scott, F.R.S., described a new type of sphenophyllaceous cone from the Lower Coal-measures; the cone shows the anatomy and general organisation characteristic of the group, but is distinguished by its branched sporangiophores terminating in peltate, bisporangiate scales, and by the absence of any sterile appendages.

In conjunction with Mr. E. A. Newell Arber, Dr. Scott also presented a short account of two new Lagenostomas. In one of them, *L. Kidstoni*, the seeds are naked, but in the other, *L. Sinclari*, there are indications of an external envelope or cupule. The new seeds were apparently borne on the ultimate branches of a frond in which the lamina had been greatly reduced. There are indications that the fronds were of the Sphenopteris type.

Prof. C. Eg. Bertrand (Lille) contributed a paper by Prof. Cornaille and himself on "La structure de la trace foliaire des Filicinées inversicatenates."

Miss Sibille O. Ford gave an account of the anatomy of *Psilotum triquetrum*, from which she concludes that the Psilotaceæ not only present an affinity with the fossil Sphenophyllales, but also have a strong resemblance, anatomically, to some of the fossil Lycopods, especially to the stem of *Lepidodendron mundum*, as well as to the axis of the cone of *Lepidostrobus Brownii*.

Mr. T. G. Hill, in a paper on the presence of parichnos in recent plants, pointed out that in the mature sporophyll of *Isoctes Hystrix* in the lateral expansions of its base are two longitudinal mucilage-containing cavities which arise by the mucilaginous degeneration of two strands of parenchyma. He suggests that this represents the parichnos occurring in Lepidodendron, Sigillaria, Lepidocarpon, &c.

Dr. Marie G. Stopes described her recent observations on some new points observed in the ovular anatomy and structure in the different genera of Cycads, with the conclusion that there are well marked indications of two integuments.

Mr. L. A. Boodle read a paper on the reduction of the gametophyte in *Todea Fraseri*. Owing to delay in the dehiscence of the sporangium under certain conditions, many of the spores germinate within it. The prothallus may consist of only two or three cells with an antheridium. This is of special interest when compared with the microspores of Salvinia, as illustrating how a reduction of the thallus of a fern approaching that shown by Salvinia may be brought about by the non-dehiscence of the sporangium.

Dr. William H. Lang, in a paper on the reduction of the marchantiaceous type in Cyathodium, concludes that it appears probable that Cyathodium has been derived by adaptation to damp and ill lighted situations from a well characterised marchantiaceous form of about the same grade of differentiation as Targionia.

Dr. J. P. Lotsy (Leyden), in an interesting account of the virgin woods of Java, discussed the modifications produced in the vegetation by the two great forces moisture and light, and proposed the use of a new term, biaiomorphose, indicating that the form of each individual plant is not a form innate to that plant, but is the result of its specific structure and the sum of all external circumstances which have acted upon it.

Mr. E. A. Newell Arber presented a paper on a new feature in the morphology of the fern-like fossil Glossopteris.

Dr. Otto Stapf exhibited and described the fruits of Melocanna, Melocalamus, and Ochlandra.

Mrs. D. H. Scott gave demonstrations of kammatograph photographs showing the opening and closing of flower buds, the visits of insects to flowers, and other interesting records of the movements of plants.

Mr. Alfred P. Maudslay gave an account of some measurements he had made of the great swamp cypress at Santa Maria del Tule, Mexico. The area of a cross section of the trunk of this tree, at a height of 6 feet from the ground, is 408 square feet.

Dr. K. C. Miyake (Tokio) read a paper on the centrosome of the Hepaticæ, from which it appears that it is very doubtful whether centrosomes occur at all in these plants.

Lord Avebury, F.R.S., in a note on the forms of the stems of plants, brought forward the view that the shapes of the stems of plants are dependent upon the arrangements of the leaves, and the consequent distribution of the strengthening tissues in the stem so as to secure the greatest strength with the least expenditure of materials.

A short discussion on the present state of our knowledge of the cell structure of the Cyanophyceæ was opened by Mr. Harold Wager, F.R.S., who pointed out that the central body of the cell must be regarded as a nucleus, but that it is of a simpler or more rudimentary type than the nucleus of the higher plants.

Prof. E. Zacharias (Hamburg), whilst admitting that the central body contains, under certain conditions, that essential constituent of the nucleus, nuclein or chromatin, could not accept the view that it is a nucleus, and especially objected to Kohl's conclusion that it is a true nucleus in which both chromosome and spindle formation can be observed.

Prof. R. Chodat (Geneva) considered that the central body of the Cyanophyceæ is merely a specialised region of the cytoplasm in which granules of reserve substance accumulate, and not of the nature of a nucleus at all.

Mr. E. R. Burdon gave an account of the pineapple galls of the spruce which are caused by the hibernating generation of certain Aphidæ belonging to the genus Chermes.

In the early stages the chlorophyll, tannin, resin, resin canals, and secretory cells of every description disappear within the gall area, which consists entirely of enormously swollen parenchymatous cells. Starch is found in great abundance round the periphery of the gall area, and it is suggested that it may be the ultimate product of the disintegration of the tannin.

The nuclei of the galled cells also become enlarged, and the chromatin network becomes aggregated into numerous wart-like nucleoli. The mitotic figures are of the usual somatic type, and no indication of heterotypical mitoses has yet been found.

Mr. R. T. Baker exhibited specimens illustrating (1) the comparative constancy of specific characters of Eucalyptus, (2) the relation between the leaf venation and the oil constituents.

Prof. R. Chodat exhibited some beautiful examples of pure cultures of algæ, and Prof. G. S. West some photomicrographs of fresh-water plankton.

Physiology.

Dr. F. F. Blackman gave an interesting address on the important investigations which have been carried on by Miss Matthaei and himself on the question of sunshine and carbon-dioxide assimilation. The address was illustrated by a series of experiments, and the numerous elaborate and ingenious pieces of apparatus which have been devised by the authors for the automatic recording of the complicated data required were exhibited and explained.

Prof. S. H. Vines, F.R.S., gave an account of his researches on the proteases of plants, the general occurrence of which he has demonstrated in all parts of plants. They are not of the nature of pepsin, but correspond rather to either the trypsin or the erepsin of the animal body. Trypsin and erepsin differ from each other in their capacity for peptonising the higher proteids. Thus trypsin can peptonise so complex a proteid as fibrin, whereas erepsin cannot, though it can peptonise casein. It has been found that in certain cases the juices or extracts of plants can peptonise fibrin, indicating the presence of a tryptic protease; but more commonly they do not possess this capacity.

Prof. L. Errera (Brussels), in a paper on the localisation of alkaloids in plants, pointed out that, although the physiology of alkaloids is far from settled, a critical study of their topography, as well as their behaviour in germination, growth, etiolation, maturation of seeds, &c., supports the view that they are waste-products, resulting from the catabolism of cytoplasm, and secondarily utilised for defence against animals. A few grams of an alkaloid constitute a protection not less efficient than the strongest spines.

Prof. Errera also read a paper on the struggle for pre-eminence and inhibitory stimuli in plants, and Dr. J. P. Lotsy (Leyden) gave an account of his discovery of a new alkaloid in *Strychnos nux-vomica*.

Important papers were also read by Prof. R. Chodat (Geneva), on oxidising enzymes and katalases in plants; by Prof. G. Klebs (Halle), on the artificial formation of a new race; by Prof. F. Czapek (Prague), on the importance of the anti-ferment test in geotropically stimulated roots; by Prof. K. Fujii (Tokio), on the pollination of Gymnosperms; and by Dr. G. J. Peirce (California), on the dissemination and germination of *Arceuthobium occidentale*.

Mr. J. Parkin gave an experimental demonstration of a brilliant pigment appearing after injury in species of Jacobinia, the shoots of which when bruised and extracted with water yield a beautiful purplish liquid. Such a reducing agent as stannous chloride decolorises it. Micro-organisms can also readily bleach it when oxygen is excluded, but on allowing air to enter the original colour at once returns. The whole phenomenon bears some resemblance to the way in which indigo arises in plant-tissues.

Papers were also contributed by Dr. Otto V. Darbishire on the transpiration stream in small plants, and by Dr. George Barger on saponarine (soluble starch).

Fungi.

Prof. H. Marshall Ward, F.R.S., gave an address on recent researches in parasitic fungi. The investigations of De Bary and others were shortly described, and then Prof. Ward described his own experimental work on the determination of the external conditions necessary for the germination of the spores of fungi. He showed that a knowledge of the germinating capacity of the spores is necessary in order to arrive at definite conclusions as to the immunity of new varieties of cereals from disease. In opposition to Prof. Eriksson, he maintained that there is no evidence to show that fungus diseases are spread in any other way than by spores, and that his experimental and microscopic investigations do not in any way support Eriksson's mycoplasm theory.

Prof. Eriksson (Stockholm), in a paper on the vegetative life of some Uredineæ, dealt in considerable detail with this question, and sought to show that the evidence before us as to the infection of cereals by the disease could only be explained by the presence of mycoplasm in the seed.

Mr. V. H. Blackman and Miss Helen C. I. Fraser gave an account of the development of the æcidium of *Uromyces poae* and the life-history of *Puccinia malvacearum*, in which many new facts were brought forward, especially concerning the sexual fusion of nuclei in the æcidial cells.

Mr. E. S. Salmon described some further cultural experiments with biologic forms of the Erysiphaceæ which demonstrate the fact that the infection-powers of a "biologic form" are not altered by its residence for one generation on a strange host-plant, and give also some evidence in favour of the idea of the hereditary nature of the infection-powers of certain "biologic forms."

Mr. R. H. Biffen, in a paper on the inheritance of susceptibility to and immunity from the attacks of yellow rust, brought forward evidence to show that the liability to certain diseases is inherited, and from the results of crossing together races of wheat relatively immune from and highly susceptible to the attacks of *Puccinia glumarum*, it appears that susceptibility is dominant over immunity in the hybrid.

Miss C. M. Gibson gave an account of her infection experiments with various Uredineæ, which show that the germ tubes from the spores of any uredine may enter almost any plant, and that the attractive substance causing entry is not specialised in each species, but is something common to all plants.

Dr. A. H. Reginald Buller presented papers on the destruction of wooden paving blocks by the fungus *Lentinus lepideus*, Fr., and the reactions of the fruit-bodies of *Lentinus lepideus*, Fr., to external stimuli; and Mr. B. T. P. Barker on the structure of the ascocarp in the genus Monascus, and on some further observations on the ascocarp of Ryparobius.

Dr. A. F. Blakeslee (U.S.A.) briefly described his investigations on the sexuality of zygospore formation. According to their method of zygospore formation the Mucorineæ may be divided into homothallic and heterothallic forms. In the first group zygospores are developed from branches of the same thallus. In the second group, comprising probably a majority of the species, the zygospores are developed from branches which belong to thalli diverse in character. The sexual strains in an individual species show a more or less marked difference in vegetative luxuriance. The author concludes that the mycelium of the homothallic species is bisexual, whilst that of the heterothallic species is unisexual.

In the agricultural subsection, which met under the presidency of Prof. W. Somerville, the following papers were read:—improvement of wheats and Mendel's laws, R. H. Biffen; hybridisation of cereals, Dr. J. H. Wilson; the clover mystery: a probable solution of it, R. H. Elliott; analysis of soil by the plant, and the probable error of agricultural field experiments, A. D. Hall; determination of available phosphates, T. S. Dymond and G. Clark; sulphates in their relation to growth of crops, T. S. Dymond and F. Hughes; the improvement of clay pastures by leguminous plants, Prof. T. H. Middleton; formation of ammonia, nitrites, and nitrates, Dr. E. J. Russell; chemical composition of mangels, and variation in mangels, T. B. Wood and R. A. Berry. Prof. W. D. Atwater (Middletown, Conn., U.S.A.), who was present at the meeting, also communicated a paper to the section.

EDUCATION AT THE BRITISH ASSOCIATION.

AFTER the president's address (published in NATURE of September 15), the first paper on the programme was on the present educational position of logic and psychology, by Miss E. E. C. Jones, in which attention was directed to the fact that, on the one hand, logical and psychological studies hold a position of growing importance in English thought and education, while, on the other hand, the quality and organisation of the instruction supplied leave much to be desired. Some logic and psychology are now required for teachers' training examinations; it is also desirable that all students of religious doctrine or of the great questions of philosophy should be equipped with logical method and psychological knowledge.

The section listened with interest to the lucid account of the advances made in the teaching of experimental science in the secondary schools of Ireland given by the Right Rev. Gerald Molloy. The result of three years' work is splendid, thanks to a cordial and remarkable cooperation of teachers, of schools, and of local authorities with the Intermediate Education Board and the Department of Agriculture and Technical Instruction. These latter bodies have adopted a common programme in science subjects, and are carrying out a common system of examination and inspection. All the secondary schools of the country, about 250 in number, are enjoying the benefits due to judicious introduction of practical work in the laboratory, and the administrators may justly be congratulated on the fact that there are more than 9000 pupils following the preliminary course, and 1500 pursuing a more specialised course after passing through the preliminary. The manner in which the first great difficulty, that of providing competent teachers, was overcome is interesting, but it is of more importance now to note that the organisers took the right road to efficiency by putting men first and bricks and mortar second. (Might not some of our local authorities and governing bodies in England receive a useful hint?) For the future "the Department propose to grant the 'Irish Teacher's Science Certificate' to all students who pass through a three years' course, prescribed for the purpose, in the Royal College of Science, Dublin. They will also recognise as qualified teachers students who have followed a similar course in any university or technical college, and who have obtained the corresponding degree or diploma."

The discussion was mainly congratulatory, but one criticism deserves, and will no doubt receive, careful consideration from the authorities. It was felt by many that among subjects relegated to the optional courses were some of such fundamental importance as to be an indispensable part of an all-round education. This, of course, is part of the wide and difficult problem which is getting more and more pressing, viz. what can be safely *left out* of the secondary school curriculum? It is safe to reply to Dr.

Molloy's question, as to the advisability of limiting the preliminary science course to those who do not take the classical, by affirming that *all* boys and girls should take a science course of some kind at some period of their school life. Sir Philip Magnus insisted that science is not an "extra," but a necessary part of the curriculum (not for the whole time of all pupils). Inspection should precede examination—it is unnecessary to *examine* junior pupils. Mr. George Fletcher, speaking as an inspector, stated that other subjects of the curriculum have not suffered by the introduction of science into Irish schools. Their unparalleled progress was made possible by the voluntary sacrifice of their holidays by the teachers. Prof. Armstrong regretted that the courses of demonstrations, which had been instituted by the London School Board and had proved so valuable a help to science teachers, had been discontinued.

A paper which has attracted a widespread interest was that by Dr. J. de Körösy, director of municipal statistics at Budapest, entitled "Comparison of the Intellectual Power of the Two Sexes." The author had received reports since 1873 of 800,000 individual children. One method of testing applied was to take the percentage of children who had to repeat the year's work instead of passing on to the next standard. In the elementary schools the figures were all in favour of the girls, the two sexes being nearly level at first, but the advantage of the girls increasing with age. This result is more marked in the higher elementary or "citizen" schools (age ten to sixteen), but in this case the boys are drawn from a class less gifted than ordinary, while the opposite holds for girls.

Another test was the frequency of "very good" and "good" marks in the fourth standard. These best marks were obtained in arithmetic by 10·8 per cent. of boys and by 35·3 per cent. of girls. A truly surprising result! Several subsequent speakers admitted the superiority of girls at school and college, but contended that there it ended, but few women being eminent in learned professions, and the majority falling behind men when it came to the "struggle for existence." Dr. Beverley, of Norwich, differed from this view, arguing that women needed only equality of opportunity.

Mr. J. H. Leonard read a short paper on specialisation in science teaching in secondary schools. The contention was that the efficiency of science teaching in schools is itself threatened with a particular kind of specialism, *e.g.* objection was taken to the performance of titrations before sufficient progress has been made in elementary chemistry. The effect of according undue prominence to one study is that the school time is not fairly allotted—*e.g.* botany and physiography are often omitted—while the scholars are wearied instead of being interested. Unfortunately there was no time for discussion of Mr. Leonard's views.

Lieut.-Colonel McKinlay gave a description of his method of "realistic arithmetic." The "appeal to the eye" is thoroughly effective. The apparatus has been used in schools with favourable results.

School Certificates.

The main feature on the morning of August 19 was the discussion on school-leaving certificates. Prof. Armstrong led off by reading a "Report of the Committee on the Influence of Examinations." He explained that the question of examinations had entered upon a new phase by the issue, on July 12, by the Board of Education, Whitehall, of suggestions for a system of *school certificates* submitted by the consultative committee to the board. The committee was not in a position, therefore, to publish a report in the true sense of the word, but was presenting a compendium including the proposals of the consultative committee, notes on the Scotch leaving certificate, the London University scheme, and extracts from the Mosely Commission Report referring to the American accrediting system. Dr. Gray (Bradfield College) read a paper, communicated by Canon Bell, narrating the origin of the proposals of the consultative committee. Attention was directed to the vexatious multiplicity of examinations, no fewer than 64 in the United Kingdom and 140 in the Empire being accepted as qualifying for entrance into one or more professional courses.

Sir Arthur Rücker said the position was complicated by the fact that Oxford, Cambridge, and London Universities have already carried out something in the nature of school-leaving examinations. The consultative committee had left the financial question out altogether. There had been no opportunity for the universities to consider the scheme of the consultative committee, but he, personally, was in favour of its general principles. Mr. Ernest Gray, M.P., regretted that the antiquated procedure of the British Association had left those attending this section in the dark as to the subjects to be brought forward until the meeting actually commenced. He thought that the scheme would revolutionise secondary schools, by enlarging the staff and increasing the length of school-life. The difficulties connected with fees must be met from other sources. The proposal was really a dual certificate, a junior and a senior; this principle was accepted by learned societies. A most valuable feature was the active share which the teachers are to take in the examination of their school; he thought that English teachers should be prepared to take the responsibility of recommending pupils, as is done in France. Schools should direct examinations, not *vice versâ*. Local authorities will insist on some form of examination, and will probably wish to see local schools grouped round local universities.

The Rev. R. D. Swallow, on the other hand, regarded the idea of encouraging local authorities to hold to local universities as most detrimental. Secondary schools of the old-fashioned type would remain under the influence of the old universities, but a new type was springing up which the consultative committee had ignored, the higher elementary school with the words higher elementary painted out and secondary painted in. Dr. Mangold (Berlin) sympathised with systems of examination in which the teacher plays an essential part. Proved to be very satisfactory in Germany, the plan of taking into account the teacher's knowledge of the character and abilities of his pupils should act well in this country.

Principal Griffiths (Cardiff) referred to the experience of the Central Welsh Board. There was a tendency for a central board to become rigid, and he hoped that any such board would perform advisory and inspective rather than executive functions. We have to remove from local authorities their distrust of teachers. The curious worship of examination results by such authorities seemed to be a growing evil. Sir Oliver Lodge stated that Birmingham will put into action a scheme similar to that recommended by what was, on the whole, the admirable report of the consultative committee. Teachers should determine the relative order of pupils; the outside inspector should standardise and not pretend to read all the papers. He hoped universities would accept each other's certificates, and that no vested interests would stand in the way of reform.

Mr. Alderman Fordham (vice-chairman Cambs. County Council) thought that the alleged distrust of teachers did not, in reality, exist. It was recognised that the highest respect must be paid to teachers of every grade as the vital bases of every part of their work. He was in favour of the Swiss system of public examination for all children, and was dissatisfied with the existing mode of testing elementary schools. Miss Cooper wanted varieties of examination, equatable by their known equivalents. Mr. Oscar Browning thought that parents were insufficiently considered; a parent has a right to know whether his child has been taught to a reasonable standard. Mr. Mollison (Clare College) pointed out that America had a great advantage in freedom from examinations, and urged that the establishment of a fresh State board would be a disaster. Dr. Gray, as a member of the Mosely Commission, feared that the absence of a national desire for education made it necessary for us to have something more than the accrediting system. Dr. Roberts, Messrs. Flather, Fitzpatrick, and Cloudesley Brereton also spoke. The chairman, summing up, expressed his conviction that we had little need to fear State control, as we have inherited so long a struggle for freedom that we are hardly likely to be tyrannised over. The consultative committee had looked the finance difficulty in the face—*and passed on.*

National and Local Provision for the Training of Teachers.

The discussion on this urgent problem opened on Monday, August 22, with a paper contributed by the Right Hon. Henry Hobhouse, M.P., the object of which was "to

indicate the difficulties which beset local bodies in their endeavours to perform what is really a national task."

By the recent regulations training is insisted upon as a condition for registration, but the actual establishment of training colleges has been left, *more suo*, to private initiative. Under the Act of 1902, the burden of supplying the deficiency is thrown, not upon the State, but upon local authorities. In addition to the difficulty which the smaller bodies would experience in raising funds for new institutions with expensive buildings and equipment, there is the further one of getting proper cooperation between so many authorities, autonomous and often jealous of each other. The most serious drawback of all lies in the "localisation" of the individual teacher. Certain local authorities may prefer to secure teachers trained elsewhere by the offer of high salaries rather than train them themselves. As a counter-move, a local authority may bind each teacher it trains to serve for a reasonable number of years exclusively in its own schools, a system of indenture which, however sound financially, is educationally unsound, and which will seriously prejudice free circulation of educational energy, with special detriment to the weaker counties and boroughs. The present problem is how to encourage and impel our local authorities each to bear its fair share in the task of increasing the supply of competent teachers without forcing them all into one groove, and depriving them of all initiative and independence.

Mr. H. Macan sent a paper which arrived too late for an abstract to be made thereof, and was too lengthy to read in full. In the circumstances justice could not be done to this contribution. *Inter alia* he pointed out that a central hall costing 30*l.* per place was worthless compared with good teachers. As a large number of teachers at present leave the profession at an early age, he suggested that there should be two classes of teachers, one highly trained, the others less qualified short-service persons sufficiently equipped for the journeyman-work of teaching. (The writer of these notes does not know what "journeyman-work" means as applied to teaching.)

Mr. Gray, M.P., said it was impossible to escape from the conclusion that the training of teachers should be a national charge. Secondary-school teachers needed better training in the art and craft of their profession, and the barrier between elementary and secondary should be removed. Mr. G. F. Daniell considered that the supply of men for secondary schools would be met if the kind of training required was made known, and proper pay, position, and conditions of work and tenure provided.

The Rev. W. T. A. Barber said that elementary teachers should have some practice in secondary schools during their training. The training college should be in connection with some university. To add a year's training in pedagogics to the costly years spent in graduating at a university would stop the supply of teachers for secondary schools unless the chances of the profession were improved. Dr. Ernest Cook, chairman of the Bristol Education Committee, complained that the ordinary training college provided secondary education, but very little instruction in the art of teaching.

Principal Griffiths referred to the position in Wales, where there is to be a congress of representatives of education committees, of the university, of teachers' associations, and of politicians to consider the position in the Principality. At present they needed to import 280 teachers from the neighbouring kingdom of England. He feared the effect of enlarging day training colleges, and wished to remove distinctions between "normal" and ordinary university students. Sir John Gorst said the difficulty of supplying teachers had increased since the 1902 Act was passed, and pressed for energetic measures to be taken both by Government and the local authorities. "Supply and demand" would not suffice except for the great public schools. The pupil-teacher system was rather a failure, and the training college system not a success. The burden laid on the young pupil teacher was greater than anyone could bear. The qualifications of teachers should be certified by the university, which should supply pedagogics, no new expensive buildings being required, and the attempt to distinguish between elementary, secondary, and technical education should be abandoned. Assistance for training should be given from both Government and local funds. He thought the value of Ireland as a recruiting ground should receive attention.

Mr. J. L. Holland pointed out that we needed to know the actual number of teachers required, and stated the average life as a teacher to be, for a man, a little under 14·3 years, for a woman about 7 years. This means a fresh teacher per annum for every 2000 to 2500 of the population, and it should be noted that for every boy there are five girls going to be teachers. (The number of pupils in secondary schools in 1900 was:—boys a fraction over, girls a fraction under, five per thousand of the population.) The scholarship ladder is in danger of becoming a treadmill, leading from the school as a pupil to the same school as a teacher, through the bad influence of "localisation." Miss Walter said that the short professional life of teachers was due to low pay, and urged that more money be spent on salaries, in which case less would need to be spent on training.

M. Émile Havelaque, Inspector-General of Public Instruction in France, made a particularly interesting speech, in the course of which he dwelt on the advantage that would accrue if a larger number of English students for the higher branches of the profession could be induced to take up residence at French schools and colleges, under a newly instituted scheme. The student would be able to study French educational methods; the teaching of the mother tongue, for instance, has received particular attention in France, while it is surprisingly neglected in England.

Dr. Mangold observed that in Germany the training of teachers was a national charge, the masters of method receiving a small addition to their salaries as teachers. He was astonished that it should be desired to remove the differentiation between elementary and secondary—such removal would be impossible in Germany at present.

Manual Training.

Sir Philip Magnus opened the discussion on methods of imparting manual instruction in its broadest sense in the various types of schools. Other speakers included Mr. George Fletcher, Mr. Millett, Mr. Oscar Browning, Mrs. Marvin, Prof. Armstrong, Miss Cooper, and Miss Taylor. There was agreement as to the value of manual training as a part of general education for all boys and girls, and it was also felt by the opener and others that the instruction should have the same aim for the two sexes. On the other hand, the subjects used for this purpose should be different, the manual teaching of girls being associated closely with the domestic arts.

Reports of Committees.

Mr. Hugh Richardson presented an interim report of the committee on the courses of practical, experimental, and observational studies most suitable for elementary schools. Useful work is being done, and it is satisfactory to note that a grant has been made for its continuance.

The report of the committee on the conditions of health essential to the carrying on of the work of instruction in schools emphasised the need of teachers themselves being trained to understand how the laws of health entered into every department of school life. Suggestions were made for the curriculum for such training. The report was followed by a discussion on hungry and exhausted children, led by Sir John Gorst, who boldly advocated that local authorities should be empowered to feed half-starved children and to punish those responsible for their neglect.

Afternoon Lectures.

On August 19 Mr. A. D. Hall lectured on the need of scientific method in elementary rural instruction, and on August 22 Prof. Armstrong gave a short address on the research method applied to experimental teaching.

The founders of the section should be well satisfied with the position which it has taken in so short a time. The gathering at Cambridge was remarkable for the bringing together of workers in every branch of the diverse paths of education. The debates were thoroughly well sustained, and with better arrangements for continuing the work of committees between the annual meetings, and some improvement of machinery for advertising the subjects to be discussed beforehand, there can be no doubt that Section L will exercise a useful national influence. G. F. D.

THE OPENING OF THE MEDICAL SESSION.

THE beginning of October always sees the opening of the medical session, and introductory addresses have been delivered at many of the London and provincial schools. At others, however, the session opened without formality.

At University College Prof. Norman Collie, F.R.S., delivered the introductory address, taking for his subject the relation of chemistry to medicine. He said that it is now more than ever imperative that medical men should have a good grounding in chemistry, and he directed attention to the numerous instances in which chemistry has a bearing on medicine. The question of the action of ferments, of great importance to the medical man, must ultimately be answered by the chemist. The physiological action of toxines and antitoxines has for some time largely engaged the attention of medical science, but it will probably be the chemist, after he has determined their molecular structure, who will be able to explain how and why they are produced. In the process of the assimilation of food the changes that occur are purely chemical. The composition of the various secretions also can only be arrived at by an analysis in a chemical laboratory.

At King's College the session was opened with an address by Dr. Thomas Buzzard, F.R.S., on the future relation of King's College to its medical school and hospital. After a few words of welcome to new students, and impressing on his audience the value of the degrees of the University of London, he briefly sketched what will be the position of college and hospital when the latter has been removed to Camberwell. It is intended that the two should be distinct, the preliminary and intermediate studies being pursued at the college, the subsequent more purely medical studies at the hospital. At the same time the two will be autonomous, and there will be no obligation on a student who completes his preliminary studies at the college to pass on to King's College Hospital; he will be at liberty to go where he pleases. In order to carry out this separation, composition fees will be abolished, and no member of the hospital staff will be permitted to teach any preliminary or intermediate subject at the college.

Dr. A. E. Wright, in the opening address at St. Mary's Hospital, emphasised the importance of research and the need for the provision of adequate salaries for scientific workers.

Dr. F. J. Wethered, in his address on practice and theory in medical study at the Middlesex Hospital, also spoke of the need for the endowment of chairs in the University of London. He pointed out that medicine is not only a science, it is a practical art, and no amount of theoretical knowledge can replace study and observation in the wards and out-patient room.

At Charing Cross Hospital the opportunity of the opening of the session was taken for the delivery of the Huxley lecture. The lecturer this year was Sir William MacEwen, who prefaced his remarks with some allusion to the life-work of Huxley before passing on to his subject, "The Recent Advances in Science and their Bearing on Medicine and Surgery."

Prof. Alex. Macalister, F.R.S., was the lecturer at St. George's Hospital, and delivered an instructive address on "The Evolution of the Medical Curriculum."

At the London (Royal Free Hospital) School of Medicine for Women, and at the Royal Veterinary College, the sessions were opened by Miss Murdoch and by Prof. Brodie, F.R.S., respectively.

THE EDUCATION OF A CHEMIST.[1]

THE education of a chemist (and the word "chemist," of course, includes the qualification "technical chemist") must be conceived in the sense that it consists in an effort to produce an attitude of mind, rather than to instil definite knowledge. Of course the latter must not be neglected; the definite knowledge may be likened to the bricks which the architect has at his disposal in erecting a beautiful building; he knows their shapes, their capacity for resisting stresses, and, in short, what can be done with them. But the conception of the design is the result of many attempts to create; just as the poet has to utilise words, or the architect bricks, so the chemist has to know the materials with which he is dealing. The training of a bricklayer, however, will never make a man an architect; nor will the dry research of a grammarian train a poet. In short, it is the inventive faculty which must be cultivated.

Now how can this be brought about? The answer is perfectly simple: by offering examples. Every teacher in the laboratory, from senior professor to junior assistant, must be engaged in research, and, most important of all, they must not be reticent, but willing to converse freely on their problems. It is that which creates a "chemical atmosphere."

The qualities tested by such examinations as have been customary for the past forty years in England are the last which one would wish to have in a student of science—readiness of memory, to the exclusion of deliberate judgment; the faculty of spreading knowledge thin, and making a veneer of scientific facts instead of the power to correlate them and increase their value; and the skill to gauge the capacity of and hoodwink the examiner, instead of the power to incite enthusiasm in others. They are ideal qualities for a successful barrister, because they pay in his profession; but their reward has been the bane of science. A sound judgment, though it may be a slow one; persistence in struggling against obstacles; the knowledge where to get information when required, and to use it when found; and the inventive faculty—these are the qualities required, and they can be gauged only after long-continued observation. Moreover, the pernicious system of competitive scholarships and fellowships, instead of eleemosynary support given to the necessitous and deserving youth, has also contributed much to the debasement of the scientific spirit; for it has early implanted in the young mind the idea that to outrun his fellows, and to work solely for a money reward, are the ends to be aimed at, instead of the joy of the exercise of a divine gift, and the using that gift for the benefit of man.

The ideal plan of education for technical chemists would be some system analogous to the apprenticeship of engineers, after they have been educated in the science; that is, after the correct habit of mind has been largely formed. But it is difficult to see how this can be brought about. The obstacles in the way appear to me to be insurmountable. The chemical manufacturer is not willing to throw open his works to students, nor would he do so even if very considerable premiums were paid. Indeed, in England, it is not uncommon for the "chemist," so-called, to be refused admission to the works, and to be confined to the laboratory. In the larger German works, where many chemists are employed, it is possible for a young man to gain the requisite experience. I have been informed by the managing director of a chemical works in Germany where seventy chemists are employed that nature has divided the young men into three large classes, the members of which are fairly easily distinguished and do not greatly overlap. There is first the routine chemist, the young man who declines responsibility, but who is hardworking and trustworthy; he finds his place as an analyst, testing raw materials and analysing the products at various stages, including the finished products. Second, there is the young man to whom the management of some department may be entrusted; one with a firm will, plenty of energy, and the quality of governing men. And third, there is the research chemist, who delights in new problems, whether suggested by others or conceived by himself. All three classes are utilised; and after serving as analysts for some time, the young men naturally range themselves in one or other department, where their natural tendencies find scope. But even in Germany the number of works which employ seventy chemists is not great, and with a small number it is more difficult to effect the division of labour so satisfactorily.

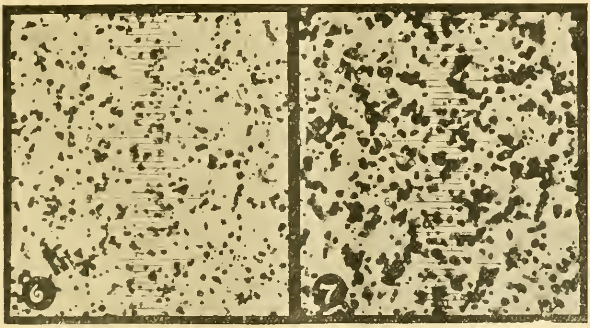
In conclusion, let me make one more remark. It is that the scientific curiosity of to-day often becomes the trade necessity of to-morrow. A scientific friend of mine once directed my attention to the fact that most of the changes which have been introduced in industry have had their origin in the universities. Why? Because the investigator is un-

[1] From an address delivered before the Society of Chemical Industry, at New York, September 8, by the president, Sir William Ramsay, K.C.B., F.R.S.

fettered. If a man sets himself to improve an existing process, he very likely may succeed, but he will not effect a revolution in manufacture. The purely scientific investigator who is free to follow indications of no apparent commercial import has not infrequently made discoveries of a radical nature, which have entirely changed some particular industry. I do not recommend the one to the exclusion of the other; both are best; and both are best attained by an intimate association between the universities and the chemical works. The investigator often learns much by the study of industrial processes. The chemical manufacturer who is keenly alive to his own interests will not fail to keep himself in touch with every discovery, however little it appears to be connected with his own industry.

THE GRAIN IN PHOTOGRAPHIC FILMS.

IN the September number of the *Astrophysical Journal* Mr. R. J. Wallace gives an account of his investigation of the circumstances that control the size of the silver particles in a developed gelatino-bromide plate. Of four rapid plates of American make, the "Seed 27, Gilt Edge" was found to give the best results. It was the most uniform in speed from time to time, and gave the least amount of "chemical fog," the smallest particles of silver, and the most regular distribution of them. While the particles were found to be, generally speaking, spherical in ordinary plates, isochromatic plates of several makes showed the peculiarity of having almost exclusively elongated (the author calls them "spicular") grains at the surface of the film, while in passing downwards through the film they gradually gave place to rounded particles, until close to the supporting glass these latter were the only ones found. Intensification increases the size of the particles; this is the common experience of those interested in these matters,



Before Intensification (1·3 to 4·0μ). After Intensification (2·8 to 10·4μ).

FIG. 1.—Photomicrographs of Silver "Grain."

but the author's demonstration is of special interest, as he performed the intensification with a brush, using the mercury and ammonia method, without shifting the plate, so that he was able to photograph the identical particles before and after the operation. The same grains can easily be traced in the two photographs reproduced. The magnification is 430 diameters. The author also shows the difference between rapid and slow development. In the first case he considers that the silver particles most nearly approach the size of the original particles of silver salt from which they are produced, while by prolonged development they become enlarged by reason of the formation of "group-particles" as well as by accretion. For the finest grain the author deprecates slow development. In a postscript reference is made to the deduction of Messrs. Lumière and Seyewetz from their recent experiments to the effect that neither the temperature, concentration, nor duration of development practically affects the size of the grain. The author considers that these investigators have neglected the formation of "group-particles" because they dissolved off the film after development and examined a new film made from the product.

THE DUCHESS OF SUTHERLAND'S SCHOOL AT GOLSPIE.

AS announced in our columns last year (September 24, 1903), the formal foundation of the Duchess of Sutherland's Technical School at Golspie was inaugurated on September 8, 1903, by Lord Balfour of Burleigh, at that time Secretary for Scotland. The building is, we are informed, now completed, the total cost of erection and equipment having exceeded 16,000*l*., exclusive of the site and grounds given by the Duke of Sutherland. The school is a handsome structure in white freestone, and three storeys in height. It contains altogether fifty-six rooms, including fourteen class-rooms, workshops, laboratories, museum, &c. The dormitories are 50 feet by 21 feet, with bathrooms and lavatories attached. The school when full can receive sixty pupils. The curriculum covers a period of three years, and the subjects comprised are such as are most likely to meet local industrial requirements, the whole course being framed on a sound scientific basis. In drafting the original scheme the duchess had the cooperation of Prof. R. Meldola, Prof. Magnus Maclean, Lord Balfour of Burleigh, the Right Hon. R. B. Haldane, and Mr. Struthers, of the Scotch Education Department. A formal deed has been executed by the duchess ensuring the perpetuity of the school, and appointing for its management a local board of governors, the duchess herself being chairman and the duke a member of this board. An advisory committee has also been appointed consisting of leading educationists and representatives of Highland societies, as well as Her Grace's original advisers.

The building and equipment fund has been raised entirely by private voluntary subscriptions, the Duke of Sutherland having contributed 8000*l*. Other munificent supporters of the scheme are Mr. Andrew Carnegie and Lord Strathcona, the Dukes of Portland and Westminster, Mr. James Coats, of Paisley, and Mrs. Carnegie. The cordial support which this new educational departure has received in Scotland will be recognised when it is stated that out of the sixty places in the school forty are provided for by bursaries guaranteed by various benefactors interested in the counties of Sutherland, Caithness, Ross and Cromarty, and one (by Mr. Dewar) for a student from Inverness-shire. Another indication of the local practical interest in the scheme is that at the opening of the school for regular work on October 3 the claims of more than sixty applicants for admission had been considered by the board of governors. Out of these, twenty-five bursars have been admitted as the first batch, and further admissions of bursars will be sanctioned for next year and for 1906.

It is proposed to work the school as a higher grade school under the Scotch Board of Education, and, in addition to the scientific and technical subjects, the ordinary literary and humanitarian subjects will be carried on from the elementary school stage, the standard of qualification required for admission as a bursar being that he should have completed his thirteenth year and have received the "merit certificate" or its equivalent. It is of interest to learn that the elementary schools from which the technical school will be supplied with pupils are cooperating most sympathetically in carrying out the scheme. One of the difficulties, as we learn from Prof. Meldola, which has beset the school in Essex founded by Lady Warwick, sister of the Duchess of Sutherland, has hitherto been the want of cooperation on the part of the local elementary schoolmasters.

The head-master of the new school is Mr. E. W. Read, of Cambridge, formerly agricultural instructor at the North-eastern County School, Barnard Castle, Durham.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

The degree of Doctor of Science has been conferred upon Sir William Ramsay by Columbia University.

Dr. F. Cavers, lecturer in biology and botany at the Plymouth Technical Schools, has been appointed to the vacant professorship in biology at the Hartley University College, Southampton.

It is reported in *Science* that Prof. E. Wichert, of Göttingen, has been appointed to a chair of physics at Königsberg; Prof. Eduard Brückner, of Bern, has been elected professor of geography at Halle.

Prof. Hugh L. Callendar, F.R.S., will deliver an address to-day at the Victoria and Albert Museum on the occasion of the distribution of prizes, medals, &c., to students of the Royal College of Science.

We learn from *Science* that by the will of the late Dr. Henry Tuck, Harvard University will receive one fourth of the estate should his children not survive. The estate is valued at 1,000,000*l.* The effort to raise necessary funds towards the 30,000*l.* required for the new Eastman building of Rochester University, to be used for biology and physics, has been successful. Of the desired amount, the sum of 24,000*l.* is in hand, including 3000*l.* contributed by Mr. Hiram W. Sibley. Mr. Eastman, of Rochester, has given 12,000*l.* to the fund.

For the purpose of furthering the cause of education in the Transvaal, Mr. Alfred Beit has presented to the Government the Frankenwald estate, situated 12½ miles north-east of Johannesburg. The area of the estate is 1000 acres. The Government has purchased an adjoining piece of ground of 1000 acres, and Mr. Beit has spent an additional sum of 10,000*l.* himself on acquiring more ground. The total area available will thus be 2600 acres, a large portion of which is planted as orchards, vineyards, and nurseries, and part with timber trees, making the site admirably adapted for an agricultural college.

The Board of Education has issued the following list of successful candidates for royal exhibitions, national scholarships, and free studentships (science):—*Royal Exhibitions:* Albert Eagle, Henley-on-Thames; Sidney H. E. May, Portsmouth; William B. Wood, Sheerness-on-Sea; Edmund W. Spalding, Cambridge; Joseph Lloyd, Pembroke Dock; Albert E. Monkcom, Portsmouth; John S. G. Thomas, Morriston, Swansea. *National Scholarships for Mechanics:* Sidney R. Dight, Plymouth; Harold H. Perring, Devonport; Stewart S. Spears, Sheerness-on-Sea; Edwin M. Vigers, Plymouth; Thomas A. Colvill, Chatham. *Free Studentships for Mechanics:* Arthur G. London, Southsea; Bert H. Penn, London. *National Scholarships for Physics:* John F. Mitchell, Cathcart, N.B.; Tom Harris, London; Harry Moore, Bradford; Hubert Watson, Darwen; Frank P. Fuller, London. *Free Studentships for Physics:* David C. Jones, Bala, N. Wales; Lucy Alcock, London. *National Scholarships for Chemistry:* John Keegan, Burnley; Harold Talbot, Farnley, Leeds; Charles Salter, Leeds; Alexander M. Hird, South Woodford, Essex; Herbert W. King, South Tottenham; Frank D. Miles, Carlisle. *Free Studentships for Chemistry:* Harold Mountain, London; Alan C. Webber, Brighton. *National Scholarships for Biology:* Frederick J. F. Shaw, London; Frederick J. Bridgman, London; Arthur B. Lister, Burnley. *National Scholarships for Geology:* Thomas Reed, Burnley; Herbert G. Smith, Burnley; Henry J. Jeffery, London.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 26.—M. Mascart in the chair.—On a cause of variability of the errors of division in certain graduated circles: G. **Bigourdan.** It is usual to cut the actual graduations on a circle of silver let in to a support of another metal, such as brass or cast iron. The errors of graduation in astronomical instruments are usually determined once and assumed to remain constant, but it is now shown that owing to the differences between the coefficients of expansion of the metal and its support considerable errors may arise. Cast iron should not be used as the supporting metal, brass or bronze being preferable, but it would be better to drop the use of silver, which tarnishes rapidly in towns, and make the whole circle of one metal, a nickel-steel for preference.—The Perseids in 1904: Lucien **Libert.** Observations were carried out at Havre from August 11 to 20 under good conditions; 339 meteors were counted, and 93 trajectories determined.—On the energy dissipated in iron by hysteresis at high frequencies: Ch. Eug. **Guye** and A. **Schidlof.** It has been shown in a preceding note that the loss of energy in iron due to hysteresis may be represented as a quadratic function of the frequency, provided that the wires are of small diameter. It has now been found that if the wires are made still thinner, 0·0038 cm., the equation becomes sensibly linear. In other words, the energy consumed per cycle, for the limits of frequency used in the experiments, is independent of the speed with which the magnetisation cycle is carried out.—The constitution and properties of the tungsten steels: Léon **Guillet.** Tungsten steels fall into two groups—perlitic steels, which possess analogous properties with those of carbon steels, but which take a greater breaking load the higher the proportion of tungsten, and double carbide steels, the properties of which are nearly independent of the percentage of tungsten, and the fragility of which is independent of the amount of carbon.—Carbinol salts and cyclohexanerosanilines: phenomena of decoloration: Jules **Schmidlin.**

ŒCOLOGICAL PLANT-GEOGRAPHY.

Plant-Geography upon a Physiological Basis. By Dr. A. F. W. Schimper. Translated by W. R. Fisher, B.A. Revised and edited by Percy Groom, M.A., D.Sc., F.L.S., and I. Bayley Balfour, M.A., M.D., F.R.S. Pp. xxx+839. (Oxford: University Press, 1903.) Price 42*s.* net.

WE welcome most heartily the appearance of this translation of Schimper's great work, "Pflanzen-Geographie auf physiologischer Grundlage," and the more so as it stands alone in being the only comprehensive work on œcological plant-geography in the English language.

The beginnings and gradual development of the study of œcology may be traced during the course of the last century in the writings of Humboldt, the De Candolles, Darwin, Grisebach, Drude, Kerner, Engler, and others. A new phase was marked by the appearance in 1896 of Warming's "Lehrbuch der ökologischen Pflanzen-Geographie" (the original Danish edition was published in 1895), and in 1898 of the larger work of Schimper. The latter, which forms the subject of this notice, possesses a wealth of well chosen illustrations absent from the text-book of Warming. But even these later works are, in spite of the undoubted advance which they mark, to be regarded largely as pioneers, for, to quote from the author's preface to the book before us:—

"A satisfactory general survey of œcological plant-distribution cannot be attempted with the material at present available. This book is therefore chiefly of a tentative nature, and attempts by a precise statement of pending questions to stimulate further research."

The work is divided into three parts. In the first (pp. 1–156) the various factors affecting plant-life are considered. The second (pp. 159–206) discusses the arrangement of vegetation into "formations" and "guilds"; while the third and largest part (pp. 209–839) is less general, and is largely occupied with a description of the vegetation of the zones and regions, thermal and other, into which the surface of the earth may be divided.

At the outset the author emphasises the fact that "the characteristics of organisms are physiological," and this application of the principles of physiology to the problems of morphology and distribution forms the idea underlying the whole of the book.

In addition to the generally accepted classes of "hygrophytes" and "xerophytes," Schimper recognises a third or intermediate type, which he calls "tropophytes." Under the latter term are included "all plants whose conditions of life are, according to the seasons of the year, alternately those of hygrophytes and xerophytes." Good examples of this class are our deciduous trees; these possess hygrophilous leaves, which are shed periodically, while the axes and buds, which alone are called upon to endure the "physiologically dry" conditions of winter, are distinctly xerophilous in character. Warming's class of "mesophytes," or plants adapted to medium conditions as regards moisture, was a convenient one, but the term "tropophytes" is to be preferred, as it directs attention to the physiological significance of many adaptations correlated with an alternation of wet and either dry or cold seasons.

Just as humidity is the dominant factor in determining the form of plants, so temperature plays the most important part in their distribution. The œcological importance of light, in spite of its powerful influence on the form and life of plants, is, according to the author, less than that of heat and rainfall, because the amount of light in different climatic regions is less variable than is the supply of the other two factors.

The remaining chapters of part i. are devoted to a discussion of the air, the soil, and animals as œcological factors.

In part ii., under the heading of "Formations and Guilds," the conditions which determine the differentiation of the earth's vegetation are dealt with. According to Schimper there are three controlling factors—the type of "vegetation" in the tropical and temperate zones is determined by the climatic humidity; the type of the "flora," especially as regards the larger systematic groups, is, so far at least as existing factors are concerned, dependent primarily on heat; while "the soil as a rule merely picks out and blends the material supplied by these two climatic factors, and on its own account adds a few details."

Two œcological groups of "formations" are distinguished:—(1) "climatic or district formations, the character of whose vegetation is governed by atmospheric precipitations"—these include three main types, woodland, grassland, and deserts—and (2) "edaphic or local formations, whose vegetation is chiefly determined by the nature of the soil"; such edaphic formations are moors, swamps, sand-dunes, &c. This grouping is an excellent one, but some will regret the use by the author of the term "formations"; admittedly it is difficult of definition, but as used here the term is unnecessarily wide, and includes groups of very unequal value. Another objection to its use is the fact that it has been employed by different authors in a variety of senses. Perhaps it would have been better to have followed the usage of Warming in the work cited above, and applied the term "vegetation" to the larger groups such as woodland, grassland, &c.; while for the smaller local ones, which are characterised by the presence of one or more dominant species, "plant-associations" ("Pflanzenvereine") could perhaps have hardly been improved upon.

Part iii. contains a masterly description of the vegetation of the globe from the œcological point of view. The primary division is into "zones," dependent on temperature, *i.e.* tropical, temperate, and arctic, and these occupy respectively the first three of the five sections which make up this part of the work. Each section begins with a general discussion of the characters of the climate of the particular zone under consideration, and stress is laid on the fact that periodic phenomena, or alternations of rest and activity in the functions of plants, occur as generally, though less obviously, in tropical as in temperate climates. Some

200 pages, or nearly a quarter of the whole work, are occupied by an excellent account of the tropical zones. Much of the recent advance in our knowledge of these regions is due to the establishment in the tropics of such botanical laboratories as those of Buitenzorg and Peradeniya: a research laboratory has also been recently established in the temperate desert regions of Arizona, and it is much to be hoped that the author's wish for the foundation of a similar institution in the arctic zone may ere long be realised.

The concluding sections of the book are devoted to a discussion of mountain and aquatic vegetation.

To sum up, the work is a thoroughly scientific exposition of our present knowledge of the factors which control the distribution of plants, and though the book in no sense expresses finality, yet, to quote from the editors' preface to the English edition, "its 'precise statement of pending questions' should not only 'stimulate research,' as the author hoped, but should also have a steadying influence in a field of investigation which tempts to trifling."

The usefulness of the book is greatly enhanced by the illustrations, which are admirably reproduced, and form, perhaps, its most striking feature; and also by the presence of numerous meteorological and other tables, and of a bibliography at the close of each chapter.

For the rest, the translator and the editors are to be congratulated on the successful completion of their task, which adds another standard work to the useful and important series of translations issued by the Clarendon Press.

To the contents of the original German edition have been added an "appreciation" by Prof. Percy Groom, which gives an interesting sketch of the life and work of the late Prof. A. F. W. Schimper; and a frontispiece, consisting of a photogravure portrait of the author, whose "untimely death," to quote once more from the editors' preface, "has robbed the English edition of modifications and improvements which he had intended to make." R. H. Y.

THE COMPARATIVE HISTOLOGY OF VERTEBRATES.

Lehrbuch der vergleichenden mikroscopischen Anatomie der Wirbeltiere. Herausgegeben von Prof. Albert Oppel. Vierter Teil. Ausführapparat und anhangsdrüsen der mannlichen Geschlechtsorgane. By Prof. Rudolph Disselhorst. Pp. x+432. (Jena: Gustav Fischer, 1904.) Price 20 marks.

It is now nearly eight years since the appearance of the first volume of the "Lehrbuch der vergleichenden mikroscopischen Anatomie der Wirbeltiere." In the preface to that volume Prof. Oppel gave an account of the general scope and object of the work, which was to provide a comparative description of the minute anatomy of every organ of the body throughout the entire vertebrate series. Vol. i., which deals with the histology of the stomach and is unequalled for its wealth of detailed information, was followed in the next year by a second part, giving an account of the œsophagus and intestine, while in 1900 the third volume, which is devoted to the consideration of the mouth, pancreas, and liver, and concludes the description of the alimentary tract, was issued. These three very elaborate volumes are from the pen of the editor. But at the outset it was obvious that the task was too gigantic for one man alone, and Prof. Oppel in the preface to the original volume refers to the almost certain necessity of obtaining collaboration. Thus the preparation of the fourth part—the one under review—which deals with the accessory glands and ducts of the male reproductive system, was entrusted to Prof. Disselhorst, and of this volume it is high praise to say that it maintains the level of achievement reached by its predecessors.

The book is divided into seventeen sections, and of these the first fifteen deal with the minute anatomy of the organs, each section being devoted to a particular group or order of the vertebrate phylum. Thus the first two sections contain accounts of the accessory ducts and glands in the two main divisions of the pisces; the third, fourth, and fifth deal respectively with these structures in the amphibians, reptiles, and birds, while the following ten sections comprise descriptions of the same organs in the chief groups of the mammalia. The last two sections consist respectively of a condensed summary of the previous part of the volume and a short sketch of the history of the subject, to which are appended some notes on the physiology of the structures described.

A work like the present is necessarily of the nature of a compilation. Thus there occur frequent references to such books as Oudemans's "Die accessorischen Geschlechtsdrüsen der Säugetiere," and to Prof. Disselhorst's own work on the same subject. The references on the whole are extremely full, but it is inevitable that there should be some omissions. For instance, I find no mention of Dr. Nicolas's "Contribution à l'Étude des Organes érectiles," published in the *Journal de l'Anatomie et la Physiologie* (1887), neither is Garrod's paper entitled "Notes on the Osteology and Visceral Anatomy of Ruminants" (*P.Z.S.*, 1877) referred to, in spite of the fact that it contains the best and indeed practically the only comparative account of the curious modifications undergone by the copulatory organ in the Ruminantia. Perhaps it is hardly reasonable to expect a complete series of references to papers dealing mainly with the anatomy of animals in a book professedly devoted to histology, yet the titles of a great number of less important papers treating in many cases of single species duly appear in the bibliographical lists. It cannot be said, however, that omissions such as those mentioned detract seriously from the value of the book as a whole. It is to be noted that the lists of references, instead of forming one long bibliography at the end of the book, as in the previous parts of the work, in this volume are appended to the various sections, so that the titles of papers referring to any one particular group occur together. The book is copiously illustrated by zincographs and by reproductions from photo. process blocks. In addition to the 435 figures appearing in the text, the chapter on the monotremes and marsupials, which is perhaps the most interesting

and at the same time the most complete, is further illustrated by seven large folding lithographed plates. These are bound at the end of the volume.

Suffice it to say that this piece of work is a matter for congratulation to Prof. Disselhorst, and its publication a credit to all concerned

Francis H. A. Marshall.

SPECTRUM ANALYSIS.

An Introduction to the Study of Spectrum Analysis. By W. Marshall Watts, D.Sc., F.I.C. Pp. vii + 325. (London: Longmans, Green and Co., 1904.) Price 10s. 6d. net.

It is somewhat remarkable that, in spite of the great interest and importance of the subject, there are few, if any, text-books on spectrum analysis which really meet the requirements of beginners who desire to take up the matter practically. The announcement of an introductory work by the well-known compiler of the "Index of Spectra," however, led to the hope that this gap in the literature of the spectroscope would at last be adequately filled, but it is disappointing to find that the needs of the practical student are again almost disregarded.

The book includes a brief account of the optical principles underlying the different forms of spectroscope, and general explanations of the methods of producing and mapping spectra, besides which there are short statements relating to the arrangement of lines in series, and the applications of the spectroscope to the study of the heavenly bodies. When it is stated that nearly half the book is occupied by wave-length tables, and that there are 135 illustrations—many of them large ones—it will be seen that the general treatment can scarcely be otherwise than sketchy. The descriptions of the modes of procedure are consequently often lacking in details which would have been of the greatest use to the student. Thus, with reference to the spectra of gases, the only method of observation indicated is that of a ready-made Geissler tube, which, as the author remarks, does not always show the spectrum of the gas present in the greatest proportion; it would have been useful to explain how the student might examine the spectrum of a gas collected or prepared by himself. Later on, there is a short account of stellar spectra, but no directions whatever as to how such a spectrum may be observed.

Another very serious defect from the student's point of view is the use of the arbitrary scale of Bunsen in the maps and earlier descriptions of the characteristic lines of the different elements. It is afterwards shown how such measurements may be reduced to wave-lengths, but surely it would have been better to define the various lines by their wave-lengths from the very beginning; as it stands, a great deal of unnecessary labour is involved in the comparison of the descriptions and maps with the wave-length tables given at the end of the book.

The book, in fact, leaves a great deal to be desired, whether considered as a laboratory guide or as a descriptive work. Many important facts are left unnoticed, though space might have been found for some of them by the omission of superfluous or insufficiently described illustrations. In the section on nebulæ, for instance, there are no less than eight diagrams showing the telescopic appearances of these objects, but no reference to the fact that all nebulæ do not exhibit bright line spectra; the reader is, moreover, likely to get the wrong impression that the chief nebular line is due to nitrogen.

Though brought well up to date in some respects, the book is far behind the times in others. It is erroneously stated (p. 106) that the spectrum of the solar corona includes lines of helium, hydrogen, and calcium, and the important subject of enhanced lines in relation to many celestial spectra is overlooked altogether.

Many other examples of the shortcomings to which attention has been drawn might be given, but the above will sufficiently indicate that the selection of material has not been judiciously made. By far the most valuable feature of the book is the series of abridged tables of wave-lengths, showing the more important lines in the spectra of nearly all the known chemical elements.

OUR BOOK SHELF.

Text-books of Physical Chemistry.—Electrochemistry. Part i. General Theory. By R. A. Lehfeldt, D.Sc. Pp. viii + 268. (London: Longmans, Green and Co., 1904.) Price 5s.

Students of physical chemistry have to-day no cause to complain of a dearth of books upon the subject. There are a considerable number of large volumes treating of this branch, and now we have the series of text-books edited by Sir William Ramsay. The book under review is the second of the series, and has been entrusted to Dr. Lehfeldt, who is well known as a worker on the physical side of electrochemistry.

Dr. Lehfeldt has not followed any hard or fast line laid down by previous writers upon the subject, and for this reason the book may be read with more than ordinary interest. The book is divided into three chapters, which might perhaps better be designated parts i., ii., and iii. Chapter ii. is written by Mr. T. S. Moore, and deals with the relation of chemical constitution to conductivity. This chapter is very carefully thought out and arranged, and the author has consulted the latest literature. It deals, in the first place, with the relation of charge carried to constitution, this portion being really a repetition and enlargement of what has already been dealt with in the previous chapter. In fact, chapter ii. is to a certain extent an addendum to the first chapter, but it should in no wise be skipped by the student who desires to comprehend the bearing of electrochemistry on chemical problems. Other points treated in this chapter are relation of the number of ions in solution to constitution, pseudo acids and bases, amphoteric electrolytes, and so on.

Chapter i. commences with a description of certain voltameters. We would rather that the author had adopted the term coulommeter, because the instruments are for measuring current and not potential.

although, of course, the author is only using the term commonly applied to these instruments.

Dr. Lehfeldt then discusses the mechanism of electrolytes. We are not sure what a certain school of chemists will say to the following rather didactic statement:—

"It was Arrhenius who first put forward reasons for supposing that an electrolyte might be largely, . . . dissociated in solution . . . this view has gradually gained support from experiment since, and may be looked upon as thoroughly established."

Dr. Kahlenberg, for instance, would hardly subscribe to this statement. In this chapter the author also deals, among other subjects, with the conductivity of the electrolyte, ionic velocities, and electrolysis in non-aqueous solutions.

The last chapter is devoted to the theory of chemico-electromotive force. The section on thermodynamic theory and the calculation of electromotive force of a voltaic cell well repays perusal, as does the section on standard cells.

Dr. Lehfeldt is thoroughly at home with his subject; we are not, however, sure whether the average student will find the style very interesting. Of course, a book of this kind cannot be read in a cursory way; if it could, we doubt whether it would be worth reading, but we are of the opinion that it will be welcomed by all interested in the subject.

Traces of the Norse Mythology in the Isle of Man. By P. M. C. Kermode. Pp. 30. (London: Bemrose and Sons, Ltd., 1904.) Price 2*s*. 6*d*.

In this work Mr. Kermode, whose name is well known in connection with Manx archæology, has printed a lecture delivered to the Antiquarian Society of his native island in December of last year. The Isle of Man contains a large number of cross-bearing gravestones, which, as the inscriptions clearly show, belong to the period when the Scandinavian element was predominant in the island. It is not improbable that in some cases the symbols on these stones may refer to the old Scandinavian mythology rather than to Christian belief and legend, and Mr. Kermode has endeavoured to determine how far this is the case. After a very brief sketch of the Scandinavian settlements in the west, and more especially in Man, a short account is given of some leading details of the old Norse mythology as preserved in the Eddas. Both here and in the following section an interest in the subject is sometimes more evident than familiarity with it in all its bearings. It is, for example, quite erroneous to state that "of the seven days of the week all but the first two are called after Scandinavian gods." Even on his own lines, Mr. Kermode cannot thus account for *Saturday*, and a closer study of the old English forms would have shown him the true origin of the other names. The influence of the Scandinavian tongues on English has been very great, but it requires a close study of philology to decide the particular cases in which it appears.

The concluding section consists of a detailed description of the illustrations, under eight heads, and with references to the ten plates at the end of the booklet. These are neatly executed, and exhibit typical specimens of Celtic crosses and ornamentation, as well as the symbolic figures which Mr. Kermode believes to represent subjects taken from the old mythology. In many cases the explanation he offers is extremely doubtful, as there is always an equal, if not greater, possibility that the symbols are of Christian origin. Thus, what Mr. Kermode takes to be an eagle (=Suttung) pursuing a falcon (=Odin), might equally well, for all one can see, represent Noah's raven and dove. The harper whom he identifies with the "gladsome Eggthér" of *Völuspá* may just as well be King David; and if the fish is a Christian symbol on Plate X., why not also on Plate III.? In many of these cases it is probably hopeless to determine what the sculptor had in his mind, and there is no particular gain in making guesses at it.

In minor points there is not always as much precision as is desirable. The Icelandic words and names are too frequently misprinted, while such equations as *Hnikarr* and *nykr*, *Rig* and *Eirik*, are evidence of shaky philology. Mr. Kermode's lecture, however, may be of service in helping to waken or encourage interest in that Scandinavian influence on Britain which is an important factor in the history of our country.

W. A. Craigie.

Eton Nature-study and Observational Lessons. Part ii. By M. D. Hill and W. M. Webb. Pp. xvi+174. (London: Duckworth and Co., 1904.) Price 3*s*. 6*d*. net.

Part ii. of this book, like part i., is excellent. That nature-study as here recommended is educationally sound is beyond dispute. What makes instruction so wearisome to the learner is often, to put it plainly, the unceasing sound of the schoolmaster's voice. What a boy, if he has any go in him, wants, is to do something for himself. It would be best if he could make out everything unaided. "I never tell my pupils anything," once said a mathematician devoted to the maieutic method; and Hesiod quaintly remarks, "The best man of all is he who finds out everything for himself." But this is hardly possible for us moderns, and the authors of this book are wise enough not to make a craze of a sound principle. In the chapters, to take examples, on earthworms, woodlice, the defensive armour of plants, and plants that have no flower, there is plenty of information given to stimulate interest. If the pupil is the right kind of boy, he will be keen to follow some of the lines of investigation pointed out. Many persons are led to the out-of-doors study of natural history by reading. They want to see some of the wonderful things that naturalists have seen, not always to get them at second hand. Indeed, the importance of reading in connection with observation should be insisted on. Many boys, though full of zeal, never get beyond a very restricted field in natural history, because they will not read in order to discover how the little that they have learnt by the use of their own eyes finds its place in the vast accumulation of knowledge. The observer should be a reader, and the reader an observer.

A great deal may be learnt by trying the experiments recommended in this book, *e.g.* by hatching trout eggs, by keeping a fresh-water aquarium or an observatory hive of bees, by making a formicarium, by photographing such things as birds and birds' nests. But here a difficulty arises. At school, how is a boy to keep an observatory hive of bees or to hatch trout eggs? In fact, some of the suggestions bring out sadly the limitations of school life. Others, no doubt, are quite possible. But headmasters might well study a book like this. If teaching is to proceed on a truer and more natural plan than hitherto, something must be done to remove existing restrictions.

The subjects for observation (*e.g.* a frog's egg, a hen's egg, the development of tadpole and chick, a silk worm, an opening flower) are well chosen. The illustrations are all good. Some of the photographs ought to induce boys to make their photography a help to accurate observation instead of a mere amusement.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Forest-pig of Central Africa.

IT may interest many of your readers to know that the "forest-pig" heard of, at the same time as the okapi, by Sir Henry Stanley, and later on by Sir Harry Johnston, has at last been obtained and presented to the National Museum by Mr. R. Meinertzhagen.

This gentleman first had news of it from the natives of Mount Kenya, and took great pains to secure a specimen, but only succeeded in obtaining pieces of skin, from which no idea of its affinities could be gathered. At last, however, in the Nandi Forest, near the Victoria Nyanza, at an altitude of 7000 feet, he received two skulls, one quite perfect, and some further portions of skin.

These trophies show that the animal represents a most interesting new genus connecting the aberrant wart-hog (Phacochærus) with the more ordinary Suidæ, such as Sus and Potamochærus. It agrees with the first named in the number of its incisors, and shows a tendency towards it in the development of the canines and the structure of the molars. On the other hand, in the general proportions of the skull it is more like Sus.

Altogether, if it cannot be called absolutely ancestral to Phacochærus, it must at least be looked upon as representing an early stage in the specialisation of that most remarkable type.

The animal itself is about as large as a wart-hog, and is well covered with long coarse black hair.

It is proposed to be called *Hylochoerus meinertzhageni*, and I hope to give a full description of it at an early meeting of the Zoological Society.

OLDFIELD THOMAS.

British Museum (Natural History), October 7.

Appeal for Cooperation in Magnetic and Allied Observations during the Total Solar Eclipse of August 29-30, 1905.

THOSE who are in a position to take part in the above cooperative work are earnestly requested to make the necessary preparations and to put themselves in communication with the undersigned.

As this will be the best opportunity for some time to come to test and observe further the magnetic and electric phenomena which have been found to occur in connection with total solar eclipses, and as these phenomena are destined to play an important *rôle* in the theory of those variations of the earth's magnetism and electricity ascribed to outside forces, it is very much hoped that all countries through which or near which the belt of totality passes will organise and send in the field observing parties.

Owing to the minuteness of the expected magnetic effect, the burden of proof as to its association with the eclipse will largely consist, as in the two previous eclipses, in the connection of the times of the magnetic effects with the times of passage of the shadow cone at the various stations. The observing parties, therefore, should be distributed at intervals along as much of the entire belt as possible.

The above is merely a preliminary notification of the work proposed. Fuller details and suggested directions to be followed will be given later.

Instinct and Reason in Dogs.

THE following statements may be of interest to those of your readers who have at times discussed the question of instinct and reason in dogs.

A friend of mine was in a strange town, having with him an Irish terrier. Finding it necessary to fasten the dog up outside a house, he did so by tying it with a piece of cord. On coming out of the house he was just in time to see his own dog being led away by a strange dog holding the cord in his mouth, having bitten it through. My friend often takes this same terrier, together with a fox terrier, out with him when calling. He ties the fox terrier by a cord to the scraper; as often as not the Irish terrier bites through the cord and frees his friend.

My own fox terrier seldom if ever goes to the stables, and whilst I am absent from home for a few days remains in his usual place; but almost invariably on the day when I am expected back he pays frequent visits to the stable, and is anxious to go with the carriage if he sees it being got ready; at all other times he is not willing to go with the carriage unless I am in it. On the two last occasions when I was expected home the dog acted as previously, but, in addition, jumped into the carriage as soon as it was brought out of the coach-house, a thing which he has never done before.

October 8.

Misuse of Words and Phrases.

As a constant reader of NATURE and of papers read before scientific societies, I have been struck by what seems to me an inaccurate use of language by English men of science which is rarely chargeable upon Americans—which is, at any rate, at variance with American usage. I will illustrate with the following examples:—

One star is five light-years distant; another is twenty-five light-years distant. The English astronomer will say that the second is *five times farther away* than the first.

A mass of aluminium weighs one pound; a mass of lead of equal size weighs something more than four pounds. The English physicist will say that aluminium is *more than four times lighter* than lead.

Both expressions seem to me incorrect and unworthy of a man of science who endeavours to express himself accurately. In the one case he should say that one star is five times *as far away* as the other. In the other case the whole expression is vicious. Weight, heaviness, is an attribute of matter; lightness is absence, or deficiency, of weight. To say that one article is a certain number of times *lighter than* another is like saying of two vessels unequally exhausted of air that one is four times emptier than another.

It is good English—is it not?—to say that one article is twice as heavy as another. If it is twice heavier, it is three times as heavy.

I submit this criticism of an Anglicism as an offset to some one of many criticisms of Americanisms.

Boston, U.S.A.

NATURAL HISTORY ESSAYS.[1]

ON the whole, Mr. Renshaw appears to have been well advised in re-issuing in book form the sixteen articles and lectures which constitute the volume before us, since several of them contain much important information with regard to species now verging on extinction, or which have been already exterminated, while all are eminently readable and full of interest. Whether the author has quite done himself justice in the title he has chosen for his work may be open to question, seeing that all the articles relate to a single subject, namely, the mammals of Africa. Undoubtedly the most generally interesting and important articles of the series are the two dealing with the quagga and the blaauwbok, next to which may perhaps be ranked those on the white rhinoceros, the pigmy hippopotamus, and the giraffe. The book is abundantly illustrated with reproductions from photographs, many of which, like the one here shown, are excellent examples of animal photography.

While there is much to commend in the work before us, there are also matters with which to find fault. In the first place, the author has not revised his articles

[1] "Natural History Essays." By G. Renshaw. Pp. xiv+218; illustrated. (London and Manchester: Sherratt and Hughes, 1904.) Price 6s. net.

so as to bring them up to date. A striking instance of this is afforded by the one on giraffes, which takes no notice of the new forms described in "Animal Life" for 1903, and in the *Proceedings* of the Zoological Society for the present year. A minor instance is the statement (p. 212) that the aard-vark is represented in the exhibition galleries of the Natural History Museum by a specimen mounted in 1841, that specimen having been removed considerably more than a year ago, and replaced by a new one. Again, on p. 56, Mr. Renshaw repeats his statement that an antelope skull in the Museum of the Royal College of Surgeons is that of the extinct blaauwbok, whereas Mr. O. Thomas has expressly stated in the *Field* that it pertains to the roan antelope. If the author adheres to his original view, he should at least have attempted to refute the statement of an expert like Mr. Thomas.

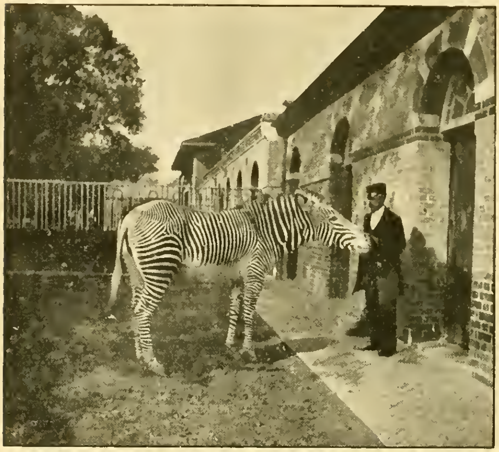

FIG. 1.—A Grévy's Zebra. From Renshaw's "Natural History Essays."

A further instance of what may be called "opinionism" on the part of an amateur is afforded by the case of the quagga in the Natural History Museum, which Mr. Renshaw, in opposition to the museum authorities, believes to be one which was brought to London in 1831. The evidence indicates, on the contrary, that this specimen is without doubt one received by the Zoological Society in September, 1858, which died, or was killed, in June, 1864, and was acquired by the museum in July of the same year, as is indicated by its register number (64.7.2.3). Equally erroneous, unfortunately, is the statement on p. 191 that the Amsterdam quagga was a Knowsley Menagerie specimen, as has been pointed out in a recent issue of the *P.Z.S.* *Per contra,* Mr. Renshaw is to be credited with pointing out that the quagga depicted in "Wood's Natural History" is one of the specimens living in the "Zoo" during the 'sixties, since the figure indicates an animal clearly identical with those represented in the "Knowsley Menagerie," and thus serves to identify the quaggas of the 'sixties with those figured in older works, which have been thought to be different. The reference to a statement made in 1801 as to the protective nature of the markings of the zebra (p. 165) is likewise a point on which the author is to be congratulated.

Reverting to errors, we may direct attention to the misappropriation of the name *Felis pardina* (p. 19) to the ocelot, of which the proper title is *F. pardalis*, *pardina* being the appellation of the Spanish lynx. In popular works the use of scientific names should, in our opinion, be mostly avoided, but if they are used they should be correct; a transposition of names like the above is every bit as bad as calling a lion a tiger! Another example of the necessity for care in the employment of scientific names in works of this nature occurs on p. 133. In one sentence on that page we find the name *Rhinoceros antiquitatis*, and later on the title "woolly rhinoceros," but there is nothing to indicate to the uninitiated that these denote one and the same animal.

If only the author had paid a little more attention to the revision of his articles he might have converted a very interesting volume into a really valuable record of the past history of several extinct and waning forms.

R. L.

DEVELOPMENTS OF THREE-COLOUR PHOTOGRAPHIC PROCESSES.[1]

II.

HAVING obtained the three colour records it remains to use them for locating the colour in the production of the final print. If the coloured lights are to be added, as in Ives's chromoscope, then a transparency is made from each colour record (which is, of course, a negative), and each transparency is made to furnish light of a similar colour to that of which it is the record. If the colours are to be superposed, as when they are printed one over the other, or when coloured transparencies are made and superposed in the method of making coloured lantern-slides, then a complementary colour to that of each record must be used, because the absorptions are added instead of the lights. In the chromoscope the colours are in the form of screens; they remain in the instrument, and therefore are provided once for all. In the other cases they are stains or inks, and an amount is used up in the production of each print; they are therefore used in quantity. In the choice of inks and stains, the perfection of colour is only a matter of degree, and those colours that most nearly approach perfection may not be suitable otherwise. The best colours may be (and in some cases are) fugitive, so that for practical purposes an inferior colour has to be used. If the colour is perceptibly different from the theoretical tint, then the colour records must be adjusted to make the best of the available colours. When the colours are superposed, as in printing on paper, at least two of the three inks must be made of transparent colours, or obviously the top colour would hide those beneath. This last matter is, as Hübl remarks, one of the most important difficulties in trichromatic work, and, he adds, the colour last printed will always predominate over those previously applied. Hübl, in his treatise, describes how to select the inks by means of his circular spectrum colour scheme, and how to mitigate the errors due to the defects of the selected colours, chiefly by retouching and by setting off one defect against another. The inks may be selected also by the use

[1] "The Water-Colour Drawings of J. M. W. Turner, R.A., in the National Gallery." By T. A. Cook. Pp. vi+86 and 58 plates. (London: Cassell and Co., Ltd., 1904.) Price 3 guineas net.

Continued from p. 555.

of Abney colour sensitometers, or by spectroscopic methods, but it is not sufficient to judge of the colour by the eye alone. It is necessary that the colours shall not only look right, but that they shall be right when analysed spectroscopically. Each colour is used, not so much for its own sake, as to give the proper tints when the light it reflects or transmits is mixed with the light from the other colours.

But supposing that the inks or stains selected were theoretically perfect in colour, and perfectly transparent, so that when superposed the lowest produced its full effect, it still remains to see that each is laid on in its due proportion, for if one is in error the whole will be thrown out, and what should be neutral greys will be tinted with colour. And there is still another difficulty to consider. The gradation produced by the same treatment of a sensitive plate generally becomes more steep as the wave-length of the light used increases. This is certainly the rule, though there may be exceptions to it. Therefore, if the pink, yellow, and blue inks are properly proportioned to give a neutral black where the colours are in full quantity, the greys may be expected to be bluish, and in the lighter colours there may be expected a deficiency of red. To overcome these difficulties, some have sought to use four, or even five, colours instead of three, and others have used a fourth plate with black ink to give the blacks and greys, removing from the plate those parts where pure colours are required. Obviously, the use of additional printing plates is a confession that the three-colour process cannot be worked on the theoretical lines, but such variations as these do not appear to be at all generally adopted.

There are many methods by which the three colours may be brought together to make the final picture. The simplest of all, both theoretically and practically, and at the same time perhaps the most perfect and therefore the most beautiful, appears to be the production of transparencies by the superposition of gelatine reliefs produced from the colour records, each appropriately stained by immersion in a suitable dye solution. There is nothing to regulate the depth of colour to which each relief should be stained but the judgment of the worker, and the fact that the greys and blacks of the original should be untinted by colour in the reproduction. A relief may be more highly coloured by a further immersion in the dye solution, or lightened by immersion in water.

For printing on paper, either the collotype process, lithography, or typographic blocks may be employed. Some very excellent work has been done by the first of these methods, but in both collotype and lithography, as already stated, it is difficult to regulate, to a nicety, the amount of ink applied, and the successful impressions generally form only a small proportion of the whole. The process that is the most used, and that certainly at the present is the most suitable, consists in printing from typographic blocks as ordinary letterpress is printed. The photographic production of blocks from half-tone negatives is practised to so great an extent, and the machinery for letterpress printing is so perfect, that uniformity is more easily secured by this than by other methods. In pointing out the advantages of this process, Colonel Hübl states that it gives a better blending of the colours, and that the inks are not brought into contact with water so that they remain pure, and as the paper remains dry during the printing a better register is secured. But the process has its own defects—Hübl says that "the gradation is limited and incorrect," and that "the final result depends more on the clever work of the retoucher than on the perfection of the photographic negative." This last statement conveys, perhaps, rather an exaggerated view of the facts of the case.

The dots in the impression from a half-tone block are, as is well known, in lines, as determined by the ruling of the screen that is placed in front of the plate when the grained negative is made. Now when lines at regular intervals cross each other at a small angle a pattern is produced known as a "moire" or "watering" effect, from its similarity to the appearance of "watered" silk. The effect can easily be seen by looking through two pieces of muslin superposed with the threads not quite parallel. Two rows of park railings, if near enough, will often show it, the railings in each row being parallel to each other, but not quite parallel to those in the other row. In superposing three impressions from blocks made by means of cross-lined screens, it is important to avoid any approach to parallelism of any set of lines or rows of dots with any other, especially as regards the relative positions of the red and blue impressions, as these are darker than the yellow, and therefore more conspicuous. It is obvious that if the screen used has its crossing lines at right angles, the three impressions will give six sets of lines, and an angle of 30° between each and the next if the angles of crossing are kept equal. Circular lined screens mounted in aluminium cells, so that they can be rotated to any desired angle with precision, are much used in America and are coming into use here. A common method, which is being superseded by the circular screen, is to use two rectangular screens, one of which is ruled at such angles that, by turning it round from back to front, it gives the rulings in the third position. Other methods are sometimes used for the purpose, for the shape of the aperture in the diaphragm affects the character of the dots, and it is possible to use a slit diaphragm and rotate the lens that carries it. But the most notable variation in the preparation of the blocks is to get rid of the lines, or even rows of dots, altogether, by using an irregular grained screen. Of the many attempts that have been made in this direction, the one that seems to offer the greatest promise of success is Wheeler's "metzograph" screen, in which an irregular wavy surface of the glass gives the concentrations of the light required.

There is one matter in connection with three-colour printing by means of half-tone blocks that sometimes presents a difficulty to the minds of those who have a slight acquaintance with the subject, and certainly is not altogether without effect, namely, the fact that the dots of the different colours are sometimes superposed and sometimes side by side, according to accident in printing. This difference is not very important. The colours are arranged on the supposition that they are superposed. If otherwise, much the same tint results, but it is mixed with white, because the result is the sum of the lights instead of the sum of the absorptions. But if the dots were completely superposed, then there would be a greater area of white paper between the dots, and the white light from this source doubtless about compensates for the other. Perhaps, in the circumstances, the juxtaposition is advantageous, as the tendency for the ink last applied to show more conspicuously than the others would not hold in this case.

A notable example of the excellence that is now possible by three-colour typographic printing may be seen in "The Water-Colour Drawings of J. M. W. Turner, R.A.," a selection of fifty-eight subjects, published by Messrs. Cassell and Company, the reproductions being made by Messrs. André and Sleigh at their works at Bushey. In such a case the question that is naturally asked is, Are the colours of the reproductions similar to those of the original? Of course they are not the same pigments—this is not intended; the only aim of the printer is to give colours

that cannot be distinguished from the original by simple observation. Mr. Theodore Andrea Cook, in his preface to the volume, refers to "mechanical accuracy, assisted and improved by skilfully delicate and reverentially careful handiwork," and thus sums up the position according to the facts of the case. The colours are not accurate by reason of the fact that the printing blocks are made by photographic means, although this may be claimed for the drawing—that is, the outline. In describing the process of three-colour printing, we have endeavoured to show how that imperfection and compromise qualify every step of the work. It is therefore necessary to examine the first proof by critically comparing it with the original, and then to make such alterations as are required in the three printing plates, by re-etching wholly or partially, by hand engraving, burnishing, and similar methods, continuing to make proofs and effect the needed changes until the differences are eliminated. At Messrs. André and Sleigh's this examination and hand work are carried out by trained artists, as distinguished, that is, from photographers and printers, and it is to the scrupulous care bestowed upon this adjustment of the plates by hand that the perfection of the prints depends. The justification lies in the result, and, whatever may be said for or against any principle of work, it is by the practical result only that it can, at present, be finally judged. If a copyist were to paint a copy of a picture, we should naturally seek the opinion of eminent painters as to the merits of the copy. Three-colour reproductions put forward as these are must naturally be judged in the same way, and it is a source of gratification to all interested in the technics of three-colour work to know that these reproductions have received the warm approval of many of our best known painters. But it is easy to believe that there is room for a little difference of opinion, and that a critical comparison with the originals would reveal possibilities of improvement. Such have been pointed out, and presumably no three-colour work will ever be done for which absolute faultlessness can be rightly claimed. But there is a possibility of error even in this criticism. For as the reproduction is not done in the same pigments as the original it follows that the effect of a difference of illumination will not be the same on both. If the reproduction were perfect as compared with the original by ordinary good daylight, there would probably be differences noticeable to a trained eye if they were compared on a dull day; and this probability must exist however the copy is made if the pigments used are different from those in the original. Moreover, no work in colour appears as it is intended to unless it is illuminated by the light by means of which it was produced or a quite similar light, and this is a physical law which must ever obtain.

There have been a few attempts to simplify the three-colour process by the use of one screen only, the three colours being arranged upon it. Perhaps the best known of these is due to Prof. Joly, who arranges his colours in triple parallel lines. The most recent, and the boldest in its conception, has only just been published by Messrs. Lumière. They sort out from potato starch granules from 0.015 to 0.02 mm. in diameter, and colour separate lots of these red, green, and violet respectively. When quite dry the coloured granules are mixed in such proportions that the mass appears grey, with no predominance of either colour, and a waxed glass is coated with them to form a layer only one granule thick. To prevent the interstices from passing white light, they are filled up with a fine black powder. There is next applied a varnish which has as nearly as possible the same refractivity as the starch. By this means is obtained an irregular-grained triple-colour screen. To prepare it for producing the picture it is coated with a suitably sensitised emulsion. The plate is exposed through the glass, developed, the silver image dissolved away, and the remaining silver salt reduced to the metallic state to form the image. Thus is obtained the completed transparency. It is obvious that if such plates ready for exposure were supplied commercially, the making of coloured transparencies would be much more simple than when three negatives and three prints have to be made. There must be many practical difficulties to surmount in the preparation of such compound plates, and, as in all cases of three-colour work, the process must at present be judged by the results that it yields rather than by the apparent soundness or otherwise of the theories upon which it is based.

The small volume by Mr. R. Child Bayley forms a good introduction to the subject of colour photography, as it is written in such simple language that it may be "understood and followed by any reader, even by one without the slightest acquaintance with photography," as the author states in his preface. At the same time sufficient formulæ and precise details are given for the practical working of those processes that are within the experimental possibilities of the photographer.

CHAPMAN JONES.

NOTES.

THE French physicians and surgeons who are visiting London arrived on Sunday. On Monday the president and council of the Royal College of Surgeons received the visitors, who were shown the collections in the museum. Parties have during the past three days visited the principal hospitals, general and special, the physiological laboratories of the University of London and the laboratories of the Cancer Research Fund, the Lister Institute, the Middlesex Hospital cancer department, the pathological laboratory of the County Council Asylum at Claybury, and the London School of Tropical Medicine. Receptions have been given by the editors of the *Lancet*, Dr. and Mrs. Dundas Grant, and the Dean of the Faculty of Medicine of the University of London and Mrs. Butlin. On Wednesday night the visit was brought to a close by a banquet at the Hotel Cecil.

THE Government of the Federated Malay States has decided to establish an agricultural department in Malay, and has appointed Mr. J. B. Carruthers, the Government mycologist and assistant director of the Royal Botanic Gardens of Ceylon, to be director of agriculture and Government botanist. The Federated Malay States have an area of more than 25,000 square miles, and the agricultural potentialities are very promising. Large areas are being planted with rubber plants, and sugar and cocoanuts are extensively cultivated. There are two botanic gardens and a rubber experiment station in the Malay States, and all three are, we understand, to be administered by the new department.

ON October 6 the Antarctic relief ship *Morning* arrived at Plymouth from Lyttelton after an absence of about two and a half years.

THE first monthly general meeting of the new session of the Institution of Mechanical Engineers will be held on Friday, October 21. A paper by Mr. R. M. Neilson on "A Scientific Investigation into the Possibilities of Gas Turbines" will be read and discussed.

ACCORDING to the Paris correspondent of the *Daily Chronicle*, Dr. Laveran, of the Pasteur Institute, has discovered a remedy for sleeping sickness, and has already tried it with success upon animals previously inoculated with the disease.

AT the meeting of the Royal Microscopical Society on Wednesday, October 19, a demonstration entitled "The Re-construction of a Fossil Plant" will be given by the president, Dr. Dukinfield H. Scott, F.R.S.

A REUTER telegram from Paris states that a radiographic station has been opened at Ushant for the purpose of communicating with ships at sea. The station will transmit messages from the mainland, and will receive messages for addresses in France, Algeria, Tunis, Monaco, and Andorra.

THE *Chemist and Druggist* states that a congress of chemistry and pharmacy, organised under the auspices of the Pharmaceutical Association of Liège and the Chemical Society of Belgium, will be held in connection with the International Exposition to be held at Liège in July, 1905. Communications should be addressed to one of the secretaries, M. J. Raymond, 16 Place des Carmes, Liège, or M. J. Wauters, 83 rue Souveraine, Brussels.

THE Childhood Society announces that a course of four public lectures will be delivered at the Parkes Museum, Margaret Street, W., on Thursday evenings at 8 p.m. The dates, subjects, and lecturers are:—on October 20, discussion on physical deterioration, to be opened by Mr. E. W. Brabrook, C.B.; on October 27, physical condition of working class children, by Dr. T. J. Macnamara, M.P.; on November 10, mental hygiene in childhood, by Dr. T. B. Hyslop; and on November 24, education of girls, by Miss M. E. Findlay.

THE session of the London School of Tropical Medicine was opened on Friday last with an inaugural address by Sir Charles Bruce, G.C.M.G., ex-Governor of Mauritius, Sir John Craggs presiding. Sir Charles Bruce detailed some of his experiences in the colonies, and gave interesting particulars, from the layman's point of view, of tropical diseases with which he had come in contact, notably the remarkable outbreaks of malaria and of surra in Mauritius. Sir Patrick Manson, in the course of proposing a vote of thanks, directed attention to the munificence of Sir John Craggs in giving a scholarship and prize to the school, and expressed a hope that funds for endowment might soon be forthcoming.

IN the October number of the *Century Magazine* Mr. Gilbert Grosvenor, in an article entitled "Inoculating the Ground," describes the method of preparing and using the cultures of nitrifying micro-organisms which are now being employed as fertilisers under the name of nitragin; photographs are given of two plots side by side, one of which had been planted with inoculated and the other with uninoculated seeds, also of the average plants from each plot. There is a surprising difference between the two, the crop from the inoculated plot being much the more luxuriant, and Mr. Grosvenor expresses the opinion that there is not a section of the United States which will not profit by the use of nitragin.

THE New York correspondent of the *Lancet* announces that the Bureau of Chemistry of the National Department of Agriculture is about to establish a laboratory in New York for the examination of imported foods and the detection of adulterations and imperfections. The occasion which led the national authorities to create this laboratory was the result of a recent investigation which proved that in the last two months three shiploads of food products imported into New York were returned to the ports whence they came on account of the adulterations found. The new law requiring a thorough examination of the food products imported into the United States is being rigidly enforced, and this new laboratory is a proof that the investigation is to be on a large scale.

WE have seen with regret the announcement of the death of Mrs. Isabella Bishop, the well known traveller and author, at the age of seventy-two. Mrs. Bishop was the eldest daughter of the Rev. Edward Bird, and became a traveller on account of her continued ill-health. A visit to Prince Edward Island resulted in her first book of travel. Later sea voyages were ordered to the Mediterranean, America, Australia, and New Zealand, and Miss Bird returned by way of the Sandwich Islands, where she spent some months, and she also visited the Rocky Mountains, describing her adventures in two books which were published in 1873 and 1874. Miss Bird next began her travels in the East. She seems to have been the first European woman who made her way into the heart of Japan, and her "Unbeaten Tracks in Japan" (1880) records her experiences. Her "Journeys in Persia and Kurdistan," in two volumes, appeared in 1892—the year when she was elected the first lady fellow of the Royal Geographical Society—and "Among the Tibetans" in 1894. In 1896 she published an interesting collection of photographs which she had herself taken in western China and Korea. Her travels in Korea, Siberia, and China lasted for three years, and their results are shown in "Korea and her Neighbours" (1898). Since then have appeared from her pen "The Yangtse Valley and Beyond" (1899), and "Pictures from China" (1900).

PROF. FRIEDRICH RATZEL, whose death occurred on August 9, was one of the foremost in the band of ardent geographical students who have done so much, on the Continent at least, to win for their subject recognition, both as a valuable intellectual discipline and as a fundamental part of the training of all who aspire to a leading place in public affairs. While not confining himself to any one branch of the subject, it is as an exponent of the geography of man that Ratzel will be principally remembered. By his development and clearer definition of the principles enunciated by Carl Ritter and his school, of the influence exercised throughout human history by natural environment, he may almost be said to have created a new department of study, which, under the somewhat clumsy name of anthropogeography, has taken a firm hold in the educational curricula not only of Germany, but of France and other European countries, while his influence has likewise been felt, if in a less degree, in our own country. Brought up as an apothecary's assistant, Ratzel seized every opportunity of improving his scientific knowledge, zoology being in these early days his favourite study. But it was as a travelling correspondent (1869–75) in central and southern Europe, in the United States, Mexico, and the West Indies that his geographical leanings first found scope, the utilisation of which brought him eventually, as university professor, to the distinguished chair at Leipzig, where for the rest of his life he continued to exercise a predominant influence on the progress of higher geographical education in Germany. In addition to his "Anthropogeographie," by which he is perhaps best known, Ratzel was the author of important works on the United States, on the races of man, and on political geography from the comparative standpoint.

In its September issue, the *Field Naturalists' Quarterly* publishes the first two of a series of plates (reproduced from photographs) illustrative of the development of the frog. Among the other contents, we may allude to an illustrated article by Miss O. Hill on the acquisition of a portion of Ullswater for the nation, and to the fifth part of Mr. J. L. Kershaw's "The Naturalist in China," which is illustrated with exquisite portraits of the "rainbird" and the Chinese francolin.

THE *South-Eastern Naturalist* for the current year contains Mr. F. W. Rudler's presidential address to the South-Eastern Union of Scientific Societies, in which, after allusion to several points connected with the geology of the district, reference is made to the future of these and similar bodies. Now that many local societies have been relieved of the custody and up-keep of their museums by the county councils, it has been suggested that their work is practically over, and that they should prepare for winding-up their affairs. With this the president does not agree, pointing out that local societies have plenty to do in cataloguing the natural history and archæological products of their respective districts, to say nothing of recording the meteorology. The volume includes notes on the Lepidoptera of mid-Kent by Captain Savile Reid, and a list of localities for uncommon plants by Mr. W. H. Griffin.

PARTS ii. and iii. of the thirty-second volume of Gegenbaur's "Morphologisches Jahrbuch" contain several important papers on vertebrate morphology. In the first of these Dr. K. Kjellberg reopens the question of the homology of the various elements in the articular region of the jaw of mammals and sauropsidans, devoting special attention to the meniscus of cartilage found between the mandibular condyle and the glenoid cavity of the squamosal in many mammals. The author considers that the quadrate of sauropsidans represents the incus of mammals, and the articular of the former the malleus of the latter. The mammalian meniscus is, on the other hand, to a great degree a new element, since it is formed by the cutting off of the upper part of the external pterygoid muscle as it passes between the jaw-articulation to the malleus (its connection in the Sauropsida being with the articular). In another article Dr. A. Schumann points out the curious parallelism between the osteology of the hind-leg of the jerboa and that of birds. In a third Prof. H. Dexler describes the histology of the central nervous system of ungulates, while in a fourth Messrs. Fleischmann and Blendiger discuss the cribriform bones of the nasal cavity of mammals. A fifth article, by Dr. U. Böhi, is devoted to the study of the visceral cavity and genital appendages of the salmon.

IN the third part of vol. lxxvii. of the *Zeitschrift fur wissenschaftliche Zoologie* Mr. L. Freund describes in detail the osteology of the flippers of the dugong as displayed in "sciograph" pictures, of which several are reproduced in the plates accompanying the article. It has long been known that the carpus of the adult consists of three large bones. Of the two in the first row, the one is now shown to consist of the fused radiale and intermedium, and the other of the ulnare plus the pisiform and the fifth carpale, the distal bone being composed of the four inner carpalia. In the manati the reduction of the carpus has been carried to a less extent, the radiale being in some instances distinct from the intermedium, while in other cases in which these two bones are fused the four inner carpalia remain separate. Studies in the oligochæte worms by Mr. A. Ditlevsen, and investigations into the development of the eye of the bee by Mr. O. Dickel, complete the contents of this number.

In the fourth and concluding number of the same volume special reference may be made to a richly illustrated article by Dr. E. Mascha on the minute structure and development of the flight-feathers of birds. It is specially noteworthy that cells of two types are found in the medulla of the quills, those of one type being very common, while those of the second occur in the owls and the nightjars—a feature confirming the alliance of these two groups. Elaborate diagrams of the different types of feather-structure characteristic of various groups illustrate the memoir.

A PRICE list of botanical apparatus has been recently received from Messrs. Gallenkamp, Sun Street, Finsbury Square. The apparatus required for plant physiology is a special feature, and the various pieces have been prepared in accordance with Detmer's practical book. A particularly useful item is a standard barometer which is priced at *3l. 7s. 6d.*, working on the Fortin principle.

THE latest number of the *Records* of the Botanical Survey of India, vol. iii., No. 1, contains an account by Captain A. T. Gage of the vegetation of the district of Minbu, in Upper Burma. The district shows three distinct regions, a mountainous zone of the Arracan Yomahs and parallel ridges, an alluvial belt fringing the Irawaddy, most of which is under cultivation, and an intermediate desert zone, which lies between the two former. The systematic census is confined to the plants collected on an expedition which only extended over one month. A list of economic and medicinal plants is appended.

THE exact nature and purpose of the spines which bristle on the surface of so many Cactaceæ and similar xerophytes must have puzzled many observers and have not been satisfactorily determined. Dr. Darbishire takes up this subject in the *Annals of Botany* (July), and bases his views on an investigation of *Mamillaria elongata*. His conclusions do not coincide with previous explanations, but he gives reasons for maintaining that the tubercle, from which the spines arise, represents a leaf base, and possibly also a part of the stem, while the spines are modified portions of the leaf-blade, and act as a *paraheliode* or screen against excess of sunlight.

WE have received from the Deutsche Seewarte the results of meteorological observations made at selected stations for the lustrum 1896–1900, and for the twenty-five years 1876–1900. The results for each lustrum, from 1876 to 1895, have been previously published; the present volume differs from those which have already appeared by giving the dates on which the extreme values were observed. A table has also been added showing the average number of days in each month, and for each station, on which the rainfall has exceeded 0·2 mm. (0·008 inch). The work is a valuable contribution to the climatology of the German Empire.

AT the jubilee meeting of the Central Meteorological Office of Vienna on October 26, 1901, the Minister of Public Instruction promised that the meteorological results of the previous fifty years should be published in a monumental work, giving an exhaustive representation of the climate of the various parts of the Austrian Empire. The first portion, dealing with the climatology of Lower Austria, has been published by the Vienna Meteorological Office, and has been prepared by Hofrath Dr. Hann, formerly director of the Austrian Meteorological Service, to serve as a pattern for the future discussion, on a uniform plan, of the meteorology of the fifteen other provinces. It is obvious that such a gigantic work would be beyond the powers of any one individual, and it is also desirable that the discussions relating to various districts

should be prepared by persons who have lived in them and have made special studies of the varied conditions of climate. Undoubtedly no meteorologist living could be found who is better qualified than Dr. Hann, whose laborious works are well known to our readers, to prepare a pattern for the guidance of the persons undertaking the subsequent parts. His memoir embraces 104 pages, containing fifty years' monthly and yearly means of different localities, a general summary, and special discussions of the more important phenomena. The work is in every respect worthy of the very high reputation of its author.

An interesting note on the form of Britain, as described by Tacitus, is contributed to the Lombardy *Rendiconti* (xxxvii., 16) by Prof. Giovanni Ferrara, who considers that, of all the Romans, Tacitus had the clearest ideas as to the configuration of our island, and that Ptolemy's map was to a large extent founded on his descriptions.

Prof. Luigi Gabba, writing in the Lombardy *Rendiconti*, (2) xxxvii., 16, discusses the problem of teaching chemistry for technical purposes in Italy, and strongly supports the recent resolutions proposed at the Turin Congress of 1902 by Prof. Cannizzaro urging the Government to provide instruction in technical chemistry, in addition to the existing university instruction of a more theoretical character.

The learning of modern languages is of such importance to science workers that interest attaches to Prof. Charles C. Ayer's paper on the subject in the University of Colorado *Studies*. The author considers that the ability to speak a foreign language fluently depends very largely on a kind of dramatic instinct or power of imitation which seems to project the speaker into a new and foreign personality, and he instances the case of Americans who return from a comparatively short residence in England, letter perfect in the English pronunciation, vocabulary, phrasal intonation, and English manner generally.

What is the "Codex Atlanticus"? is a question which Signor Luca Beltrami answers in a paper reprinted from *Lettura*, and published at the offices of the *Corriere della Sera* at Milan. The name has been given to one of the most interesting works of Leonardo da Vinci, on account of its resemblance in form to an atlas. In 1637 it was given to the Ambrosian Library at Milan, and a reprint has now been produced under the auspices of the Reale Accademia dei Lincei, of which Messrs. Hoepli, of Milan, have a few copies still in their hands. The thirty-five parts occupy more than 1300 pages, and contain 1384 heliotype illustrations, many of them in colours. The edition was limited to 280 copies, the first of which was presented to President Loubet on his visit to Milan. The work of transcription was undertaken by Dr. Giovanni Piumati, and an interesting feature of the first part is the preface, written by the late Prof. Francesco Brioschi, describing the history of the "Codex" from the death of Leonardo da Vinci to the present date.

M. Charles Féry describes in the September part of the *Journal de Physique* a convenient form of telescope pyrometer for measuring temperatures between 500° and 1200°. The heat rays are concentrated by a silvered concave mirror upon a thermo-couple placed at its focus; the reading of a galvanometer connected with the thermo-couple gives the temperature, and the instrument is so designed that the indications are independent of the dimensions of the source of heat and its distance.

The August number of the *Physical Review* contains an interesting note by Mr. W. Coblentz on the infra-red absorption spectrum of selenium. Whereas commercial selenium, which contains sulphur, gives immediately after fusion and re-solidification an absorption which rapidly and regularly increases from 1μ to 14μ, after two days it shows nearly a constant transmission throughout the whole of the same range. This peculiar change in transparency is not observed with pure selenium, as the same transmission curves are obtained immediately after solidification and after an interval of thirty days. It is a striking fact that the transmission curves of sulphur are totally different in character from those of selenium.

A paper by Mr. F. E. Hackett on the photometry of the *n*-rays, which is published as part x. of vol. viii. of the *Transactions* of the Royal Dublin Society, appears at a very opportune moment. In view of the failure of Profs. Rubens and Lummer to reproduce M. Blondlot's results, and Prof. R. W. Wood's strictures on the methods hitherto employed in their investigation, a method for their quantitative measurement becomes particularly worthy of notice. Mr. Hackett has studied the variation of sensitiveness over the retina when habituated to darkness, and claims to have eliminated in this way all subjective variation. The method of measurement adopted shows that whilst the *n*-rays emitted by unannealed glass cause an increase of approximately 10 per cent. in the brightness of a phosphorescent screen, the increase produced by a silent tuning fork is very small, being about 3 per cent. The experiments described are stated to be of such a nature that any person without special training with a little patience may reproduce them.

In the August number of the *Physical Review* Mr. K. E. Guthe has made a comparative study of the various types of silver voltameters which are used for measuring the strength of electrical currents. From the measurements which are recorded it appears that there are two distinct classes of silver voltameters, one class including the ordinary type and Leduc's modification, the other Richard's and the "large anode" types. The voltameters of the second class give a deposit weighing about 0·05 per cent. less than that given by the first class. It appears that in those types of voltameters in which the anode is enveloped merely by filter paper or muslin, the heavy liquid surrounding the anode penetrates through and reaches the kathode, depositing there a complex silver ion. As a consequence, the observed increase in weight is greater than that corresponding with the true electrochemical equivalent of silver. In Richard's voltameter and the "large anode" modification, the deposition of a complex ion is prevented by surrounding the anode with a porous pot so as to exclude contact between the anode-liquid and the kathode. As in this case the variation in the amount deposited by the same current in various experiments does not exceed 1 in 10,000, it is recommended that, in future, the "legal" form of silver voltameter should be superseded by the improved form. A re-determination of the electrochemical equivalent of silver gave a mean value of 1·11683 mg. per coulomb.

The publication committee of the Chemical Society has adopted the word "radicle" in the place of "radical" in their publications. The alteration does not meet with the approval of a hundred and seventy-nine fellows of the Society, who have addressed a letter to the president of the society asking him to bring the matter before the publication committee with a view to its alteration. The signatories point out that:—(1) The new word "radicle" does not convey the sense which the authors of the word

"radical" intended, or that which is still attached to it in chemistry. (2) The use of "radical," though coming through the French, can be defended on purely philological grounds. (3) The original word should be retained out of regard for its historical origin for the same reason that we still employ the word oxygen, although the original meaning has been modified. (4) The original word "radical" is still retained by continental countries and America, and it is only in this country that the change has been made.

MESSRS. F. H. PARSHALL and H. M. Hobart have in hand a work on electric traction which will shortly be published by Messrs. Constable and Co.

A SECOND, revised edition of Dr. C. B. Davenport's "Statistical Methods with Special Reference to Biological Variation" has been published by Messrs. John Wiley and Sons in New York, and by Messrs. Chapman and Hall, Ltd., in this country. The first edition of the book was reviewed in our issue of December 14, 1899, when the opportunity was taken to suggest one or two directions in which improvement was desirable. In addition to the adoption of some of these suggestions, Dr. Davenport has embodied many of the new statistical methods elaborated by Prof. Karl Pearson and others in the new edition of his work.

THE new edition of Dr. A. R. Wallace's work on "Man's Place in the Universe," which has just been published by Messrs. Chapman and Hall, Ltd., at the price of six shillings, contains an appendix in which an argument based on the general theory of organic evolution is used to support the conclusion arrived at as to the unique development of man in the material universe. With this exception, the work remains practically in its original form; for Dr. Wallace remarks that few errors in his facts or fallacies in his conclusions have been brought under his notice, while as to the argument, no student of science has dealt with it in any detail, and "no biologist appears to have thought it worthy of careful consideration."

OUR ASTRONOMICAL COLUMN.

DISCOVERY OF A NOVA OR A NEW VARIABLE.—*Circular* No. 68 from the Kiel Centralstelle announces the discovery of a nova or a new variable star by Mr. Stanley Williams, of Hove, on September 20.

The object was first observed on a photograph taken with a 4·4-inch portrait lens between 15h. 59m. and 16h. 23m. (G.M.T.) on the date named, and was then of about the ninth magnitude, its approximate position being:—

$$\text{R.A.} = 22\text{h. } 19{\cdot}0\text{m., dec.} = +29^\circ\ 44'\ (1855).$$

Eleven other plates of the same region, taken between September 27, 1899, and January 16 this year, show no trace of any object in that position, although most of them show stars of the eleventh magnitude or fainter, whilst two plates show stars down to the thirteenth magnitude.

On October 3 the star was observed visually with a 6·5-inch reflector, and was estimated as being about one quarter of a magnitude fainter than B.D. $+29^\circ.4655$ (9·1 mag.). Its colour was recorded as intensely red, almost crimson, and was not unlike that of Nova Persei at the epochs when that object became red.

The above position lies in the constellation Pegasus, about 2° south of the middle of the straight line joining η and π Pegasi.

THE LICK OBSERVATORY PROGRAMME FOR NEXT YEAR'S SOLAR ECLIPSE.—Mr. William H. Crocker has generously undertaken to defray the cost of the Lick Observatory expeditions to observe the total solar eclipse of August 30, 1905. Three expeditions will be fitted out, one going to Labrador, another to Spain, and the third to Egypt.

At each of these stations the programme will include a photographic search for an intramercurial planet and the photographing of the corona with a camera of 5 inches aperture and 40 feet focus.

The Spanish expedition also proposes to make a study of the polarised light in the corona, and to obtain spectrograms of the sun's edge at second and third contacts and of the green coronal line; the latter are to be used expressly for the measurement of the wave-length of that line.

Attempts will also be made to secure spectra of the "flash" and of the general light of the corona at both the Spanish and the Egyptian camps (*Science*, September 23).

VISUAL OBSERVATION OF PHŒBE.—Whilst searching for Saturn's ninth satellite, Phœbe, with the Yerkes 40-inch telescope on August 8, Profs. Barnard and H. H. Turner found an object resembling a star of about 15·5 or 16·0 magnitude the apparent place of which at 18h. (G.M.T.) was

$$\text{R.A.} = 21\text{h. } 23\text{m. } 1{\cdot}0\text{s., dec.} = -16^\circ\ 36'\ 8''.$$

On September 3 Prof. Barnard found that the object was missing from this place.

As the Harvard ephemeris for the satellite gives the approximate place on August 8 as

$$\text{R.A.} = 21\text{h. } 23\text{m. } 0\text{s., dec.} = -16^\circ\ 36'{\cdot}4,$$

the above was probably the first visual observation of this object.

An editorial note attached to the paragraph in the *Astronomische Nachrichten* (No. 3970) in which the above information is recorded enters a *caveat* as to the actual correctness of the figures given, because the manuscript received was very badly blotted.

THE ORBIT OF CASTOR.—A graphically determined orbit of Castor was published in No. 3525 (1898) of the *Astronomische Nachrichten*, but since its publication Prof. Doberck, of Hong Kong Observatory, has determined the three sets of possible elements given below by purely analytical methods, and now publishes them in No. 3970 of the same journal, together with a five-yearly ephemeris calculated from the set of elements No. 4.

The observed angles can be represented equally well by orbits having periods of 200 to 600 years, or even more, but the observed distances are best given by the No. 4 set of elements, which also appears to represent correctly the present decrease in distance.

Elements.

	III.	IV.	V.
Ω =	$29^\circ\ 29'$	$33^\circ\ 56'$	$42^\circ\ 34'$
λ =	$84^\circ\ 44'$	$82^\circ\ 26'$	$118^\circ\ 11'$
γ =	$73^\circ\ 3'$	$63\ 37'$	$61^\circ\ 56'$
e =	0·7513	0·4409	0·2321
P =	268·16 years	346·82 years	501·80 years
T =	1936·65	1969·82	1963·30
a =	$7''{\cdot}3265$	$5''\ 756$	$6''{\cdot}467$

According to the ephemeris, the position angle at the beginning of 1900 was $225^\circ{\cdot}72$, and the distance was $5''{\cdot}627$; at the commencement of 1905 the corresponding figures will be $223^\circ{\cdot}58$ and $5''{\cdot}564$.

In the same publication Prof. Doberck gives a set of elements, and a yearly ephemeris, for the orbit of ζ Sagittarii.

THE MEETING OF THE ASTRONOMISCHEN GESELLSCHAFT, 1904.—In No. 3970 of the *Astronomische Nachrichten* Herr Elis Strömgren gives a brief outline of the papers read at the meetings of the Astronomischen Gesellschaft, which took place at Lund on September 5–8 under the presidency of Prof. Seeliger. Numerous reports of the work suggested by the committee were given by the observers by whom it had been undertaken.

Among these there are reports by Herr Albrecht on the International Latitude Service, by Herr Müller on the catalogue of variable stars, and many others.

ENGINEERING AT THE BRITISH ASSOCIATION.

AT the conclusion of the president's address an interesting function took place. Dr. Schröter, on behalf of the German Society of Civil Engineers, presented to Mr. Parsons the society's gold medal. Dr. Schröter, in making the presentation, directed attention to the conspicuous part which had been played by the president in the advancement of science and its application to practical purposes, and he mentioned that the society which he represented consisted of no less than 19,000 members, and they were proud to think that they were the first engineering society to recognise by a public award the man to whose genius the success of the steam turbine was due.

The afternoon of this day of the meeting, Thursday, August 18, was devoted to a lecture by Mrs. Ayrton on the origin of sand ripples. The lecture drew a very large audience, and was illustrated by lantern slides, diagrams, and by a number of most interesting experiments. The experiments were carried out by means of tanks with glass sides, which were caused to reciprocate, and waves were thus set up; the actual formation of ripples could, therefore, be seen going on. Mrs. Ayrton was of opinion, and showed this fact by some of her experiments, that when water was flowing quite steadily in one direction, that is, without oscillation or wave motion, and without any disturbance, sand ripples could not be produced, and that such a flow of water over previously existing sand ripples would tend to obliterate them. It may be mentioned that on this point she disagrees with Prof. George Darwin, who gave one of the evening lectures, and dealt with the same subject.

The first three papers taken on the morning of Friday, August 19, were concerned with internal combustion motors, viz. flame temperature in internal combustion motors, by Mr. E. Dugald Clerk; the specific heat of gases at high temperature, by Prof. H. B. Dixon; and the calorimetry of exhaust gases, by Prof. B. Hopkinson. Mr. Clerk, in the introductory portion of his paper, stated that had we lived in a world of a much denser atmosphere, there was every probability that the internal combustion engine would have developed on somewhat different lines, that is to say, that the non-compression engine would have been much more successful. The author then described a method he had introduced by which it was possible to reduce the maximum temperature reached in the engine at the time of explosion and still maintain throughout the working stroke a high average pressure, the principle upon which he worked being to produce, as it were, an artificially increased atmospheric pressure. An additional charge of air, compressed by a pump, passed into the cylinder after the working charge had been completely drawn in, and Mr. Clerk showed that in one set of experiments he was able to increase the thermal efficiency from 28·7 per cent. to 34·4 per cent., reducing at the same time the maximum temperature from 1700° C. to 1200° C. The National Gas Engine Co. had constructed to his designs an engine of 300 h.p. to use producer gas, in which this system of air supercompression was used; the front end of the cylinder was arranged to act as the pump for compressing this additional air supply, and the pressure of the charge was raised by this means about 7 lb. per sq. inch above the atmospheric pressure. Mr. Clerk also utilised some of this compressed air for scavenging purposes.

Prof. Dixon in his paper dealt with the experiments he has been carrying out for many years on the specific heat of gases at high temperatures. He stated he had proved that it was impossible completely to burn carbonic oxide gas at very high temperatures. He had found as a general result of his experiments that in the case of carbonic oxide the specific heat rose with the increase of temperature up to a certain point, and then dissociation began. Prof. Dixon then described by means of blackboard diagrams some exceedingly beautiful methods of photographing actual explosions when taking place in glass tubes. Prof Hopkinson's paper dealt with a method of measuring by means of a calorimeter the heat passing away from an internal combustion engine in the exhaust gases. The exhaust gases were cooled down in this calorimeter from the exhaust temperature to atmospheric temperature, and therefore the amount of heat they carried away from the engine could be accurately determined. He suggested that it might be possible with this method to carry out thermodynamic tests of large internal heat engines more accurately than by the method hitherto adopted, in which the heat given to the engine per unit of time was calculated by the aid of calorimeter experiments on the combustible gases employed in working the engine. The only item in the heat account which was not determined in his method was the small loss due to radiation. The indicator cards, or the brake, gave exactly the amount of heat converted into useful work, the amount of heat sent away in the jacket water was easily measured, and by this new calorimeter the amount of heat carried off in the exhaust gases could now be determined. It was pointed out in the discussion that this method of determining the heat required in a given time by a heat engine by measurement of the exhaust waste was analogous to that introduced by Hirn in the case of steam engines many years ago. Papers by Mr. J. W. Hayward on receiver drop in a compound engine, and by Mr. A. H. Peake on superheated steam, concluded the day's programme.

Monday, August 22, as usual, was devoted to the electrical papers, and the proceedings opened with a paper by Mr. A. A. Campbell Swinton on electricity from water power. The author stated that he had been able to obtain accurate statistics which showed that about 1,500,000 h.p. for electrical work was now generated by water power, nearly one-third of this huge total being in the United States, while the total for Great Britain was only about 12,000 h.p. He considered, therefore, that in all probability the real amount of water horse-power devoted to this purpose at the present time would be nearly 2,000,000, equivalent to a coal saving of nearly 12,000,000 tons a year. After giving some details of long distance transmissions abroad, he described two or three systems now at work in Great Britain, and then dealt with the water-power schemes with which he was officially connected, which had been undertaken by the Scotch Water Power Syndicate. In this scheme it is intended, first, to make use of Loch Sloy, which is about 757 feet above Loch Lomond; a dam will be built to raise the level of the loch by about 60 feet; the power-house is to be built on the shore of Loch Lomond at Inveruglas, and overhead wires will convey the electric current to the industrial districts of the Vale of Leven and the Clyde. The author estimated that about 50 per cent. to 58 per cent. of the total energy of the water would be delivered to the customers after making allowance for all the losses in the pipe lines, turbines, dynamos, transmission lines, &c. The company intends to employ from the start a pressure of 40,000 volts in view of the fact that it has powers for a considerable extension of its scheme in the future, when the demand for power justifies it. The total cost of the Loch Sloy scheme was estimated at 200,000*l.*, and assuming 5000 h.p. delivered, this comes to about 40*l.* per h.p. everything included, a comparatively low figure.

The next paper, by Messrs. C. H. Merz and W. MacLellan, entitled "The Use of Electricity on the North-Eastern Railway and upon Tyneside," gave an account of the first important transformation of a steam locomotive-worked railway into an electric railway; the North-Eastern Railway Co. has adopted this latter method for the whole of the suburban passenger traffic on the north side of the Tyne. The company decided to use the third rail and continuous current system, the electricity being generated as a three-phase alternating current at a pressure of 6000 volts. At five substations this is converted into a continuous current of 600 volts. The service given on all the line will be practically quarter-hour trains, except on the riverside line. The electrical energy is obtained from the Newcastle-on-Tyne Electric Supply Co., and Parsons steam turbines, each of them having a normal capacity of 7000 electric horse-power, have been adopted by this company at their Carville power station; these are by far the largest steam turbines at present at work in this country. The authors stated that preliminary tests have shown that the steam consumption would not exceed about 12 lb. per electrical horse-power hour at any load between 4000 I.H.P. and 7000 I.H.P.

Messrs. W. M. Mordey and A. G. Hansard then read a paper on energy losses in magnetising iron, and described

the method they had adopted for measuring by a watt meter the total losses due both to hysteresis and eddy currents.

Dr. W. E. Sumpner and Mr. R. W. Weekes, in a paper on the Hopkinson test as applied to induction motors, stated that they had found Dr. Hopkinson's well known method, with certain modifications, so satisfactory in testing induction motors that they considered it was desirable to direct attention to the experimental details and to give particulars of the arrangements of the machines and the instruments needed for the test, and of their methods of determining the belt losses. In an appendix the results obtained in testing three-phase motors by this method were given.

Dr. W. M. Thornton contributed a paper on distribution of magnetic induction in multipolar armatures. The object of this paper was to discuss the best methods for determining the most suitable radial depth of an armature core for either continuous or alternating machines.

The last two papers dealt with on August 22 had reference to standards of light. Prof. J. A. Fleming, in his paper entitled "Large Bulb Incandescent Electric Lamps as Secondary Standards of Light," described a method he had devised of using as a secondary standard of light an incandescent filament fixed in a large bulb about 12 centimetres in diameter and about 20 centimetres long. The use of this large bulb diminished considerably the deposit of carbon upon the interior of the glass, and therefore the rapid falling off of candle-power with age of the lamp. He had found such lamps very suitable for photometric purposes. His method of employing them was equivalent to the well known system of double weighing. One of these standard lamps was balanced in the photometric gallery by an ordinary incandescent lamp, and then the standard lamp was removed and the lamp the candle-power of which it was desired to determine was substituted for it, and moved in or out towards the photometer disc until it also balanced the ordinary incandescent lamp previously used against the standard lamp. The second of the two papers was by Mr. Clifford Paterson, and was entiled "Some Investigations on the Ten Candle-power Harcourt Pentane Lamp made at the National Physical Laboratory." The author has been carrying out an investigation at the National Physical Laboratory on the effect of changes in the barometric pressure and of moisture in the atmosphere on the flame standard, and the work is still going on.

On Tuesday, August 23, the first business was the reading of the report of the Committee on the Mersey Tidal Regime. Briefly the committee has found that though extensive dredging has now been carried on in the Mersey for such a long period of time, the regime of the tides has hardly been altered.

Major Sir Hanbury Brown then read a most interesting communication on the control of the Nile, the paper being fully illustrated with lantern slides. The author described the whole of the engineering works which have been constructed for the purpose of increasing the area of irrigation in Egypt since the days of Arabi Pasha's abortive revolution. Two great schemes have now been completed, first, the reconstruction of the old delta barrage so that it now can be completely utilised for its original purpose and a head of 20 feet of water can be held up, and, secondly, the construction of the great Assuan dam and Assiut barrage. The wonderful increase in the industrial prosperity of Egypt which has been brought about by these great engineering works reads almost like a fairy-tale, and not the least important of the social advantages has been the abolition of forced labour or corvée. In the discussion, Sir Colin Scott-Moncrieff, who has been responsible for so much of this splendid work, told an amusing story of how, during the reconstruction of the great delta barrage, the last hole, which had almost baffled the engineer, was at length closed by the use of costly curtains taken from an unused Khedivial palace standing near the barrage.

Mr. J. H. Wicksteed's paper on a universal testing machine of 300 tons for full sized members of structures described the machine made for the French Government by his firm, Messrs. Buckton and Co., of Leeds, which was officially inaugurated at the Conservatoire Nationale des Arts et Métiers on June 16 of this year. This formidable machine will take in columns or tension bars 88 feet long by 3 feet 3 inches by 3 feet 3 inches, and it will admit beams 3 feet 3 inches broad by 6 feet 6 inches deep on a 20 feet span, and can be changed from one form of test to another with great rapidity. On the day of the inauguration, a steel tension bar was broken under a load of 228 tons, and immediately afterwards a thick slab of armoured concrete was broken on a span of 16 feet 6 inches.

Prof. J. O. Arnold then read a paper on the fracture of structural steel under alternating stresses, in which he described a method he had devised and the special machine he had invented for placing test specimens under severe alternating stresses slightly beyond the elastic limit; his method, as it were, carried out the Wöhler tests in two or three minutes. Though the investigation was still going on, the author stated that the results obtained so far convinced him that the micrographic methods of examining steel had in their turn failed to show the cause and prevention of sudden rupture under vibration and alternation of stress.

The last two papers on August 23 were contributed by Mr. R. A. Hadfield. The first was on the production of magnetic alloys from non-magnetic metals. In it he stated that Dr. Heusler had produced a magnetic alloy of copper, aluminium, and manganese, and that the magnetic properties of this alloy were to be attributed entirely to the presence of the manganese. Mr. Hadfield himself had made the alloy, and was still carrying on an investigation in reference to it. The alloy was very brittle, and could not be forged either cold or hot. The second paper, on experiments relating to the effect upon the mechanical properties of iron and alloys of iron produced at liquid air temperatures, gave a brief account of some interesting experiments on the effect upon pure iron of great cold. Much fuller details of this investigation are to be given at the forthcoming meeting of the Iron and Steel Institute.

On Wednesday, August 24, the last day of the meeting, several papers of interest were taken, the first being a paper by Mr. Horace Darwin and Mr. C. V. Burton on side-slip in motor cars. The results which had been obtained by the authors in their investigations into this question were illustrated by a small model car, which ran down an inclined plane. The authors were of opinion from these experiments that side-slip would be considerably reduced by steering with the hind wheels and driving with the front wheels, though this car would not be so convenient for steering as the ordinary car.

Prof. Ernest Wilson gave a further account of his experiments on the electrical conductivity of certain aluminium alloys as affected by exposure to London atmosphere. The author has recently been employing micrographic methods in his investigations. He was of opinion that the great difference which existed between the tensile strengths and the other qualities of these alloys was not due to variation in structure.

Mr. J. Casey then described the proposed barrage of the River Thames, and two brief papers, one on the testing of alternating current motors by continuous current, by Mr. Wm. Cramp, and the other on the action of lightning strokes on buildings, by Mr. Killingworth Hedges, brought the proceedings of this section to a close.

It is pleasant to record that the attendance at Section G at Cambridge was considerably above the average, and this was all the more gratifying inasmuch as several of the papers contributed were of unusual importance and of high scientific value.

T. H. B.

PHYSIOLOGY AT THE BRITISH ASSOCIATION.

THE president, Prof. C. S. Sherrington, F.R.S., delivered an address on the morning of August 18, choosing for his subject the "Correlation of Reflexes and the Principle of the Common Path." This address has already appeared in NATURE (September 8).

Prof. J. A. MacWilliam read a paper on reflex and direct muscular response to galvanic currents in fishes. His experiments had proved that eels were remarkably responsive to electrical currents, a responsive fin movement of a reflex nature being readily elicited. The negative pole was usually the effective one. Frogs, newts, carp, &c., gave negative results. After death of the spinal cord much stronger

currents were necessary to evoke any movement, and these were of a different character, being direct responses of the muscles.

Prof. W. H. Thompson read a paper on the metabolism of arginine. If arginine, an important crystalline base obtained by the cleavage of proteids, is administered to animals either by injection or with the food, from 80 per cent. to 90 per cent. of its nitrogen is excreted as urea. In the laboratory only 50 per cent. of the nitrogen can be split off from arginine as urea, the remainder appearing as ornithin. Hence in the body the ornithin nitrogen is also converted into urea, largely or entirely.

Prof. A. Kossel (Heidelberg), referring to the structural formula of arginine, pointed out how half of its nitrogen could be split off as urea by a simple hydrolysis, while the remaining moiety required oxidation before it could be obtained in this form. Dakin and he had shown recently that the liver and some other tissues produced a ferment capable of effecting this hydrolysis. Moreover, they had also found another ferment which possessed the power of acting upon this base in an exactly similar manner while it was still combined within the molecule of certain of the simple proteids (the protamines). The significance of these facts is of great importance in view of the wide distribution of arginine throughout the cell proteids of the body.

Dr. F. G. Hopkins stated that he had some time previously himself taken by the mouth a mixture of the hexone bases, and subsequently watched the hourly elimination of urea. He found that the rate of excretion of urea showed two maxima, the first of which he had ascribed to that part of the N of these bodies which could be obtained in the laboratory as urea, and the second maximum to the remaining N (ornithin, &c.).

Prof. E. H. Starling read a paper on the relation of trypsinogen to trypsin. Pawlow and his pupils have shown that fresh pancreatic juice, obtained from a pancreatic fistula, possesses no power of digesting proteids, but that after it has been acted upon by intestinal juice it gains that power. He concluded that the intestinal juice contained a ferment (enterokinase) which acted upon the trypsinogen of the fresh pancreatic juice, converting it into trypsin. Against this view French observers have brought forward another, viz. that the interaction of the two secretions is analogous to that of the cytases, and that the trypsinogen can only act upon proteids in the presence of enterokinase. Bayliss and Starling have studied the action of enterokinase upon trypsinogen, and by observing the rate of its action have, by finding that it follows the usual laws of ferment action, brought strong evidence to prove that Pawlow's view is the correct one, and that enterokinase is a "ferment of ferments." They have now further evidence in the same direction. By injecting rabbits with solutions of enterokinase, they found that an antibody could be produced which, acting upon enterokinase, was able to inhibit its action upon trypsinogen. Although this in itself could not be regarded as definite proof because the facts might bear another interpretation, yet taken in conjunction with the former evidence it was confirmatory of their view.

Dr. F. A. Grünbaum pointed out that the last evidence brought forward by Prof. Starling did not disprove the view that enterokinase and trypsinogen acted in a complementary manner to one another, since the result might be readily explained on the assumption that the antibody possessed a relatively greater attraction to the enterokinase than to trypsinogen.

Dr. W. E. Dixon communicated the results of his experiments upon the action of alcohol upon the heart and circulation. He pointed out that much of the literature upon the subject was valueless because the experiments had been conducted upon animals already under the influence of anæsthetics. The previous administration of chloroform or ether entirely abolished the first effects of alcohol. The experiments must therefore be conducted upon unanæsthetised animals or upon surviving organs. He proved that the first effect of alcohol upon the pulse was a slight acceleration, which he thought was due to an irritative effect of peripheral origin. The first action upon the heart was distinctly a stimulating one, as proved by cardiometer experiments. The effect upon the peripheral blood-vessels was a dilatation of the limb vessels associated with a constriction of the vessels of the splanchnic area. The effect upon the blood-pressure was a preliminary rise which was only converted into a fall when considerable doses had been given. If larger doses were suddenly administered the effect upon the heart was usually marked inhibition, which he ascribed to a direct action of the drug upon the cardiac centre.

Prof. E. A. Schäfer remarked that in some recent experiments he had found that if a mixture of chloroform and alcohol was made to replace the chloroform with which the animal was being anæsthetised, the result was an acceleration of the heart-beat, together with an increase in its force. This was not due merely to the diminution in the amount of chloroform administered.

The morning of August 19 was devoted to a discussion upon the relation of oxidation to functional activity. A report of this discussion appears in another part of NATURE (p. 590). Mr. Hankin's remarks on the spread of plague will be printed separately in another issue.

Dr. W. H. R. Rivers communicated the results of some of his observations on the senses of the Todas. These were made by methods similar to those which had been employed in the work of the Cambridge Anthropological Expedition to the Torres Straits, and the results were in general confirmatory of those reached by that expedition. The observations on Papuan and Toda seem to show that there is no marked difference between uncivilised and civilised races in purely sensory powers. Any superiority in the sensory and perceptual feats of the savage is probably due to his powers of observation and of drawing inferences based on his familiarity with his surroundings. Where there are differences between Papuan, Toda, and European, the Toda occupies in general an intermediate position between the Papuan and European, just as he occupies an intermediate position between them in intellectual and cultural development.

The only striking feature which marks off the Toda from the others is the great frequency of colour-blindness. Whereas this condition is absent or very rare in some savage races, the proportion of colour-blind persons amounts to 12·8 per cent. in Toda males as compared with about 4 per cent. in European races.

Dr. C. S. Myers communicated a paper upon recent developments in Helmholtz's theory of hearing. He alluded in the first place to Ebbinghaus's conception of an internodal vibration of the basilar fibres, and showed its value in providing a theoretical basis for the degree of relationship between the various musical intervals. Next he referred to the discovery of intertones (Zwischentöne) by Stumpf, and to their importance in determining the number of adjacent basilar fibres thrown into vibration by any simple tone, and in modifying the principle of specific nervous energy as applied to the ear. Schäfer's theory of the origin of subjective combination-tones was then described, and the difference between objective and subjective combination-tones was discussed. Lastly, Dr. Myers showed the great value of Helmholtz's theory in best explaining the known pathological phenomena of hearing, and suggested that the hair-cells rather than the basilar fibres might be the sympathetically vibrating end-organs. Such a modification involved the application of altered physical considerations to the organ of Corti, but appeared more rational and less difficult on the whole.

In the morning of Monday, August 22, the work of the section was devoted to a discussion on conduction and structure in the nerve-arc and nerve cell.

Prof. J. N. Langley, in opening this discussion, said that he restricted himself to a consideration of the general scheme of structure and arrangement of the nervous system in vertebrates, and the broad relation of this scheme to nervous functions. At present there are two main ideas of structure, one often called the neurone theory, according to which the nervous system is made up of a multitude of neurones or cells which have no connection with one another, and the fibrillar theory, according to which the nervous conducting part consists of minute fibrils joined together here and there into a network. Prof. Langley argued that whatever view is taken of the structure of the nervous system, the facts of degeneration of nerves show that it is made up of a number of trophic units, and that the theory of trophic units held whether the unit consisted of one or

of a hundred cells, and whether the units were in continuity with one another or only in contiguity.

A second point which seemed certain was that the properties of the central nervous system required for their explanation some structure not present in the peripheral nerves. This structure might be, in part, the nerve-endings of the trophic units, but, in part, it must be referred to the nerve-cells, which, in fact, consisted of different protoplasm from that of either nerve fibres or nerve-endings.

If the fibrillar theory were true, there were facts which showed that the fibrils must be different in different parts of their course. This was illustrated by the action of nicotine and of other poisons on the different parts of the nervous system. With this modification, the fibrillar theory simply transferred to a part of the cell functions which were commonly supposed to belong to the whole. But it could not be regarded as certain that there were any fibrils at all in the nerve cell, for the microscopic appearances varied considerably according to the method of preparation.

A point which was much contested was the question whether the trophic units were continuous with one another or not. This point was not of great physiological importance, but the physiological facts were best explained on the assumption that the units were contiguous but not continuous.

The last point considered was whether the unit consisted of a single cell or of many cells. The study of the development of nerves had led different observers to entirely opposite conclusions. Experimentally, the question was of interest in connection with the regeneration of nerves. Numerous surgeons had found new nerve fibres in the peripheral ends of cut nerves, but their observations failed to show that some central connection had not been established. In some recent experiments made by Prof. Langley in conjunction with Dr. Anderson, it was found that without a single exception, the new fibres had become connected with the central nervous system. The balance of evidence was then against the occurrence of autogenic regeneration and in favour of the unit consisting of a single cell.

Dr. A. Hill stated that he was entirely prepared to give his approval to the neurone theory as defined by Prof. Langley, but he objected that this was merely a statement of the cell theory and did not require the special title given to it by Waldeyer. He was inclined to think that the more light we gained on this subject the more should we find that Bethe's view was correct. Apathy has shown a network of neuro-fibrillæ in nerve cells of invertebrates. This network is easily shown, and is beyond all doubt a structure existing during life. In the spinal ganglion cells of vertebrates a somewhat similar appearance is obtainable. It was easy to make preparations of vertebrate nerve cells in which fibrillæ were indisputably present, but how far this appearance was due to reagents it was impossible to say; but there was a strong probability that the net arranged itself about an existing system of fibrils. The connecting link appeared to him to be the "thorns," and it was a remarkable fact that the spacing of the thorns corresponded to the spacing of the pericellular network. Far as we were from being in a position to form a conclusion on this subject, it was not impossible that neuro-fibrillæ, Golgi's net, and thorns form a system of conducting fibrils of extreme tenuity and almost infinite complexity.

Prof. Graham Kerr gave an account of the results of his researches on the development of the nerves in Lepidosiren. His first studies on the mode of growth of the nerves in these animals seemed all in favour of His's view that the nerves developed as outgrowths from the spinal system, but more extended observations upon embryos in various stages of development led him to the conclusion that the fibres originated as strands of undifferentiated protoplasm extending between the neuroblasts of the spinal cord on the one hand and the developing myotonic cells on the other. At a somewhat later stage fibrillæ appeared in these strands, and still later a sheath was formed from mesoblastic tissue which surrounded and enclosed the group of fibrillæ. A more doubtful conclusion which might perhaps be drawn was that the original path was one along which impulses surged to and fro, and that consequent upon this use the fibrillary structure was developed as a more convenient substratum for the maintenance and extension of that function.

Dr. Mann pointed out that nerve cells might be theoretically in one of three states, viz. separate units, or continuous with one another, or at one time continuous and at another separate. In all embryos at a certain period the motor cells in the cord form a syncytium with scattered nuclei, an arrangement which later on becomes less and less marked until in most cases the cells form separate units. Cells not derived from a common mother cell are never in continuity. He pointed out that great care was needed in drawing conclusions from any preparations where such electrolytes as corrosive sublimate were used for purposes of fixation, inasmuch as all coagulation by electrolytes invariably leads to a very distinct fibrillar appearance. This is much less marked after the use of such non-electrolytes as osmium tetroxide or formaldehyde free from formic acid. At present, therefore, we are not in a position to make any assertions as to the existence or non-existence of fibrils in nerve cells or in tissues.

Dr. W. B. Hardy also directed attention to the treacherous nature of the evidence of fibres and networks in cells. A fibrillar structure can be produced from a perfectly homogeneous solution of egg-white by fixing it with the ordinary reagents and staining it in the usual way. Again, if a concentrated viscous solution of egg-white be stretched between two points and then treated with the ordinary fixing reagents, it can be shown that the fibrils produced in it run longitudinally, and are connected by less prominent ones which run transversely. These fibrils must, of course, be purely artificial.

Dr. H. K. Anderson emphasised the point that though the neurones might be physically continuous, yet on the whole they must be trophically discontinuous. Experimenting upon very young animals, he had found that section of a post-ganglionic segment led to degenerative changes in the corresponding preganglionic segment. On the other hand, the converse was not true. As a further point against the view that the fibrillæ of a preganglionic segment were continued down into the postganglionic fibres, he pointed out that Langley had shown that the mode of termination of the preganglionic fibres in the sympathetic ganglia was not specific, since an ordinary motor nerve can be made to grow down to a sympathetic ganglion, and terminating there in its own specific manner could yet establish physiological continuity.

Dr. E. Overton pointed out that it had been proved that the presence of sodium ions was an essential condition for the physiological activity of both muscular and nervous tissues, and, in the second place, it had been shown that both sodium and calcium ions were essential for the proper action of nervous interconnections, thus tending to prove that some third substance intervened between the two units, *i.e.* that there was discontinuity.

Dr. W. MacDougall argued that the fact that motor neurones could not conduct backwards was the best evidence of discontinuity. Upon the same hypothesis depended also the simplest explanation of another typical characteristic of nervous activity—the effect of summation of weak stimuli. Moreover, the "law of nerve habit" was most difficult to explain except on the assumption that there is some intermediate structure between successive nerve elements which offers a resistance to the transmission of impulses, a block, however, which can be overcome by the action of appropriate stimuli.

Prof. Langley, in replying on the whole discussion, suggested among other points that the strands of material described by Dr. Kerr in the development of nerve fibres might be simply connecting structures along which the nerve fibrillæ, *i.e.* the true nerve element, grew down from the developing neuroblast.

Prof. E. A. Schäfer demonstrated a method of artificial respiration which is a modification of one first suggested by Dr. B. Howard in 1869. In Howard's method the patient in a case of drowning is first turned downwards and the back is pressed on two or three times to force out water from the lungs, after which he is turned face upwards. The operator is then directed to grasp the lower part of the chest and to press gradually forward with all his weight for three seconds, then with a push to jerk himself back and wait three seconds, repeating this eight to ten times a minute.

This method is simple, can be performed by one person,

and is fairly efficient so far as air exchange is concerned. The drawbacks are that the tongue in the face-up position tends to fall back and block the passage of air through the pharynx; that there is risk of rupturing the liver; and that there is risk of breaking the ribs if the operator is heavy and powerful and if the patient is advanced in years.

These drawbacks are avoided if the patient be turned into the prone position during the whole procedure. Greater efficiency is thereby attained, and the risk of injury to ribs or viscera is reduced to a minimum. The muscular exertion required is only that needed to swing the upper part of the body backwards and forwards on the hands about twelve or thirteen times a minute, the operator kneeling by the side of or across the patient. The pressure is gradually applied and gradually released. The amount of air exchanged by this method per minute is greater than that yielded by any other which has been tried, and may even exceed the ordinary rate of exchange of the individual.

Tables showing the amount of air exchanged in the various methods which have been recommended for artificial respiration were shown, from which it was seen that only in Howard's method and in Schäfer's modification of that method did the amount reach that attained in normal respiration. Schäfer's method is easy to carry out, even for prolonged periods, and is sufficient for the needs of a normal individual who submits himself to be respired in this manner. On the other hand, in both the Sylvester and Marshall Ward methods, a normal individual is unable to refrain from himself actively respiring on account of the air-exchange being insufficient.

Dr. F. W. Edridge-Green read a paper on the necessity of a lantern test as the official test for colour blindness. Dr. Edridge-Green described two cases, both naval lieutenants, which he had examined, in both of which the men passed the wool test but failed when examined by the lantern test. These were selected because both had daily experience with coloured lights and not with wools. He concluded, then, that because a man can sort wools correctly it does not follow that he can distinguish between coloured lights. In his opinion many varieties of colour blindness may escape detection by the wool test.

On Tuesday, August 23, Prof. A. Kossel (Heidelberg) communicated the main results obtained in work conducted in conjunction with Mr. H. D. Dakin on the protamines. These are the simplest type of proteids. One of them, salmin, when treated with boiling dilute mineral acid yields only five atomic groupings, viz. urea, diamido-valerianic acid, serine, monoamido-valerianic acid, and pyrollidincarboxylic acid. They had investigated the relative proportions in which these five substances were present in salmin, and had found them approximately as follows:—ten molecules of diamido-valerianic acid, ten of urea, two of serine, one molecule of monoamido-valerianic acid, and two molecules of pyrollidincarboxylic acid. The composition of clupein was found to be complicated by the presence of alanine in addition. On the other hand, scrombine possesses an even simpler constitution, for, in addition to urea and diamido-valerianic acid, only alanine and pyrollidincarboxylic acid were found. Sturin obtained from the testes of the sturgeon presents a different constitution. Two diamido-acids are present, diamido-valerianic acid and diamido-caproic acid, the former being combined with urea. To this complex a heterocyclic group, histidine, remains to be added.

The ordinary proteids differ mainly from the protamines in an increased proportion of monoamido-acids, so that the complexity of molecule is extraordinarily great. This complexity is further increased by the addition of other groups, e.g. dibasic acids such as aspartic and glutamic acids, which are not present in the protamines.

Prof. J. E. Johansson (Stockholm) gave an account of his experiments upon the immediate effect of carbohydrates upon metabolism. These experiments dealt with the rate of excretion of carbonic acid following the administration of various carbohydrates, and were conducted upon man in a respiration chamber. He first showed that for a particular individual the rate of excretion was practically constant if taken some hours after a meal, and that this rate did not vary with differences in the previous diet nor at different periods of the year. If, then, an individual is given a quantity of a particular carbohydrate about eight hours after a meal, the amount of increase in CO_2 excreted is to be assigned to the food given. He showed in this way that an increase of CO_2 followed the administration of glucose, saccharose, or levulose, and that this increase, which amounted on the whole to from 8 per cent. to 20 per cent. of the total carbon given, began within the first half hour and lasted from two to three hours. The increase persisted longer after saccharose or levulose than after dextrose, and the total amount was greater. He further showed that the amount of the CO_2 surplus was in proportion to the amount of carbohydrate given if this did not exceed 150 grams. The effect of a dose of sugar was greatly influenced by the previous state of nutrition of the person experimented upon. Thus, after a fasting period of forty hours, the amount of carbon retained was much greater than after a ten hours' period. A further point of interest was that the amount and rate of destruction of the various sugars were not influenced by the performance of work. The two effects were additive, and did not interfere with one another.

Mr. P. P. Laidlaw gave the results of some observations on blood pigments. The iron in hæmochromogen is unstable to dilute acids a fact which shows that hæmatoporphyrin is present in the hæmatin molecule. This was absolutely proved by the artificial formation of hæmochromogen by warming iron free hæmatoporphyrin in an ammoniacal solution to which Stokes's fluid was added from time to time, when on repeatedly reducing the mixture for an hour or so hæmochromogen was formed. The method of synthesis renders it probable that hæmatin is a combination of two hæmatoporphyrin groups with one of iron. Turacin also may be synthesised from hæmatoporphyrin by boiling with cuprammonium solutions.

Dr. F. G. Hopkins wished to lay stress on a further point which had not, perhaps, been brought out very clearly in Mr. Laidlaw's paper. It had been found that if reduced hæmoglobin was treated with a mineral acid, the decomposition went as far as the production of hæmatoporphyrin, whereas, when the same hæmoglobin was converted into oxyhæmoglobin and then treated with acid, hæmatin only was produced. From this it was clear that a very fundamental part was played by the iron in the conversion of hæmoglobin into oxyhæmoglobin.

Prof. A. B. Macallum (Toronto) read a paper on the distribution of potassium in animal and vegetable cells. A solution of the double nitrite of sodium and cobalt gives a yellow precipitate with a potassium salt. If, therefore, thin pieces of the tissue to be examined be treated with this solution, and the excess of the reagent be washed away with ice-cold water, the position of the potassium in the cells is indicated by the presence of the yellow precipitate. Its localisation may be rendered more obvious by converting the yellow precipitate into a black one by further treatment with ammonium sulphide, which precipitates the cobalt as a black sulphide. In this way is was found that potassium is never diffused through the cell. It is more abundant in vegetable than in animal protoplasm, and the nucleus is always absolutely free from it. Only one tissue element was found absolutely free from it, viz. the nerve cell and the axis cylinder. All dead and inert material in a living tissue becomes charged with potassium. This is especially the case with intercellular material.

Dr. W. B. Hardy remarked on the difficulties of determining the distribution of a soluble substance in so small a structure as a cell, for diffusion may be relatively rapid, and thus the results obtained might be very misleading.

Prof. Brodie suggested that the reason why the nucleus never contained any of the precipitate could be readily explained on the assumption that the nuclear membrane was impermeable to the cobalt salt. This, too, would explain the fact pointed out by Prof. Macallum that in many instances the precipitate was found accumulated immediately around the nucleus, for if the nuclear membrane were impermeable to the cobalt salt but permeable to a potassium salt, the latter as it diffused out would be precipitated at once by the excess of cobalt salt present in the surrounding protoplasm.

Prof. W. O. Atwater described his investigations on the nutrition of man at a joint meeting with the section of economics. An abstract of the paper will appear in another issue of NATURE.

Dr. W. Page May brought forward a communication by Prof. Elliot Smith and himself on the motor localisation in the lemur. He showed the area stimulation of which produced movements on the opposite side of the body, and demonstrated that the sequence of representation of movement was in agreement with that of Sherrington and Grünbaum on the ape. It also cleared up the discussion on the homologies of a small sulcus which had previously been described as postcentral and precentral, but which is really central, as Elliot Smith, arguing merely from morphology, pointed out two years ago.

He also described the results of localisation in the dog obtained by Elliot Smith and Wilson, who have shown that the excitable area is limited anteriorly by the crucial sulcus. This result was in harmony with the histological results of Cushing.

In a second communication Dr. Page May discussed the results of previous workers on the optic thalamus, and described some experiments he had made on this subject. He showed that following lesions in the thalamus certain motor disturbances were produced, and that descending paths could be traced from the thalamus into the anterior and lateral columns of the spinal cord. He also showed photographs and specimens of a descending tract hitherto undescribed in the posterior columns of the cervical and dorsal cord. This extended downwards from the thalamic region, and occupied a position near the middle line at the anterior end of Goll's column. In rare cases fibres could be traced into the lowest portions of the spinal cord.

Prof. G. S. Woodhead communicated the results of an investigation on joint-ill in the foal. This is an affection of especial importance to horse-breeders, in which, in addition to certain constitutional symptoms, marked stiffness and swelling makes its appearance in the joints, while at a later stage abscesses form. Investigation of the cause of this disease proved it to be due to a microorganism which gained admittance into the young animal through the cut end of the umbilical cord. From the practical point of view it was therefore evident that such precautions as are taken against septic infection in the case of the child at birth should also be taken in the case of the foal.

Dr. T. S. P. Strangeways gave an account of a committee of pathological research which is being founded with the object of investigating some of the more important diseases the pathology of which is as yet undetermined. The proposed lines on which the committee intends to act is to select some special disease and make an exhaustive study of it from all sides, a study which will last for two to three years. It is proposed to found a small hospital which shall be devoted entirely to cases of that disease during its period of study. The committee is to be a comprehensive one, and include all who will watch the course of the disease or who will undertake research work on the subject. These will report to a central body, which will also be responsible for the distribution of the collected facts and literature of the subject to those actively engaged in working upon it.

Prof. C. S. Sherrington and Miss S. C. M. Sowton communicated the results of an investigation into the amount of chloroform which, when administered to the heart, can dangerously embarrass its action. For this inquiry they had adopted the method, gradually evolved of recent years, of keeping the excised heart of a mammal alive by perfusing its blood-vessels with warm nutrient solutions. The heart used by them was that of the cat. The beating of auricle and ventricle was recorded graphically. The effect of chloroform was examined by allowing the perfusing fluid, pure saline, serum, or blood, as the case might be, to be replaced by a similar fluid to which chloroform in known quantity had been added. When this was done the chloroform showed its effect, practically at once, by diminishing the amplitude of the beat without altering its rate. The amount of the diminution was proportionate, within limits, to the concentration of the solution of chloroform. When exhibited in saline solution, chloroform showed a depressant action even in a dilution of 1 part in 150,000 of the saline solution. The full amount of the depression caused by a given solution was rapidly reached, *e.g.* in a minute, and then the continued administration of that solution caused no further depression—even if continued for half an hour at a time. That is to say, there is no cumulative action of the drug detectable in the isolated heart so perfused for a period of half an hour. On the contrary, there was generally evidence of a slight waning of the depression as the exhibition of the drug was uninterruptedly maintained. This tolerance was, however, quite evanescent, for on interrupting the perfusion with the chloroform solution and then returning to it, the depression recurred in its original depth. On discontinuing the perfusion with chloroform solution and reverting to the chloroform-free fluid, the depression caused by the chloroform—unless the chloroform solution has been of great concentration—is extremely rapidly removed, even when the beat of the heart has been for many minutes practically abolished. This suggests the view that the effect of chloroform on the cardiac muscle is due to the formation of some easily dissociable compound between the chloroform and some active constituent of the tissue. It has been recently urged by Moore and Roaf that this constituent is a proteid, and in favour of this view is a further fact elicited in the present inquiry. On comparing the amount of depression of a chloroform solution of given concentration, in salt solution on the one hand and in blood on the other, it is found that the effect of that concentration in blood is much less than it is in salt solution. In other words, the effect of a chloroform solution of given concentration in blood is only equivalent to that of a solution barely one-twelfth as concentrated in salt solution. This can be explained by supposing that the salt solution, though it supports the beat of the heart, supports it less well than does blood; but the more important part of the explanation seems to be that the tension of the chloroform in the blood is much less than in the salt solution. In other words, the difference seems referable to some constituent of the blood taking up and holding, in a relatively inactive form, a considerable fraction of the chloroform added to it. The chloroform added distributes itself in that complex fluid according to a coefficient of partition. It is only what is left over freely dissolved in it which is available for acting on the heart tissue. Comparative estimations of the depressant effect in blood, serum, and saline solution show that serum is intermediate between the other two, so that evidently the corpuscles contain, in large measure, a substance that combines with the chloroform.

THE RELATION OF OXIDATION TO FUNCTIONAL ACTIVITY.[1]

In opening this discussion, Sir John Burdon-Sanderson said:—

In undertaking to open this discussion, I do not claim to contribute any results of my own researches or to speak on any subject *ex cathedra*, or with any degree of finality. I propose to state very shortly what seem to me the discussable questions, *i.e.* those respecting which we have experimental data, and to submit to the section those on which we need enlightenment.

The title is "Oxidation and Functional Activity." May I say that, without criticising it, I would ask for some latitude as regards the word oxidation. By oxidation is meant the formation of an oxide. Now we know that in the living organism oxygen may and does act without this happening, *e.g.* in those processes of which the oxygenating of the colouring matter of the blood is the type.

This is so important a distinction that I would suggest to substitute in these cases the term "oxygenation." The subject of our discussion would then be rightly stated as follows:—"The Relation between Oxygen and the Chemical Processes which Constitute Animal and Plant Life." The older notion of the part played by oxygen in the chemical processes of life was that it was a destroyer and not a maintainer of the chemical energies of the cell. We now recognise that oxygen may have a double function to perform, first as an element the presence of which is essential to the anabolic process by which living matter is built up, and secondly as equally essential to the disintegrative process which, taking muscular activity as the type of others, is associated with the performance of function. Of these two actions, in each of which oxygen is concerned the *con*structive and the *de*structive—the second is better under-

[1] Report of a discussion before the Section of Physiology at the Cambridge meeting of the British Association, August 19.

stood than the first. It can be proved experimentally that in the living organism muscular work is accomplished by the transformation of a corresponding amount of chemical energy, however imperfectly we may understand how this transformation can occur at the temperature of the body. But as regards the participation of oxygen in the process of *restitution*, we are obliged to frame for ourselves a hypothesis and to clothe it in chemical language, according to which each elementary function is represented by a specific kind of living matter, *i.e.* by an aggregate of *living molecules* each of which is endowed in equal degree with the capacity of discharging the function which it represents. The difficulty lies in this, that the physiologist finds himself compelled to use chemical language in a sense which the chemist does not recognise. What we mean thereby is that the hypothetical living molecule consists of a permanent part which is not concerned in the performance of function, and of a collateral part which is used, *i.e.* disintegrated in every transition of the molecule from the inactive to the active state, to be immediately re-constituted when action ceases. This notion of *restitution* is the nutshell in which the difficulty lies. All that we know about it is that the access of oxygen is an essential condition for its accomplishment—oxygen not as an oxidiser, but as a restorer of functional capacity.

I now propose to pass from the general to the particular, *i.e.* to the consideration of the chemical process of life as it presents itself in particular organs, namely, first in muscle and in nerve centre, and secondly in such glands as have up to this time been investigated—two groups of structures representing what Bichat called respectively animal life and organic life. On the general principle that in all our investigations we should proceed from the known to the unknown, muscle must be taken first, for its metabolism is more within reach of investigation and is better understood than that of any other organ.

When oxygen enters the living substance of muscle it is not as an oxidiser, but as a preparer and builder up of material ready for explosion. For the muscle molecule receives two things from the blood, oxygen and oxidisable material, but these two do not combine as a mere result of juxtaposition or of encountering one another. As Ostwald says, "Der freie Sauerstoff ist ein sehr träger Stoff," at the temperature of the body. It cannot be brought into action in the living organism by a stimulus so long as it is in its free state. It must first become what Pflüger calls "intramolecular," and thereby change its Trägheit for mobility. The immediate effect of the access of oxygen is that the living substance of which it becomes a part becomes more susceptible to mechanical and electrical disturbance, *i.e.* more excitable than it was before. It requires, so to speak, to be wound up so as to become capable of discharging its oxidising function when awakened by a stimulus. Dr. Fletcher's experiments, to which I will return later, show that the more perfect this preliminary anabolic process is the more complete will be the catalysis.

You will, I think, agree with me that in different stages of the metabolic process which is associated with muscular function oxygen acts in different ways, at one time taking part in an integrating process for which we might, perhaps, employ the word oxygenation, at another in a process of oxidation, the molecule in which this occurs retaining its existence notwithstanding the disintegration of its oxidisable part.

We have now to pass on to the question how oxygen takes part in the functional activity of the central nervous system. The only part of that system which is within reach of experimental investigation is the spinal cord. We have to consider in how far the results of investigations in the cord and in muscle agree or differ

Let me say on the threshold that our knowledge is largely due to work recently done at Jena and Göttingen under the direction of (or in cooperation with) Prof. Verworn. I must first ask your attention to the method.

More than thirty years ago Cohnheim taught us the use of a preparation which we used to call "the salt frog," in which the blood was replaced by physiological salt solution. He discovered that notwithstanding the defect of hæmoglobin, and consequently of oxygen, the chief functions of life could be carried on. With much more perfect methods Verworn has followed Cohnheim. The improvement consists in this, that the circulation is maintained by mechanical means, so that by varying the rate of flow and the percentage of oxygen in the liquid the supply of oxygen to the cord can be increased or diminished at will. The effect produced is judged by the mechanical responses to reflex excitation, the indications given by which are rendered more delicate by the previous administration of a trace of strychnine. The first step in the experiment is to establish a normal state of things by the circulation of salt solution which has been freely exposed to air or oxygen. Under these conditions the response to stimulation of the surface consists of a succession of brief tetani, each lasting two or three hundredths of a second. The next step is to substitute salt solution which has been deprived of oxygen, and to observe that the reflex centre is gradually paralysed, as indicated by the fact that single tetani have taken the place of the serial responses, that on renewing the supply of oxygen the former state of things is restored, and, finally, that these changes may be repeated over and over again with the same result.

All these facts come under the general statement that while oxygen has no power of acting as a stimulus it increases the excitability of the centre, enabling it when excited to discharge itself so completely that after the discharge it is wholly incapable of responding. It further shows that oxygen shortens the time required for restitution to the normal—reintegration following disintegration—anabolism following katabolism so immediately that they may almost be considered as simultaneous.

If we compare the behaviour of oxygen in the centre with its behaviour in the muscle, we shall find that they differ chiefly in one particular, namely, in their time-relations. In both cases oxygen acts as a predisposing, not as an exciting cause of functional activity. In both cases a *tertium quid* is wanted—a liberating or letting off mechanism; but in the muscle the functional cycle is accomplished in scarcely more than 1/100 sec., whereas in the centre the effect occupies a few hundredths of a second, and the preparation for it a much longer period. There is therefore no difficulty in understanding why the so-called refractory period can be so easily observed and measured in the centre (while in the muscle its presence can only be inferred), a circumstance which is helpful as affording an additional evidence of the anabolic action of oxygen; for it is easy to show that the period in question is shortened by supply of oxygen, protracted by its absence.

We now come to the last point which I am anxious to submit to you—that of the relation of oxygen to the function of glands. I must begin by saying that it is in this part of our subject that the crux lies, for the investigation of the intimate metabolism of glands is beset with difficulties even greater than those of muscle and spinal cord.

Mr. Barcroft, to whose admirable researches we shall have occasion to refer repeatedly to-day, found as the result of his estimate of the oxygen and carbonic acid yielded by the blood circulating through the submaxillary gland under different conditions that this gland takes from the blood much more oxygen when excited by the chorda tympani than when at rest, no such effect occurring when the excitation had been rendered ineffectual by the previous administration of atropine. These observations gave good reason for believing that oxygen promotes the action of the cells, but afforded no evidence that this action is attended by a corresponding discharge of carbon dioxide. Similarly Prof. Starling, whose experiments were made with Mr. Barcroft's cooperation, found that when the pancreas is made to act by the injection of secretin a similar want of relation presented itself between the quantity of oxygen taken in and of carbon dioxide discharged. Finally, the comparison which has been recently made by Dr. Brodie (who will, I hope, explain to us his very admirable method) of the state of activity of the kidneys with the state of rest, points to the same conclusion as regards that organ. When diuresis was produced by the injection of urea, the clearest evidence was given of the increased demand for oxygen, the intake of which was very largely increased, but there was no indication that the ultimate products of oxidation found their way into the blood in quantities proportionate to the oxygen supplied.

Taking these data as our point of departure, what can we infer from them as regards the resemblances and differences between the two processes we have been considering,

viz. the functional activity of muscle and nerve centre on the one hand, that of gland on the other? The *obvious* contrasts which exist between secretion, muscular contraction, and reflex innervation need not be dwelt upon; the one thing with which we have to do is the nature of the chemical processes which are associated with these three forms of activity. If analogies are to be sought for it is here they will be found.

I submit to the section, and particularly to those members of it who are engaged in experimental researches on the subject, that the most important contrast between the concomitant chemical processes of gland function and muscle function consists in this, that whereas the former is not in any marked degree katabolic, the dominant process in the oxidation which is inseparably associated with the performance of muscular function *is* katabolic. We can readily account for this by reference to the fact that whereas the processes in muscle and in reflex centre are excitatory, those in glands are for the most part determined by stimuli of a very different kind from those that evoke nervous or muscular action, which last act exclusively as liberators of katabolic processes which are waiting to be discharged.

We have long been accustomed to regard the process by which, in muscle, chemical is translated into mechanical energy as explosive and instantaneous, and to take the end-result—the discharge of carbon dioxide—as the necessary concomitant of the production of heat and work; but as I remarked before, Dr. Fletcher recently published experiments which seem to show that for the attainment of this ultimate result it is essential that the muscle should be abundantly supplied with oxygen, in failure of which the oxidation process may stop short before its completion. I trust that we shall have the advantage of hearing to-day the further results of his researches, and particularly that he will give us information as to the relation between efficiency of contraction and the degree of completeness of the oxidation process.

In conclusion, the questions which present themselves are:—

(1) Whether it may be generally stated that the oxygen which is conveyed to the living matter of the tissues by the blood *is stored as "intramolecular oxygen" until it is required for the performance of katabolic functions*, and, if so, what is the *chemical relation* between the stored oxygen and the living molecules by which it is held? In submitting this question, I must again ask that the use of the term "living molecule" may be condoned.

(2) Whether it may be assumed that every *disintegrative process conditionates a subsequent integrative process* by which the *status quo* is restored in the same living molecule; if so, does the anabolic effect which in muscle *follows* the change of form constitute as much a part of the response to stimulation as the catabolic effect which *precedes* the change of form? Can this be said of the chemical process which is associated with functional activity in gland?

Continuing the discussion, Dr. W. M. Fletcher pointed out that in the muscle cell only the katabolic processes had been effectively studied, and that these are characteristic of the special material giving energy for contraction—a material probably without analogue in the gland cell. The classical conceptions, due to Pflüger and to Hermann, of this material as a highly oxygenated substance breaking down, whether rapidly as in contraction or slowly as in survival periods, by inevitable stages to the ultimate stages of carbonic acid and water, irrespective of a contemporary supply of oxygen, were discussed and compared with the views of Verworn. It was urged that while a preliminary oxygenation of the living molecule may be admitted on wide grounds as the condition of irritability, such a conception by no means precludes the idea of additional oxidative processes occurring at some stage or stages of the katabolic disintegration. Disintegration effected under anaërobic conditions might, on this view, stop short of its normal end-products, these being replaced by representatives of earlier stages in the breakdown. Evidence in this direction has been got from three main classes of experiment. In the case of excised muscle, Dr. Fletcher's observations of the relation of oxygen supply to the yield of carbonic acid in rest and in activity, and to the onset of fatigue and of rigour, were described and held to be incompatible with the view that the entrance of oxygen conditioned the lability of the molecule without further influence upon the subsequent course of katabolism. A second class of evidence was derived from the work of Chauveau and Kauffman, Ludwig and his pupils, Minot and others, upon the respiration of muscles with artificial circulation. An increased yield of carbonic acid due to activity was claimed or denied by these observers strikingly in proportion to the success with which the artificial circulation had been made to reproduce the normal. A third and large body of evidence is supplied by observers like Araki, Geppert, Meyer, and others, who have studied the results of muscular contraction with normal circulation, but under conditions of deficient oxidation. Anaërobic conditions always appear to diminish the amount of carbonic acid expired, while increasing the amount of acid products in the tissues, the blood, or the excreta.

Prof. N. Zuntz (Berlin), in a letter addressed to the section, referred to some of the points which it had been suggested should be dealt with in the discussion, in the following terms:—"Is one justified in drawing a hard and fast line between the anabolic and the katabolic processes on theoretical grounds? Would it not be more correct to take Pflüger's view and regard that process as the normal one in which every katabolically decomposed molecule is at the very moment of decomposition anabolically regenerated by taking up oxygen and oxidisable groups? In this case one would regard the katabolic processes, which render the molecular structure less stable and give rise to free affinities, as the factor which inaugurates and makes possible normal anabolism. In this connection, however, the fact remains that anabolism can also take place later on, if an element such as oxygen, necessary to the building up of the molecule, should be wanting at the time that the katabolic processes occur. It is accordingly a subject for investigation to decide whether subsequent regenerative processes occurring in the above manner take place as easily as normal assimilation occurring at the same time as the breaking down of the molecule, or whether they use up more energy if they occur later. I have already some data which tend to show that anabolism demands more energy if it has to take place at a period after the katabolic processes, but I dare not yet give any definite verdict on the question.

In regard to the question as to how far the metabolic processes may be the work of an oxidase, I should like to lay stress on the fact that the fundamental importance of innervation for katabolic processes in muscle is not easy to reconcile with the assumption that these processes are much affected by ferments. Neither does the great influence which the tension of a muscle has on oxidation processes in it harmonise with our knowledge of the action of enzymes.

Prof. T. G. Brodie described the results obtained in experiments, conducted in conjunction with Mr. Barcroft, upon the gaseous exchanges in the kidneys under the different conditions of rest and activity. In all cases they had found that the amount of oxygen taken in by a kidney which was made to secrete urine actively was greatly in excess of that absorbed by a resting kidney, while on the other hand the quantity of carbonic acid eliminated showed far slighter variations. In the greater number of their experiments they had found that the kidney at rest eliminated a greater volume of carbonic acid than it absorbed of oxygen. Their results thus indicated that the performance of work by the kidney was accompanied by an approximately proportional increase in the intake of oxygen, while the output of carbonic acid, although increased, was usually much less in amount. From the fact that the carbonic acid output was often in excess of the oxygen intake, it would seem that the final metabolic changes, as evidenced by the carbonic acid output, was a more gradual process, though the results they had obtained, up to the present, did not warrant the conclusion that the carbonaceous waste products resulting from the activity of the tissue were confined to carbonic acid only.

Mr. J. Barcroft, in discussing the metabolism of glands generally, pointed out that there were three methods which had been used for the investigation of their gaseous metabolism. In the first, an excised organ was kept in an enclosed space, and the surrounding air analysed. This method had been dealt with by Mr. Fletcher, who had pointed out that the method shed light on the katabolic

phase of activity only. In the second method the general gaseous exchanges of the body were watched during states of rest and activity of the organ to be investigated. This, however, was inapplicable to the glands of the body on account of their small size. The third method was that of measuring the blood gases, combined with an estimation of the rate of flow of blood through the gland.

Three glands have been studied by this method up to the present, the submaxillary, the pancreas, and the kidney. In the submaxillary gland the problem was very complicated, since the blood became concentrated, losing a tenth of its water or even more, and a considerable quantity of the carbonic acid left the gland in the secretion. After due allowance had been made for these disturbing factors, it appeared that the O intake and the CO_2 output were increased from three- to four-fold during stimulation of the chorda tympani nerve. As to how far these changes might be due to concomitant vascular changes was studied by examining the gaseous exchanges of an atropinised gland during stimulation of the chorda. It was found that this led to no increase in the amounts of O withdrawn, though an increased output of CO_2 was observed.

In the pancreas, which had been studied in conjunction with Prof. Starling, there was often no increased flow of blood synchronously with a secretion following an injection of secretin. They invariably found an increased absorption of O. Usually this increase was considerable; thus from eight comparisons the mean quantity of O taken up by the resting gland was 1·5 c.c. per minute, and by the active gland 5·5 c.c. per minute. These results were entirely in harmony with those brought forward by Prof. Brodie for the kidney.

It seemed, then, that glandular activity was accompanied by a large and instantaneous consumption of O, but that it was not necessarily accompanied by an increased CO_2 output.

Another point indicated was the magnitude of the gaseous metabolism of glands. In the submaxillary and in the pancreas, when at rest, about 0·025 c.c. to 0·035 c.c. of O per minute per gram of gland substance was absorbed. In the kidney Prof. Brodie had given one instance in which the organ was using as much as one-fifth of the total quantity of O taken in by the lungs, and it was common to find the O consumption of the kidney during diuresis to amount to one-tenth of the total taken by the whole body.

Prof. T. Clifford Allbutt suggested that the theories advanced as to the part played by oxygen offered some explanation of the fact, often experienced clinically, that the administration of oxygen gave relief to patients not only in cases where the heart and lungs were affected, but in many others also. He had long since given up the idea that oxygen was effective in these cases simply on account of the more favourable conditions under which the respiratory functions were placed. This was evidenced, for instance, by the tenacity with which the patients adhered to the treatment; for example, in cases of the vomiting of pregnancy, where its administration was often of great service.

Sir John Burdon-Sanderson, in bringing the discussion to a close, remarked that it had been an exceedingly fruitful one, and none the less so because the points under discussion had not been settled, but were still under investigation. It seemed clear to him that oxygen played two parts in metabolic processes, one of which was prominent in muscle, and was responsible for the final oxidation of explosive material, while the other, which was more accentuated in glands, was akin to a building up process, as it was involved in the elaboration of new material.

GEOLOGICAL NOTES.

THE puzzling and commonly fragmental remains styled by von Gümbel Lithiotis are the subject of an elaborate monograph by Dr. Otto Reis (*Abhandlungen der k.k. geol. Reichsanstalt*, Bd. xvii., Heft 6, 1903). After being considered as plants, from algæ to palms, for some twenty years, they settled down in 1890 as bivalve molluscs allied to oysters. Von Gümbel's revision, to this effect, is now revised by Dr. Reis, who points out that certain long ridges in the hinge-area represent teeth. Two genera, Cochlearites and Lithiotis, are established, forming the Lithiotidæ, a subfamily of the Spondylidæ. The minute structure of the shells is carefully described.

The interest aroused by the publication of "Bau und Bild Österreichs," recently reviewed in these columns, has called from Dr. Friedrich Katzer a series of papers (*Verhandlungen der k.k. geol. Reichsanstalt*, 1904, pp. 123, 150, 177, and 193), in which he hopes to fill some of the gaps still remaining in our knowledge of Bohemian geology. His work covers such widely diverse subjects as the zoning of the north-eastern coalfield under the Riesengebirge, and the magnetite-ores, occurring as separation-products in garnet-amphibolite, in the neighbourhood of Kutna Hora.

In the *Verhandlungen der k.k. geol. Reichsanstalt* for 1904 Herr R. Zuber (p. 200) explains his views as to the analogy of the Flysch deposits of Europe and those forming in tropical climates, with a heavy rainfall, in the neighbourhood of the mouths of rivers, whether these flow from continental land or from the members of an archipelago. Dr. H. Vetters (p. 134) interestingly connects the structure of the Little Karpathians with that of the eastern Alps on the one hand, and of the true Karpathians on the other. The Flysch of the north side of the Alps thus reappears from under the Vienna basin, and passes into the Karpathian Sandstone series; while the characteristic Karpathian "Klippen" are also traceable in this connecting range. The author regards the so-called Silurian grauwacke of Hainburg, down against the Danube, and similar rocks of the Leitha range, as in reality the equivalents of the Liassic beds in the Little Karpathians.

The *Jahrbuch der k.k. geol. Reichsanstalt* of Vienna usually contains more massive papers than the *Verhandlungen*, though it is difficult to discriminate between the two in scientific value. In vol. liii. of the former (1903), pp. 169–252, Dr. O. Ampferer describes, with numerous sections, the Triassic and Jurassic mountains that form the impressive broken country of crag and forest between Innsbruck and the Achensee. He illustrates his view of their structure (plate x.) by a skilful drawing of a relief-model, much in the American manner, thus emphasising the simpler anticlinal and synclinal structure in the south, and the great overfold of Trias upon a recumbent Jurassic synclinal in the Gamsjoch area. It seems possible, as the author points out, that the whole highland of Triassic rocks rests upon an underfolded and underthrust knot of younger strata. Dr. Ampferer modestly regards his own researches as supplementing, and correcting at certain points, those of Prof. Rothpletz and his Bavarian colleagues. He adds, moreover, details as to the glacial phenomena throughout the district. Herr E. Fugger's paper in the same volume (p. 295) describes the foothills of the Alps in the famous Salzkammergut area, where the Flysch, with its dubious fossils, forms the oldest series, and is confidently ascribed to the Upper Cretaceous epoch. Dr. F. Ryba (p. 351) revises and amplifies the list of fossil plants from the Cannel Coal of Nýřan in Bohemia, and Dr. Waagen (p. 443) adds to our knowledge of the small brachiopods characteristic of the Tyrolese Trias.

We have received the August number of the *Quarterly Journal* of the Geological Society, which contains a well illustrated article on the history of volcanic action in the Phlegræan Fields by Prof. Giuseppe de Lorenzo; an account of the discovery of a human skeleton in Gough's Cavern, at Cheddar, by Mr. H. N. Davies, who regards the remains as of late Palæolithic age, although in the discussion which followed the reading of the paper this antiquity was questioned; and among other papers there is an important one on the age of the Llyn-Padarn dykes in Carnarvonshire by Mr. J. Vincent Elsden, who regards these deep-seated intrusions as having taken place during the latest stage of the Bala eruptions.

The summary report of the Geological Survey Department of Canada for 1903 has been issued by Dr. Robert Bell, the acting deputy head and director. As usual, the energies of the staff have been given mainly to investigating and aiding the development of the mineral resources of the country. Field work has been carried on in Yukon territory, in British Columbia, in the Keewatin district, in Ontario, Quebec, New Brunswick, and Nova Scotia. In connection with the large output of coal which is now going on in

both Nova Scotia and Vancouver Island, it is mentioned that the only coal known to occur in North America on the immediate seaboard of either the Atlantic or Pacific belongs to Canada.

Some new genera of Carboniferous Mollusca from the United States have been described by Mr. G. H. Girty (*Proc.* U.S. National Mus., vol. xxvii., No. 1372). They include Limipecten, a form considered to be near to Aviculipecten (*sic*), and with that genus to have affinities with the Pectinidæ rather than with Aviculidæ. Other new genera are Pleurophorella, allied to Allerisma, and Clavulites, having some resemblances to Dentalium.

The Miocene diabase of the Santa Cruz Mountains in San Mateo County, California, is described in some detail by Messrs. H. L. Haehl and R. Arnold (*Proc.* Amer. Phil. Soc., vol. xliii., No. 175). The diabase, in the form of tuffs, dykes, and intrusive sheets, occupies about 35 square miles in an area of 300 square miles. It is remarked that the tuffs are interbedded with Miocene limestones, sandstones, and shales, and that intrusions of limestone derived from the interbedded limy layers have been forced into fissures in the tuff. In the intrusive diabase the percentages of soda and titanium are large, and it presents the characters of augite-teschenite.

An essay on the palæontology of the Lancashire Coal-measures, part i., contributed by Mr. H. Bolton to the *Transactions* of the Manchester Geological and Mining Society (vol. xxviii., part xiv.), has been reprinted as one of the "Museum Handbooks" of the Manchester Museum, Owens College (price 1*s*.). In this work the author deals with the lower Coal-measures, and his object has been to record the horizon and geographical occurrence of each species so far as possible by reference to known specimens.

Prof. G. A. J. Cole and Mr. T. Crook have reported on rock specimens dredged from the floor of the Atlantic off the west coast of Ireland in 1901 (Dept. of Agric. and Techn. Instruction for Ireland, App. to part ii. of Rep. on Sea and Inland Fisheries). The rocks which were obtained off the west coast of Mayo and Galway appear to have been derived from submerged masses of rocks familiar in western Ireland. They include also an olivine-gabbro which is regarded as probably of Carboniferous age.

In an article published in the *Land Agents' Record* (August 20) Mr. F. J. Bennett directs attention to the important uses to which the Ordnance Survey maps, on the scale of 25 inches to a mile, might be put for estate and agricultural purposes. As he points out, much valuable information is lost, both to the landowner and farmer, to say nothing of the geologist, for want of recording it at the time. He instances the nature of the soil and subsoil as proved in draining the land and in various temporary excavations, as well as information with regard to wells, springs, stone quarries, or clay pits. The courses of the drains have rarely been laid down on estate maps. In addition to records of these matters, he suggests that the maps be used also for statistics with reference to cultivation. Thus the amount of seed sown, the kind and quantity of manure used, the weather, and, finally, the result of each field crop might be notified. If these particulars were tabulated, say for seven years, the reasons for success or failure might be judged. In the transfer of property or of leases such information would be of the utmost value to the incoming owner or tenant, and the records, which would be the private property of the occupier, should be of sale value.

We have received a number of important geological publications from South Africa. In the *Transactions* of the South African Philosophical Society (vol. xv., part ii.) Mr. E. H. L. Schwarz describes the high-level gravels which cap the flat-topped hills all over the southern coast regions of Cape Colony. The evidence shows that the gravels were river-borne, and in the Karroo district they yield gold. No gold-bearing reef has, however, been detected in that area, and the author is strongly of opinion that the gold came from the Zwartebergen, where it occurs in the Table Mountain Sandstone. Messrs. A. W. Rogers and A. L. du Toit describe the Sutherland volcanic pipes and their relationship to other vents, notably those of Kimberley. In the *Transactions* of the Geological Society of South Africa (vol. vii., part i.) there are various papers of local interest on the geology of the Transvaal, and on the Witwatersrand series in particular. In the annual report of the Geological Commission of the Cape of Good Hope for 1903 we have a record of the careful detailed work carried on by the director, Mr. A. W. Rogers, and his staff. The survey of the south-western portion of the Karroo has been completed, and much information has been gathered with reference to the sedimentary and volcanic formations. The recognition, in the Verloren Valley, of a group of rocks (the Ibiquas series) between the Table Mountain Sandstone and the Malmesbury series is of considerable interest.

"The Geology of the Country around Merthyr Tydfil" (being the fifth part of the "Geology of the South Wales Coal-field") has just been issued by the Geological Survey, price 1*s*. 6*d*. It is the work of Messrs. A. Strahan, Walcot Gibson, and T. C. Cantrill, and is an explanation of the geological map sheet 231. The area includes the North Crop of the Coal-field from Dowlais to the Tawe Valley, with a considerable tract of Old Red Sandstone in the mountainous land of Fforest Fawr, and also of Lower Carboniferous rocks. The great scarp of the Pennant Sandstone stretches across the country on the south. The stratigraphical features, the lithology, the faults and disturbances of this important coal-region are dealt with very fully; the Glacial drifts and other superficial deposits are duly described, and a short chapter is given on the economic products.

We have received an official report by Signor A. F. Umlauff on the Cinnabar of Huancavelica, issued as a *Boletin* of the Corps of Mining Engineers of Peru. The ore occurs in irregular deposits in sandstones and limestones, which have yielded Cretaceous fossils, and sections are added showing its mode of occurrence. A description is also given of the aludel furnaces, which are used in extracting the mercury, and have remained practically unchanged for more than two centuries.

From the United States Geological Survey we have received *Bulletin* No. 228, dealing with analyses of rocks from the laboratory, 1880 to 1903, by Mr. F. W. Clarke; also *Professional Paper* No. 28, giving the superior analyses of igneous rocks from Roth's Tabellen, 1869 to 1884, arranged according to the quantitative system of classification.

The occurrence of a "calcareous coal" in the Lanarkshire Coal-field is described by Mr. R. W. Dron (*Trans.* Inst. Mining Engineers, vol. xvii.), and shown by analysis to contain carbonates of lime and magnesia. The author seems to have been unaware that Mr. A. Strahan, in 1901, brought before the Geological Society an account of the passage of a seam of coal into dolomite, as observed at the Wirral Colliery in the small Parkgate Coal-field.

The glaciation of Mount Ktaadn, in northern Maine, forms the subject of an essay by Mr. R. S. Tarr (*Bull.* Geol. Soc. Amer., vol. xi.). The mountain, which is composed of granite, rises to a height of 5150 feet, and has hitherto been regarded as bearing no proof of ice-covering during the Glacial period. The author brings forward evidence to show that the ice did overtop the mountain, and that glaciers subsequently occupied the valleys on its eastern side, leaving well defined moraines some of which enclose lakes.

In the *Brazilian Mining Review* (for April and May) Mr. H. Kilburn Scott gives some account of the mineral resources of Rio Grande do Sul, which is the southernmost of the States of Brazil. The village of Lavras is at present the centre of the gold-mining industry, the gold occurring in quartz-veins or as impregnations in decomposed syenite-rock. The principal copper deposit is that of Camaquam, and the ores comprise copper glance, copper pyrites, and bornite (erubescite). Lodes occur in hard conglomerates and sandstones which have been invaded by melaphyre, and there seems to be a close connection between these metalliferous deposits and the eruptive rock.

A useful index to the mineral resources of Alabama, compiled by Messrs. E. A. Smith (State geologist) and H. McCalley, has been issued by the Geological Survey of Alabama. It includes an account of iron and manganese ores, bauxite, coal, clays, building stones, mineral paints, mineral waters, &c., and is illustrated by a small geological map and pictorial views.

The tin deposits of the York Region, Alaska, are briefly described by Mr. A. J. Collier (*Bulletin* No. 229, U.S. Geol. Survey). Stream tin was discovered in 1900, and since then

prospecting has been going on to determine its extent and to locate its source in the bed-rock. The ore is mostly cassiterite, but stannite also occurs. Pebbles of slate containing small tin-bearing quartz veins have been found in the gravels, while elsewhere the ore has been found disseminated through more or less altered granitic dykes.

PRIZE SUBJECTS OF THE INDUSTRIAL SOCIETY OF MULHOUSE.

THE Industrial Society of Mulhouse has issued a programme of the prizes to be awarded by the society in 1905; excluding the subjects which are of a purely local or technical character, the following are the principal prizes open to competition to all nationalities:—

In the section of chemistry, medals of honour will be given for experimental investigations of the alizarine reds, of the colouring matter of raw cotton, of the transformation of cotton into oxycellulose, and of cochineal carmine; for the synthesis of the colouring matter of cochineal or of some other dye used in industry; and for the production of fast dyes of a specified nature. Several medals will also be awarded for studies of special mordants and for the synthesis of some naturally occurring substance. A sum of 500 francs to 1000 francs is to be allotted to the best compilation of densities of mineral and organic substances in the solid state and in cold saturated solution. Many practical chemical problems in the bleaching and dyeing of cotton, wool, and silk are also suggested as subjects for competition.

In the section of mechanical arts, a prize of 500 francs and a silver medal is offered for a new method of construction of buildings suitable for cotton spinning, wool combing, or calico printing. The following subjects will receive medals:—a new non-tubular type of boiler; an indicator of the total work done in a steam engine; a new system for heating steam boilers; various machines for combing, carding, and weaving the textile fibres; a comparative study of electric and gas lighting in factories; a system of automatic lighting by conductors of the second class.

The following subjects deal with natural history and agriculture:—a catalogue of the plants in the neighbourhood of Mulhouse, Thann, Altkirch, and Guebwiller; an account of the fauna of Alsace; a mineralogical or geological description of part of Alsace; a study of the plants or insects inimical to agriculture in the same province. A medal is also offered for an investigation of the character of Alsace in prehistoric times.

In the sections of commerce and statistics the subjects are:—a consideration of the questions of insurance against risks of transport and fire; the influence of taxation on industry; and the effect of trusts and like organisations on commerce.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. J. J. Lister, F.R.S., of St. John's College, has been appointed demonstrator of comparative anatomy.

The Board of Geographical Studies has arranged for a course of instruction in geographical surveying, to be given by Mr. Hinks at the observatory.

The council of the Senate proposes an important scheme whereby the matriculation and senior local examinations of the Universities of London, Oxford, and Cambridge shall be mutually recognised. The object is to diminish the number of distinct examinations for which schoolmasters have to prepare their pupils. The proposed conditions are set forth in the *University Reporter* for October 11.

Mr. R. R. Webb, St. John's, Mr. G. H. A. Wilson, Clare, Mr. J. M. Dodds, Peterhouse, and Mr. E. W. Barnes, Trinity, will be the examiners for the mathematical tripos, part i., in 1905.

SIR ISAMBARD OWEN has been appointed principal of the Durham College of Science in place of the late Dr. Gurney.

DR. ARTURRO MARCACCI, of the University of Palermo, has been appointed professor of physiology in the University of Pavia.

DR. HERMANN KOSSEL, of the Imperial Board of Health at Berlin, has been appointed to the chair of hygiene at the University of Giessen in succession to Dr. Georg Gaffky.

THE first congregation to inaugurate the University of Leeds was held on October 6, and the honorary degrees announced in our issue of September 29 (p. 547) were conferred. The Chancellor of the university, Lord Ripon, presided.

WE learn from the *Athenaeum* that Dr. Hans Batterman, of the Berlin Observatory, has been appointed director of the observatory at Königsberg, and professor of astronomy at the University of Königsberg, in succession to Prof. Hermann Struve, lately appointed to the vacancy at Berlin caused by the retirement of Prof. Förster.

THE Board of Education has issued its "Syllabuses and Lists of Apparatus" applicable to schools and classes other than elementary from August 1, 1904, to July 31, 1905. A new subject, under the title "Elementary Science of Common Life (Chemistry)," number twenty-six, has been added to the list of branches of science in which the board holds examinations. The list of subjects in which no examinations are held, though the subjects are recognised by the Board, has been extended, and now includes many subjects introductory to more advanced work in technology.

THE anonymous gift of 1000*l*. to the University College of Bristol announced a few days ago is, it may be hoped, an indication that the work of this institution is being appreciated in Bristol and the surrounding district. In addition to the usual courses, appropriate and systematic instruction is given at the college in those branches of applied science which are most nearly connected with the arts and manufactures. We notice that the total number of individuals, excluding medical students, attending the college during the session 1903–4 was 1084, of whom 596 were day students.

THE new calendar of University College, London, that for the session 1904–5, gives full particulars of several interesting new developments in the work of the college. The university courses of study, especially those in economics, have been extended, and further arrangements have been made for post-graduate courses, lectures, and research—this post-graduate work is explained fully in ten pages of the calendar. The list of papers and other publications from the scientific departments of the college, since the Dean's report of last year, runs to eight full pages, and shows that the work now being accomplished in the college is of the same high order as in previous years.

IT is reported that there is apparently a deficiency of about 2000*l*. for the annual working expenses of the Tata Research Institute, and on account of this the scheme for the institute is at a standstill. Referring to this, *Capital* remarks:—"The question now is whether for the sake of two or three thousand pounds India should go without a Research Institute. Is the object good or not? If it was not good, why did the Government of India promise to help it? If it is good, why should there be any stinginess on their part about it? Should a great Government refuse its support and countenance to a scheme, the expenditure on which will be repaid not only to the people of India, but also to the Government itself a hundredfold?"

THE buildings of the new technical college at Danzig were opened on October 6 in the presence of the German Emperor. The college, which has been established on a modern basis, is intended to develop the industries of West Prussia and of the city of Danzig. Shipbuilding is to receive special attention. In a speech which he made, the Emperor referred to the importance of technical education for the maintenance of Germany's position among the nations, and described the special characteristic of the German technical colleges as being their "comprehensive many-sidedness." It is, he continued, for this reason that these colleges constitute a scientific "Universitas" which may be compared justly with the old universities, and explains why the endeavour has been made to place the two kinds of institutions on an equal footing by bestowing upon the technical colleges the right to confer degrees. "May the new college," the Emperor concluded, "prosper and flourish to the glory of German learning, to the blessing of these old Prussian provinces, and to the honour of the German name!"

A RESOLUTION adopted by the manufacturers' section of the London Chamber of Commerce, and approved by the council of the chamber, was recently forwarded to the Board of Education together with a letter from the secretary of the chamber expressing the views of the manufacturers more explicitly. The resolution states that, in order to retain our industrial position and to introduce into this country such further industries as may be profitably developed, the manufacturers' section is of opinion that it is absolutely necessary to raise the standard, and, if possible, cheapen the cost of technical and higher technical education, and that representations should be made to the Board of Education in this sense. The letter to the Board of Education points out that up to the present time manufacturers in this country have not realised that there is a scientific aspect to every branch of manufacture, requiring study to attain the highest results, and that there is hardly an industry that would not benefit from the more general employment of specially qualified scientific assistants. At present such qualified assistants as are available are mostly foreigners, the letter continues, and there is urgent necessity for providing greater facilities for obtaining a thorough training in applied science in this country. There would seem to be urgent need for technical colleges of university type in connection with each industry, where students could have opportunities of carrying out specialised study and research work under competent teachers. The fees charged should not be greater than those charged by similar Continental institutions, and poorer students of ability should be assisted by a liberal system of scholarships. Mr. Morant, replying on behalf of the Board of Education, says the board is keenly alive to the importance of encouraging a better provision of higher technical education than at present exists, and will take every step in its power towards its promotion. But these efforts will be largely in vain unless British manufacturers give every encouragement in their power to promote the employment of students at home thoroughly trained for the needs in question. Mr. Morant rightly points out, with reference to the considerations submitted, that the want of properly qualified English assistants referred to may be attributed partly to the fact that the salaries offered are frequently too low to tempt natives of this country, partly to the shortsightedness of many English parents in refusing to continue their sons' education to a sufficiently advanced point, partly to the fact that there is no adequate provision at present in Great Britain for enabling persons to acquire the manipulative skill necessary in certain branches of industry, and partly also to the inadequate endowment and the insufficient encouragement of research.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 3.—M. Mascart in the chair.—A comparison of the expenditure of the flexor and extensor muscles of the forearm, applied, each group separately, to the production of the same continuous external work: A. **Chauveau.** The energy expended was measured by means of the respiratory coefficient. It was found that the external work effected by the flexor muscles of the forearm was less than that of the extensors, the proportion being about 0·4 for the former and 0·6 for the latter. This difference appears to be due exclusively to the less favourable conditions under which the extensor muscles work.—On the loss of electricity in air in the neighbourhood of thermal springs: A. B. **Chauveau.** In the thermal springs at Cauterets, the radio-activity of the air near the spring was clearly marked, the loss observed in the neighbourhood of the reservoir being three times as fast as in the open air.—The colorations produced by the Becquerel rays; its application to crystallography and to the calorimetric determination of radio-activity: C. J. **Salomonsen** and G. **Dreyer.** The coloration produced by radium on certain crystals demonstrates the zonal structure of the crystal, and thus throws light upon the manner in which it has been built up. In the case of quartz, this zonal structure has not hitherto been demonstrated.—On a vacuum effect produced by a waterspout: Léon **Pigeon.**—On actinium: A. **Debierne.** The substance previously described by the author under the name of actinium presents many similarities with the emanium of Giesel. The opportunity has recently arisen of directly comparing the two substances, and the observations of M. and Madame Curie, M. Giesel, and the author on the characteristic phenomena of phosphorescence provoked by the two products shows that they are identical. The name emanium should therefore be dropped in favour of the earlier actinium.—The properties and constitution of the molybdenum steels: Léon **Guillet.** The series of steels studied contained only 0·2 per cent. of carbon, with molybdenum increasing from 0 per cent. to 15 per cent. A second series contained about 0·85 per cent. of carbon. In small quantity, molybdenum increases the breaking load without causing extra fragility. The general properties of the molybdenum steels resemble those of tungsten steels, but four times as much molybdenum as tungsten is required to produce the same results.—A thermochemical comparison between rosanilines and leucanilines: Jules **Schmidlin.**—On the morphology of the Chetoptera: Ch. **Gravier.**—The archaic form of the Thecosome Pteropods: Paul **Pelseneer.**—On the structure of the muscles of *Anomia ephippium*: F. **Marceau.**—On acarophytism in Monocotyledons: E. **de Wildman.**—Semeiology of the prostatic secretion: A. **Guépin.**—On a new treatment of seeds: E. **Bréal** and E. **Giustiniani.**

NEW SOUTH WALES.

Linnean Society, August 31.—Dr. T. Storie Dixson, president, in the chair.—Revision of the Australian species of Bolboceras (Coleoptera, fam. Scarabæidæ), with descriptions of new species: Rev. T. **Blackburn.**—Studies in Australian entomology, No. 14, new species of geodephagous Coleoptera from Queensland and North-West Australia: T. G. **Sloane.** Three additions to the Cicindelidæ and five to the Carabidæ are proposed as new.—The botany of Funafuti, Ellice group: J. H. **Maiden.** The author gives a list, with critical notes, of thirty-eight dicotyledons, eleven monocotyledons, five vascular cryptogams, and one lichen. All the species are more or less widely distributed in the Pacific Islands as denizens of other coral islands or of the coastal tracts of the larger islands.

ODORIFEROUS SUBSTANCES USED IN PERFUMERY.

Die Riechstoffe. By Georg Cohn, of Görlitz. Pp. viii+219. (Brunswick: Vieweg und Sohn, 1904.) Price 6 marks.

THIS useful little monograph is a section, published in separate form, of Bolley-Engler's "Handbuch der chemischen Technologie." It is not easy to find a single expression in English which could be regarded as the precise equivalent of the German "Riechstoff" in the sense used by the author. The term as here employed is meant to apply to odorous substances of a pleasant smell and of definite chemical composition—in other words, to chemical individual compounds having a more or less fragrant odour. It is obvious that the word perfume does not apply, because a perfume is generally a mixture of various odorous and non-odorous compounds, this being invariably the case with natural perfumes or fragrant plant oils.

The information contained in the present work is to be found in the larger treatises dealing with this subject, the works of Gildemeister and Hoffmann in Germany, of Charabot and his colleagues in France, and of Sawer in this country being familiar to all who are interested in this branch of chemical technology. The arrangement of the subject-matter by Herr Cohn, however, and the inclusion of the later discoveries entitle the little work under notice to take rank as an original contribution to the literature of this branch of applied organic chemistry. In fact, taking into consideration the large amount of information compressed into the volume, and the completeness with which the ground has been covered within a comparatively small compass, it may be fairly claimed that the treatment is more scientific and less technical than in the standard treatises referred to, and chemists who wish to get a general idea of the development of their science in this newer field will find the work of Herr Cohn a very valuable compendium.

The book is divided into ten chapters and an appendix. After defining the term "Riechstoff" in the sense above indicated, the literature of the subject is given in the second chapter, not the least valuable portion of which is a tabulated list of German patents classified under the chemical families to which the patents relate, such as alcohols, ethers, esters, aldehydes, ketones, &c. In the third chapter the historical development of the industry is dealt with, and it is pointed out that while perfumery as an art is of extreme antiquity, the scientific, *i.e.* chemical, history of the compounds employed is a comparatively recent development. The same may be said, it is perhaps hardly necessary to point out, of the tinctorial industry, which existed as an art ages before it came within the province of chemical science. The parallelism between these two branches of technology does not, however, end with this historical analogy, since the development of synthetical chemistry has enabled many natural odorous compounds to be made more economically than they can be obtained from natural sources, while many such compounds unknown in nature have been synthesised in the laboratory and transferred to the factory. The author gives (pp. 20–21) a list of twenty-one firms which are engaged partially or wholly in the manufacture of natural or synthetical perfumes. Of these, three are French, and the remainder German and Swiss. It is not apparent why English and other manufacturers have been excluded. The writer of this notice has a very distinct recollection, when examining the chemical products at the Paris International Exhibition in 1900, of seeing some very good exhibits of perfumes by English and colonial manufacturers. It is true that in the application of *chemical science* to the industry Germany and France are far ahead of this country, but this does not do away with the fact that we have a few factories here which ought at any rate to figure in any list having for its object the instruction of the public as regards the present state of any particular industry.

The fourth chapter, dealing with the occurrence of odorous compounds in nature and with plant physiology, is of particular interest. A list, occupying nearly nine pages, contains the names of all the plants, arranged under their botanical orders, which yield ethereal oils. Another set of tables, occupying twenty-one pages, gives at a glance the name of the ethereal oil, the part of the plant from which it is obtained, the botanical source, the yield per cent., the physical constants (sp. gravity and rotatory power), and the chemical constituents. These tables thus summarise in synoptical form the present state of knowledge of plant oils, and in view of their importance it is much to be regretted that the printing has not been arranged in a less confusing way. The entries, as read horizontally, run across both pages, and by the time the eye has reached the last column, containing the chemical constituents of the oil—to many readers the most important item of information—the connection with the particular oil named in the first column is lost or rendered ambiguous, and the entry has in many cases to be traced back again to make sure which oil contains such or such constituents. We are all familiar with, and have often been led astray by, this want of precise correspondence between the horizontal entries running across both pages of a railway time-table. If in future editions the horizontal entries could be divided by horizontal lines running across both pages there would be no ambiguity, and the tables would be very much enhanced in value.

An interesting point to which the author directs attention is the rarity of the ethyl group in natural ethereal oils. Methyl, propyl, allyl, propenyl, are all of widespread occurrence in the molecules of natural organic compounds—ethyl occurs but in a few exceptional cases, and some of these are doubtful. We could add many to the few cases of the occurrence of ethyl in natural products given by the author, but his general statement is nevertheless correct so far as our present knowledge goes. Extreme advocates of the temperance movement might even find scientific justification for their position in this fact, which is stated by Herr Cohn in the form of an aphorism:—

"Die Natur hat einen *horror* vor dem Alkohol" (p. 28).

Unfortunately for this argument, however, alcohol (ethyl) is itself a biochemical product.

The fifth chapter deals with the modes of preparation and extraction of odorous compounds, and with their synthetical production. The special part of the work (pp. 67–175), devoted to the description of the general modes of preparation of the various compounds classified under chemical families, may be looked upon as a chapter of synthetical organic chemistry having special reference to the formation of odorous compounds, and requires no further comment.

The headings of chapter vi. (physical properties of odorous compounds), chapter vii. (chemical characters and relations between odour and chemical constitution), chapter viii. (quantitative valuation), chapter ix. (physiological relations), and chapter x. (applications of odorous compounds) sufficiently indicate their contents. Chapters vii. and ix. will be found of interest to physiologists as well as to chemists.

We have not found many slips in this little monograph, and it can be safely consulted by all who are interested in the subject. The statement (p. 184) that *m*-oxybenzaldehyde derivatives do not occur in nature is erroneous (see, *per contra*, Jowett, *Trans.* Chemical Society, vol. lxxvii. p. 707). Haller's important partial synthesis of camphor from homocamphoric acid (p. 145) might have been mentioned in the reference given in the foot-note. The omission of English firms from the list on pp. 20–21, and the faulty arrangement of the tables on pp. 38–57, have already been referred to.

Those chemists who, without any special knowledge of the subject, will take the trouble to look through this volume cannot but realise that a new and important branch of industry has been developed out of the ancient art of perfume making. It is apparent also that this newer development is the direct outcome of the application of chemical science—the utilisation for practical purposes of facts and principles discovered by laboratory research. It is the history of the coal-tar colour industry re-told, and we may fairly ask, as in the case of this last branch of manufacture, what is this country doing in the matter? The writer does not propose to do more than raise the question here, because the set reply of "imperfection of patent laws" and "want of duty-free spirit" will no doubt be considered all-sufficient by the majority of our manufacturers. Passing over this point, however, there is another aspect of the modern perfume industry which is of particular interest. Concurrently with the development of synthetical processes and the introduction of new products, a keen and searching examination of volatile plant oils has for many years past been systematically carried out in the laboratories of several foreign factories. Without wishing to be invidious, the firm of Schimmel and Co., of Leipzig, may fairly be named as pioneers in this branch of work. The semi-annual report of this firm is a perfect mine of information concerning the chemical composition of ethereal oils. Now the detection of the chemical constituents of products resulting from the vital activity of plants is also a matter of physiological importance, so that the workers in this field—prompted, no doubt, primarily by practical considerations—are accumulating a stock of material for which plant physiologists ought to be grateful. Certainly no physiologist can afford to ignore this material, buried though it may be in a trade publication, and worked up without direct scientific aim. But the methods employed and the results achieved are as purely scientific and far more definite than much of the work that at the present time passes into literature as physiological chemistry. We have as pretty an illustration as modern times can furnish of the action of pure science upon industry, and the reaction of industry upon pure science.

R. MELDOLA.

SYSTEMATIC BOTANY.

The Classification of Flowering Plants. Vol. i. Gymnosperms and Monocotyledons. By A. B. Rendle, D.Sc. Pp. xiv+403. (Cambridge: University Press, 1904.) Price 10s. 6d. net.

THE practice which is gaining ground, whereby, to the exclusion of the general text-book, the specialist produces a book in which he takes up merely his own branch of a scientific subject, is satisfactory both from the point of view of the author and the reader. The author is well qualified to express his opinions, and the reader cannot fail to learn much from the critical exposition which he is tolerably sure to obtain. The book under notice is significant not only because it is written by one of our leading systematists, but also inasmuch as it is one of the first taxonomic treatises—another is Willis's "Manual of Flowering Plants and Ferns"—which follows Engler's system of classification. Bentham and Hooker's classification is followed in most British herbaria and collections, but there is much to be said in favour of training students in the system which, originally propounded by Eichler, has been modified by Dr. Engler, one of the principal reasons being that the arrangement of orders, although not developmental, at any rate provides a sequence which is distinctly helpful.

Regarding the title, whereas it is now recognised that the spore-bearing shoots of some of the Pteridophyta may be called flowers, Dr. Rendle has used the term in its ordinary signification, and the first volume deals with Gymnosperms and Monocotyledons, while a second volume will be devoted to Dicotyledons.

After a short historical review of the principal systems of classification which have been proposed, the author takes up the Gymnosperms, making six classes by the inclusion of the two fossil groups, the Cordaitales and the Benettitales. A chapter upon the morphology of the Angiosperms follows, after which the remainder of the book is concerned with the classification of the Monocotyledons.

The Gymnosperms have been very much to the fore of late years, and there is nothing strikingly new in the treatment of the group. The interweaving of the fossil classes is distinctly rational, and the reader will find a good general account, including the results of modern research. A considerable number of the distinctive features of the genera appear in the general account, and a few in the enumeration of the genera, but the latter might with advantage have been expanded.

Dr. Rendle has devoted much time to the Monocotyledons, so that it is with special interest that one turns to this part of the book. As might be expected, one finds here a valuable exposition of the morphology both of vegetative and reproductive organs, with a succinct account of all such doubtful and subtle questions as the morphology of the flower of Orchidaceæ, or the value of the vegetative body of the Lemnaceæ. A noticeable feature is the inclusion of so many facts concerned with the vegetative part of the plant. The various devices manifested by plants during germination, a subject in which the writer has made special investigations, receive very full treatment, and numerous anatomical details are mentioned; but perhaps more striking is the value which is attached to vegetative characters for the purpose of splitting the orders up into tribes. Thus in the Aroideæ anatomical structure and the leaf-nervature are considered by Engler to be the best distinguishing characters; in the Liliaceæ the vegetative habit is important; and Pfilzer makes use of several vegetative characters in separating the sections of the Orchidaceæ. It has already been pointed out that in the enumeration of the genera of the Gymnosperms it would be useful to have more details for comparing one with another, and the same applies to the latter part of the book, where geographical distribution is fully given to the exclusion of critical data. One misses, too, those broad generalisations, which serve as landmarks or guide-posts, until the last chapter—a most important one—in which the writer gives a general review of the important characters and relationships of the series and orders of the Monocotyledons. The author has had some difficulties with his illustrations, and the blocks prepared for the book, which on the whole have reproduced clearly, but are too crowded, suffer by comparison with the illustrations found in other descriptive works; otherwise the book forms a worthy and valuable addition to the standard series which is being issued by the Cambridge University Press, and will certainly be of very great use to students of botany.

A TEXT-BOOK OF NAVIGATION.

Modern Navigation. By W. Hall, R.N. Pp. viii+378. (London: W. B. Clive, 1904.) Price 6*s*. 6*d*.

THIS is a valuable text-book on navigation at a very moderate price. Its small size and general handiness are a great feature compared with other works on the subject. The proofs throughout the book are graphically explained so far as possible, and are easily intelligible to people with a limited knowledge of mathematics; the figures and illustrations are good, numerous examples are given throughout, and the answers are tabulated at the end of the book. The extracts from the "Nautical Almanac" necessary for working any of the examples are also given.

An excellent feature in the book is the great stress laid on navigation by "Sumner" or "position lines," which are the foundation of the present practice of navigation. Without a clear understanding of position lines it is impossible to comprehend the importance of the errors in position due to working with approximate data, such as finding longitude with D.R. latitude and *vice versâ*. These and other errors are thoroughly and clearly explained by the author; in many previous works these errors have been either neglected altogether or passed over without explanation of the methods used in compiling the tables given for their correction.

The method of obtaining position by combining position lines derived from a chronometer sight and from an ex-meridian is rendered complete by the plan given of calculating the final result by factors as opposed to plotting it. It is brief and accurate, and will be welcomed by those who have experienced the difficulties of plotting results in small ships in bad weather. A very short and accurate method of obtaining these results by the "nautical slide rule" is also given. The slide rule was Mr. Hall's invention, and is useful for ex-meridians and other computations.

The treatment of the short equal altitude as a dynamical problem tends to simplify the work, and renders it easier of comprehension. The chapter on the "new navigation" is much in advance of any previous discussion of this method; the explanation is clear and the work straightforward, and the figures required for the computation are reduced. An accurate means of obtaining the final result by calculation instead of plotting is also added to this method. Mr. Hall's treatment of the "new navigation" should greatly assist to popularise this valuable means of navigating, which is applicable to any heavenly body at any azimuth.

The investigation of errors due to inaccuracies in time and altitude is satisfactory, and many interesting problems in theoretical navigation are fully explained. A valuable feature in the book is the shortening of computation by using five places of logarithms and in some cases only four places. The chapter on tides is very simply and effectively written, and supplies a want much felt by seafaring men.

In a book where so much is good, it is a pity more stress has not been laid on the utility of twilight stars for position; the author refers to displacement of the horizon due to abnormal refraction, &c., as a cause of errors in position, but does not mention the best fix that can be obtained in the twenty-four hours at sea. Ex-meridians of stars north and south for latitude, and chronometers of east and west stars for longitude, the mean of the north and south stars for latitude and of the east and west stars for longitude, obviate the effects of displacement of the horizon, and the fix is not dependent on run between observations except to the extent of a few minutes. This fix is specially valuable to men-of-war, which, owing to manœuvres, are seldom long on a steady course, thereby causing the run between observations, taken at an interval of two or three hours, often to be inaccurate. The system of notation used throughout the book and the extensive use of Greek letters are likely to confuse men already practising their profession afloat and used to calling things by their old names; it will consequently not commend itself to them. Possibly young students

who have used this system of notation in other branches of their education may find it an assistance. In conclusion, the book may be recommended to anybody who practises navigation and wishes to keep up to date.

OUR BOOK SHELF.

Birds in their Seasons. By J. A. Owen. Pp. vi+145; plates. (London: G. Routledge and Sons, Ltd., 1904.) Price 2s. 6d. net.

COMPLETE originality in mode of treatment, perfection in literary style, absolute fidelity to nature in the illustrations, coupled with immaculate accuracy in regard to nomenclature and other technical matters, would appear to be the only possible justifications for adding a new one to the long list of popular works on British birds. If it be asked whether the volume before us fulfils these conditions, there will be no great difficulty in framing a reply. In the first place, the mode of treatment is by no means original; while the following sentence from p. 53, "When talking to Lady Farren, of Bealings House, Suffolk, she told me that her family had had remarkable intimacies with wild birds," can scarcely be regarded either as a sample of elegance in diction or of accuracy in grammar. As specimens of what illustrations, so far as regards colour, ought not to be, we may cite the figure of the bee-eater in the plate facing p. 16, and that of the kingfisher on the one opposite p. 32. As instances of technical inaccuracy, for which there is no excuse, we may quote the following (among other) misspellings of scientific names, viz., (p. 20) *Matacilla* for *Motacilla*, (p. 29) *Musicapa* for *Muscicapa*, (p. 54) *Cocothraustes* for *Coccothraustes*, (p. 104) *Dafilia* for *Dafila*, and (p. 129) *Acanthus* for *Acanthis*, the latter error being the more inexcusable from the fact that the name is correctly spelt on an earlier page. If further reference to inaccuracies be required, we may contrast the statement on p. 140, to the effect that in the index the various species are assigned to their respective orders and families, with the index itself, where in many cases the subfamily, in place of the family, is given.

If cheapness and (to the uninitiated) attractive illustrations were the sole qualifications for a good bird-book, the present volume might perhaps be worthy of commendation; as it is, naturalists at any rate still consider accuracy a *sine quâ non* in works of this nature, while the British public will, we venture to think, demand something strikingly original before it accords extensive patronage to a new history of British Birds. R. L.

The Cultivation of Man. By C. A. Witchell. Pp. xv+168. (London: W. Stewart, 1904.) Price 3s. 6d.

THE author of this book is very much in earnest. He condemns modern civilisation in strong terms for its many vices, especially for its worship of money and the mammonite marriages that result from it, and urges that men should apply to their own species the methods of the breeder of cattle. He recommends polygamy, apparently in all seriousness, and not as a mere counsel of perfection. It would, of course, destroy the family, but to this Mr. Witchell has no objection. He would have the child that is born "with every sign of some inherent disease of a serious character painlessly destroyed." Certainly he speaks out fearlessly, and that is no small merit. But it is to be regretted that he did not study his subject more before writing. "Natural selection," he says, "is sometimes operative, chiefly among the poor." Considering that in England nearly fifty per cent. of the population die before the average age of marriage, this is a wonderful understatement. If we bear the facts in mind, we can hardly agree with Mr. Witchell that the business man is "the surviving type," *i.e.* apparently the type that is to survive to the exclusion of others. Business men are not a separate species. There is a continual upward movement of able men from the great underlying social stratum, and from this stratum directly or indirectly our successful men, as we call them, have emerged. In the underlying *couche sociale* there is but little accumulation of capital and comparatively little marrying for money. As to style, Mr. Witchell uses his terms vaguely. We hear of the cultivation of the young (*i.e.* by education), and of cultivation by marriage (*i.e.* by selection). But in spite of its defects the book is, much of it, interesting. It dwells upon things which seem to be entirely unknown to Royal Commissions on degeneracy, and to the many people who write letters to the papers and articles in the magazines on the subject.

Richard Meyer's Jahrbuch der Chemie for 1903. Pp. xii+600. (Brunswick: Vieweg und Sohn, 1904.) Price 15 marks.

THE year-book for 1902 has already been reviewed in these pages, and what was then stated applies with little modification to the new volume. Meyer's year-book presents an excellent, though necessarily brief, *résumé* of the year's researches in pure and applied chemistry. Possibly in other hands a slightly different selection might be made, and the weight of emphasis otherwise distributed, but in the rather wide range of subjects which have to be dealt with the question of choice must naturally vary with the taste of the individual reviewer.

Although, as was previously remarked, the small proportion of contributions of English authors does not accurately represent the relative strength of English chemistry either in quantity or quality, it is only too true that our output in chemical research and chemical literature is below what it should be. That this is due to lack of interest or poverty of ideas no one could admit, but it is to be attributed to the want of proper facilities in the way of public encouragement and State assistance.

Meyer's year-book has now reached its thirteenth year, and its success, which is assured, must be placed to the credit of its excellent staff of reviewers.

Perhaps its one shortcoming, if one may so express it, is that it is so long in coming, and many of the researches which are catalogued have assumed a new phase before the year-book appears. J. B. C.

Astronomischer Jahresbericht. By Walter F. Wislicenus. Vol. v. Containing the Literature of the Year 1903. Pp. xxxiv+660. (Berlin: George Reimer, 1904.) Price 20 marks.

IT was thought that the publication of the volumes on astronomy, a part of the "International Catalogue of Scientific Literature," might affect and possibly put an end to this most useful and valuable German publication, but the appearance of this, the fifth yearly issue, renders such an idea untenable. The volume before us is full of vitality and vigour, and the compiler and his co-workers are to be congratulated both on the high standard they maintain throughout such a laborious task and on the great value of the publication to all astronomical workers. To have not only references, but brief summaries of the contents of all, or practically all, astronomical literature published

during the past year is a real help to the astronomical investigator, and saves him much time and labour. In spite of the mass of material that is embodied in the work, the volume is, according to pages, only a trifle larger than its immediate predecessor, and somewhat smaller than vol. iii. As a matter of interest, it may be stated that the number of references in the present and the two preceding volumes are 2582 for vol. v., 2411 for vol. iv., and 2513 for vol. iii.

In conclusion, the statement made with regard to the earlier volumes, namely, that they should be found in every astronomical library and observatory, may be repeated in the present case. W. J. S. L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Forest-pig of Central Africa.

I have seen Mr. Oldfield Thomas's interesting letter in your issue of October 13 relative to the remarkable forest-pig (which he has named *Hylochoerus meinertzhageni*). With regard to the discovery of this remarkable beast, there are perhaps other names which should be associated with it as well as those of the late Sir Henry M. Stanley and myself. No mention of this forest-pig appears in Sir Henry Stanley's published works, but in conversation with myself and others he frequently told us that, in addition to hearing of a "donkey-like animal with large ears" (which afterwards turned out to be the okapi), he once saw a huge black pig, and he had reason to believe that a strange new species or genus of pig inhabited that portion of the Congo Forest near the Semliki River. I heard and transmitted similar stories told me by the natives of that forest; but even more detailed accounts were collected and sent later on by the late W. G. Doggett, who, to the great loss of zoological collecting in Africa, was drowned in the River Kagera in the early part of the present year. But I think the first definite accounts of this pig (or at any rate of *Hylochoerus meinertzhageni*) were transmitted by Mr. C. W. Hobley, C.M.G., a sub-commissioner of the East Africa Protectorate, who has recently been acting as Commissioner after the departure of Sir Charles Eliot. Mr. Hobley sent a drawing of the skull and a description of the creature from imperfect specimens he had seen on the slopes of Mount Kenia. Unfortunately his letters were delayed in transmission, so far as their reaching the Zoological Society was concerned. Mr. Hobley is now in England, and it is to be hoped that he will furnish the Zoological Society in detail with the extremely interesting particulars he has given me in conversation regarding this remarkable animal. I would remind your readers that Mr. Hobley (who as regards length of service is almost the senior British official connected with British East Africa) made the important discovery last year of marine organisms in the Victoria Nyanza.

So far, the native stories of the okapi and the big forest-pig have turned out to be true. It only remains to complete the trilogy by the discovery of a third mysterious animal, also alluded to in conversation, if not in writing, by Stanley, and mentioned by Doggett and myself. This, so far as native accounts can be crystallised into a definition, would seem to be some large tragelaphine antelope resembling the nilghai in appearance, with short, twisted horns. A horn or a pair of horns attributed to this animal was, I believe, brought home by a member of Stanley's expedition, and is possibly in the British Museum. It was seen by Dr. P. L. Sclater, and attributed by him to an abnormally developed cow eland; but so far as I could learn from my own researches and those of Doggett, the natives of the Semliki Forest were careful to differentiate this creature from either the forest eland or the bongo. Their accounts of it certainly coincide to a great extent with their stories of the okapi, though they insisted on the difference between the two animals. Perhaps there is as much truth in their stories of this large antelope with small twisted horns as there has been shown to be in connection with the okapi and the forest-pig. H. H. Johnston.

Mendel's Law: a Crucial Experiment.

I see from the published account of a recent discussion at the Cambridge meeting of the British Association that the facts of Mendelian segregation are still disputed by the biometric school of evolutionists. I venture, therefore, to submit to your readers the result of an experiment carried out at the Royal Botanic Gardens, Peradeniya, which, in my opinion, proves conclusively that in a particular cross-bred form a particular pair of characters did become segregated in equal numbers of germ cells, both male and female. The characters in question were:—the appearance and absence respectively of a yellow coloration in the endosperm of grains of Indian corn (*Zea Mays*). These characters are discontinuous in the strain examined. Among about 100,000 grains which passed under my notice, I saw only two which were partly yellow and partly white; these were counted as yellow, being presumably heterozygotes.

Some of my specimens were exhibited by Mr. Bateson at the recent meeting of the British Association, but I can now add the results of a further generation.

The facts are represented in the following scheme, in which the absence of the yellow pigment is expressed by the term "white."

I. {(1) White flint corn; extracted recessive from a mongrel strain} ♀ × ♂ {(2) Yellow flint corn; of the same mongrel strain as (1)}

II. {(3) Yellow grains} ♀ × ♂ {(4) Offspring of (1); self-pollinated white}

III. (5) 1963 yellow (49·76 per cent.) + (6) 1982 white.

The plants arising from these grains, both white and yellow, were used as seed parents in the next generation, the pollen parent being "Boone County White" dent corn. There resulted:—(*a*) Offspring of white grains—some 30,000 white grains and 27 yellow grains (0·09 per cent.); the latter were accounted for by the escape of "yellow" pollen. (*b*) Offspring of yellow grains—generation iv.:—

IV. 26,792 yellow (50·03 per cent.) + 26,751 white.

(Self-pollinated)

V. 16,582 yellow + 5681 white (25·5 per cent.)

The plants arising from the above yellow grains (generation iv.) were also used as pollen parents for a cross in which the seed parents were the offspring of "Boone County White" crossed with a strain of extracted recessives from the original mongrel flint corn. There resulted:—

2507 yellow (49·2 per cent.) + 2593 white.

I would direct particular attention to the following points:—

(1) That a perfect Mendelian result was obtained among the offspring of an impure race.

(2) Lest it should be objected that possibly the ancestry of this mongrel strain included equal numbers of yellow and white individuals, a pure recessive strain ("Boone County White," imported from U.S.A.) was introduced into the pedigree, so that the next generation (iv.) possessed at least three times as many white ancestors as yellow. On self-pollinating the offspring of yellow grains, the Mendelian proportion 3 yellow to 1 white was obtained.

(3) In two generations the female germ cells borne upon the heterozygotes were tested by crossing with the recessive form. In each case half of the germ cells were found to

bear the yellow character and half of them the white. In the last generation a similar test was applied to the male germ cells with the same result.

(4) The experiments were carried out under fully "biometric" conditions, the more accurate "Mendelian" method of careful pollination between individual plants being deliberately avoided. Thus, in generation iv. pollination was effected by the aid of the wind from some 1800 recessive parents indiscriminately.

A somewhat fuller description of the early part of this experiment has already appeared in vol. ii., part ii., of the *Annals* of the Royal Botanic Gardens, Peradeniya, and a complete account will be published in a future number of the same journal. R. H. LOCK.

Peradeniya, Ceylon, September 21.

Rock Pressure at Great Depths.

IN his address to the engineering section of the British Association, Mr. Parsons speaks of sinking a shaft into the earth for a distance of 12 miles.

I think, however, he overlooks a factor which sets a limit to the depth to which a mine shaft can be sunk. If we assume that the average specific gravity of the earth's crust is 3, the superlaying rocks would exert at a distance of 12 miles a pressure of about 440 tons per square inch.

There can be little doubt that when subjected to such a pressure the rock material would give way and flow together like a viscous fluid, and so the walls of the shaft would spontaneously close up, probably before the depth of 12 miles was reached. The breaking stress of steel is only 44 tons per square inch, and so, even were the walls encased by a steel tube, this would not avail to prevent the flowing together of the walls. GEOFFREY MARTIN.

Kiel, Preusser-str. 19[I], September 17.

I HAVE to thank you for directing my attention to Mr. Martin's letter in which he gives his views as to the probable behaviour of rock around a very deep shaft boring, and his opinion that the inward viscous flow of the rock would place a limit to the possible depth.

I have to thank Mr. Martin for directing attention to the question of this possible limitation, which was considered when writing my address and dismissed as unlikely to occur up to depths of 12 miles, basing my conclusion on general engineering knowledge of the flow of metals, of the relative impressions made on hard brass and on hard rock when struck by hard steel tools, and on the general behaviour of metal when forged.

I must first beg leave to point out some errors in Mr. Martin's figures; he has misplaced the decimal point in calculating the hydraulic pressure of the superlaying rocks at 12 miles depth, which should be 40 tons and not 440 tons per square inch.

Again, of the crushing stress required to make hardened steel flow I have no data by me, but am aware that it lies between 120 tons and 300 tons per square inch, and in the case of hardened knife edges for weigh bridges, if my memory is correct, the pressure per square inch on the area of contact reaches a still higher figure.

Again, the pressure required to make the tough brass ("cartridge metal") flow is about 80 tons per square inch.

I think that the evidence at present available leads to the conclusion that after a small amount of shrinkage of the shaft sides inwards has taken place a state of equilibrium would be established enabling the surrounding rock in its state of great compression to withstand the so-called hydraulic pressure due to a depth from the surface of at least 12 miles.

Since my address I have had the opportunity of discussing the matter with Prof. G. H. Darwin, who has kindly brought to my notice the article by Tresca, "Memoirs des Savants étrangers sur l'écoulement des Corps solides," about the year 1866, and also his own paper in the *Philosophical Transactions* of the Royal Society, part i., 1882, in which the great shearing stresses that are thrown on the earth's structure by the weight of mountain ranges on elevated continents and great depths of the sea are exhaustively treated. I would only point out that such stresses have been endured for long epochs, and that in view of the established fact that rocks are viscous, it is clear that much greater stresses could be sustained for the comparatively short time necessary to complete a deep shaft boring.

It would, however, be interesting to subject a cylinder of granite or quartz rock, carefully fitted into a steel mould and having a small hole bored through its centre, to a pressure of, say, 100 tons per square inch, and see what shrinkage in the hole would result, or a hole might be bored into the specimen through an aperture in the mould while subjected to this pressure. This pressure would correspond to a depth of about 38 miles.

CHARLES A. PARSONS.

Holeyn Hall, Wylam-on-Tyne, October 7.

The Berlin "Thinking" Horse.

IN your issue of September 22 there is a paragraph among the notes (p. 510) with reference to "Clever Hans," a "thinking horse" at present displaying his powers in Berlin. With reference to it I wish to say that twelve or thirteen years ago there was on exhibition in the Royal Aquarium, London, a horse of, if I mistake not, exactly the same stamp. I happened to be then attending lectures at the Royal College of Science, and I went to see the animal. I had, moreover, a long conversation with his trainer, who eventually let me see exactly how it was all accomplished.

With all respect to the members of the "representative committee" at Berlin, I am driven to hold that the performances recorded, counting the number of the audience, picking out the tallest man present, telling the hour, &c., which seemed so deeply to impress them, partake of the nature of a stage trick. They demonstrate what training and perseverance can do with animals rather than the possession on their part of any advanced mental powers.

The Aquarium horse was named, if I remember aright, Mahomet. He could work sums in addition and subtraction, or, for that matter, in multiplication, could count the number present in the little side-show, could make a good guess at the age of an individual, and so on. He had been taught to begin pawing the ground when his trainer looked straight at him, and to cease when the trainer turned his gaze to the floor. It is easy to see the countless changes that can be rung on this accomplishment. Telling the time on a watch or the day of the month are readily recognised to be among them. Similarly, he had been drilled into bowing his head at one tone of his trainer's voice, and shaking it on hearing another. Again one can readily imagine how this bit of instruction will lend itself to a very varied and wonderful display of cleverness.

Mahomet's owner was an American and followed the business of training horses, especially circus ones. This horse, he discovered, was very easily taught—a genius among his kind—and on him he then lavished years of most careful labour, often, he assured me, sleeping of nights in the manger at his head. The results were as shown. They were in themselves sufficiently marvellous, and represent, I fancy, the very utmost that a horse can be trained to do. "Clever Hans" would seem to be blessed with a trainer as painstaking and persevering as my American friend.

After a *séance* which I had all to myself, Mahomet's owner delayed with me to see the performance of a clever dog on the central stage. The dog, a fair specimen of a rough collie, answered questions, spelt his own name, words sent up by the audience, &c. The letters of the alphabet were placed in order in a wire frame towards the back of the stage. The collie went along the letters, picked out the one he needed, and brought and laid it before the footlights. He then went for the next. Wonderful I thought the performance until my friend the horse-trainer showed me how it was done. The collie always began at A. He then trotted along up the alphabet until he reached the one he needed. His master carried his gloves in his hand. A little twitch of the gloves as the dog passed the particular letter wanted was the cue. The well trained animal took in the slightest stir of the gloves with the corner of his eye. This dog even played a game of cards—and won. A hundred and one variations might be made on the same trick.

I have read since in an American newspaper of a Tennessee

pig that acquitted itself creditably in practically the same *rôle*. Doubtless, if the report were true, the porker had swallowed an equal amount of learning.

The collie was without doubt a good, clever one. As member of the Irish Collie Club I have for years past taken a fancier's interest in this particular breed, and I have observed every degree of intelligence, from the brute that could scarcely be taught to bark at a cow—oftenest with a pedigree as long as your arm—to the affectionate animal that could guess almost your thoughts and your passing temper, and was always in perfect sympathy with your moods. The best of these, however, falls far short of a good Irish water spaniel. From my experience, I may be allowed to say in passing that no breed is so teachable—has such brain-power, if you like—as the latter, once he has reached the age of nine or ten months. As puppies I found them rather stupid.

Performances similar to that of the Royal Aquarium collie are not very rare. There are, indeed, some other ingenious stage devices by which a dog can be taught to spell—every word in the dictionary if you are so foolish as to let it be known—and to converse, so to speak, in Russian as readily as in English, but the devices are rather worked out.

Usually such show dogs modestly protest before the audience (through their trainers) their inability to do more with certainty than spell correctly words of three letters, and when pushed they get perplexed and make mistakes. This, for them, is sound policy. It is only when they grow too bold and set up as "thinkers" that they are found out. My American trainer, with Yankee shrewdness, used to claim for his dark bay charge that when he had totted up a row of figures he should be reminded of the number to be carried on to the next column. This was fair enough. It, too, served to baffle the over-canny. That the arithmetician's education could never overstep that was just the puzzle they fastened on and worried over. I wonder what the German professors, good, easy men, would have said had they seen, as I did, Mahomet figure out a sum with his tail to the board!

I may be permitted to add that about the same time I interviewed the ape famous for counting, "Sally" by name, in the London Zoological Gardens, and I was in no way impressed by her intelligence. After what I have written it is not hard to suggest two or three ways by which the oracle could have been worked. I saw her count her straws for the keeper alone, and that gentleman appeared to me none too tolerant of questions or of interference.

I am prepared for believing, however, that counting is not beyond the scope of an animal's powers. It is said that Scotch shepherds count their flocks of sheep in this wise: they drive them through a gap, and the faithful collie ticks off by a bark every score as it passes through.

It is not of late alone that clever horses have come to the front. I happen to possess a MS. diary written by a co. Leitrim man in 1658 and 1659. In the first of these years the writer, James Reynolds, accompanied to London his uncle, Sir James Ware, Auditor-General of Ireland, and famous as an antiquary. Among the sights of the metropolis he records that he saw a "Nagg" which could count, answer questions, and fire off a small cannon.

There are undoubtedly degrees of intelligence within limits in all mere animals. They are particularly observable in the dog and horse—the most highly developed in this respect of all our animal friends. As every jarvey knows, each horse has a character of its own and mental powers all its own. The same is true of our canine subordinates. A neighbour of mine has a cat which climbs up the door-post and opens the latch with her paw when she wants to enter the house. This for a cat is, I think, more wonderful than are all the performances of the Berlin "thinking horse" for a steed. It is a trick, indeed, I have seen taught two or three dogs. But the cat has had no training. She owes her cleverness solely, I am assured, to her own powers of observation.

I am open to conviction, but I am greatly afraid the "German representative committee," including the "professor of the Physiological Institute of the Berlin University," that have reported, according to the daily Press, on "Clever Hans" have written themselves down as at least not ungullible. JOSEPH MEEHAN.

Creevelea, co. Leitrim.

Misuse of Words and Phrases.

In your issue of October 13 attention was directed in the letter column to the misuse of language by English scientific writers. Since the subject of the indictment is one of importance, and since the criticism is in my opinion well founded, I am writing to support it.

There seems to be a tendency growing among writers on scientific subjects, both in pure and applied science, to modify the English language to such an extent as to give rise to no small anxiety with respect to its future state in scientific literature.

Even if language is plastic, its plasticity is limited. Since science is based upon accuracy, the communication of scientific thought should be accurate. Yet in a large percentage of scientific publications in the English language sentences that are grammatically ambiguous occur frequently, and not seldom such as have no meaning. The sense intended may be, indeed, derived from them, either through study of the context, or through exertion of one's scientific instinct; but it is surely just to demand that the unnecessary labour of a cryptogrammic research be not inflicted on the reader. Viewed in its crudest aspect, such misuse of language is an act of discourtesy to the reader; so legitimate resentment should provoke no surprise in the author.

It is common in a certain class of publications to meet files of nouns marching through the paragraphs. Although this may at times indicate a well grounded derivation of adjectives, yet it is frequently unnecessary, either since a suitable adjective exists, or since a prepositional or adverbial phrase conveys the meaning exactly.

Various other parts of speech are frequently misused.

There is no need for fine style in scientific literature; but good style is obligatory, because it is an essential concomitant of the accurate expression of clear thought.

October 17. F. ESCOMBE.

SCIENCE IN SPORT.[1]

THE late Prof. Tait was probably the first to bring scientific principles and methods of experiment to bear upon the mystery of the flight of a golf ball. Newton, in a pregnant note on the deflection of a tennis ball in air, gave the foundation principle, which curiously enough both Euler and Poisson rejected as of no account. Robins and (later) Magnus experimented on the effect, but it was left to Tait to work out the problem in detail. His papers on the rotating spherical projectile virtually form a new chapter in the dynamics of rotation. In these papers, and elsewhere in more popular form (*e.g.* in NATURE, vol. xlii. p. 420, 1890), he lays down clearly the conditions which must be fulfilled if a man is to drive a far and straight ball. Slicing, pulling, topping, are all completely explained along the lines of Newton's remark, numerical tests are supplied, and various possible curves of flight are calculated out and drawn.

Tait showed how the ball must be started if it is to finish aright. The difficulty the ordinary golfer experiences is to give the proper start. This is *his* problem; and the mode of solution is as varied as the temperament of the player. There is, in fact, a continuous gradation of style and effort from the simple minded golfer whose one aim is to hit the ball to the nervous and pathetically anxious one who looks to every detail of grip and stance as a *sine quâ non* to perfection. There must, however, be a best way for every individual, and in discovering this the aspirant no doubt should be guided by scientific principles.

This is, perhaps, the most important practical standpoint from which to view Mr. George W. Beldam's interesting and beautiful book, "Great Golfers. Their

[1] "Great Golfers. Their Methods at a Glance." By George W. Beldam. Pp. xxiv+481. (London: Macmillan and Co., Ltd., 1904.) Price 12*s.* 6*d.* net.

"The Art of Putting." By Walter J. Travis and Jack White. Edited and Illustrated by G. W. Beldam. Pp. 32. (London: Macmillan and Co., Ltd.). Price 1*s.* net.

Methods at a Glance." It is doubtful if methods essentially kinetic can be effectually disclosed by glances at a few critical positions statically pictured by instantaneous photography. Nevertheless, Mr. Beldam's idea is a good one, and has been carried out with great manipulative skill. The idea is to obtain accurate pictures of some of our best golfers, professional and amateur, in their characteristic poses as they address and play a ball, and to be able from those pictures to deduce important conclusions. By a simple system of rectangular coordinates, with origin at the ball and one axis in the desired direction of flight, the positions of the player's feet are accurately shown. The grip of the club, the poise of the body at different stages of the stroke, and the position of the arms at

Fig. 1.—Golf Ball leaving an Iron Club after impact. From "Great Golfers."

the top of the swing, are all recorded as the player is taking his normal stroke. The descriptive discussion is given by the four professionals Vardon, Taylor, Herd, and Braid in regard to their own pictures, and by Mr. Hilton in regard to the pictures of the amateurs.

It is evident that all the motions of the body, head, arms, thighs, legs and feet are governed by the way the club is raised to the top of the swing and brought down again to the finish of the stroke. Keep the head steady—best done by keeping the eye on the ball—keep down the right elbow, and practice will do the rest. The backward swing of the club and arms makes the body rotate easily about a vertical axis, and produces naturally the characteristic bending of the left knee (in a right handed player). It is interesting by measurements on the successive positions of the player as he (1) addresses the ball, and (2) reaches the top of the swing, to determine how much, if at all, the head rises. In this respect, for example, Vardon and Taylor differ decidedly. Exactly the instant during the swing at which the left leg begins to support the greater part of the weight of the body is not clearly brought out.

There are of course great difficulties, even with an exposure of only one-thousandth of a second, in catching the player at the very instant the ball is struck, or just before the impact takes place. Out of the 268 "action photographs" three only can be accepted as giving any information regarding this critical moment. It is just here, in fact, that a word of criticism might be offered. From a scientific point of view the numerous pictures representing the *finish* of the stroke are comparatively worthless—beautiful and striking and "characteristic" though they are as showing the pose of an athlete who has just done the deed. We could gladly have dispensed with half a hundred of these for the sake of even an extra half dozen like Taylor's Nos. xxi. and xxviii. Unfortunately in these particular pictures the ground is not chalked off with the pattern of six-inch squares, so that we can only roughly estimate the position of the ball when it was struck.

In plate xxviii. (here reproduced) the blurred image of the moving golf club and of the still more rapidly moving ball are finely brought out, while the player, with the exception of the right arm and hands, is as steady as a rock. We may roughly estimate the velocity of the ball to be nearly $2\frac{1}{2}$ times that of the club. The exposure is stated to have been 1/1000 of a second. The blurred image of the club head may be estimated at not less than 4 inches broad, giving a velocity of about 370 feet per second for the club head *after* impact. This would mean fully 900 feet per second for the ball. Tait gave a great deal of attention to this point, and concluded that a well driven ball rarely left the ground with a greater velocity than 350 feet or 400 feet per second. The discrepancy is great, and points to some fundamental error either in Tait's mode of measurement of the velocity or in Mr. Beldam's mode of measurement of the exposure. The photograph tells its own tale, and is above criticism; but we have no precise account of how the times of exposure were estimated. A few more pictures of the kind just discussed, showing the *motion* immediately before impact, at impact, and immediately after, with different clubs and different balls, would give some really important information as to velocities and coefficients of restitution.

Every golfer knows the value of steady and accurate putting, and how curiously variable is his "form" in this respect. Mr. Beldam's photographs bring out the very familiar fact that stance and pose are of comparative insignificance. In a small pamphlet on "The Art of Putting" Mr. Beldam has notably supplemented his volume. Here we have six photographs illustrating the style of Mr. Travis, Amateur Champion of 1904, and fourteen of Jack White, the Open Champion. Each discusses his own methods. The professional's account is particularly instructive, and touches on many difficult points, such as putting uphill or downhill or on a side slope; but here, as in billiards, a knowledge of how to do is one thing, and the power to do quite another.

It is certain that as an exponent of good method no book on golf can compare with "Great Golfers"; and we have indicated above that Mr. Beldam's photographs have a scientific value quite apart from the "science" and art of the royal and ancient game.

C. G. K.

A GERMAN'S DESCRIPTION OF ITALY.[1]

THE volume before us might not inappropriately be called an "Encyclopædia of Italy." It deals in the first eight chapters with the general geographical and geological features of the country, its shape, its surrounding seas, the relief of its principal mountain ranges, its geological construction, its climate, hydrography, fauna and flora. The next seven chapters deal generally with the Italian people and their life, the subject being classified under the various headings of population, history, products, commerce and trade, political institutions, religion, art, language and science. The sixteenth chapter, which is devoted to "Topography," extends over more than 120 pages; in it the various districts of Italy are taken in turn, and their principal towns, antiquities, rivers, and mountains are dealt with in some detail.

To write a treatise of this character is no easy task, if the book is to convey anything like an adequate account of the country. To test the completeness with which the author has accomplished his work we have consulted the book under various headings selected at random, and in few cases have we found any point of real importance or interest missing. The account given of the Italian lakes is very thorough, and contains details of their principal features, as well as information of a statistical character and several illustrations. Still greater interest attaches to the sections dealing with volcanic action and earthquakes, in which excellent illustrations are given of Vesuvius in its various aspects, the Solfatara, Etna, and the Lipari islands; and the references to the changes of relative level of the land and sea at the Temple of Serapis and the Blue Grotto may be cited. The chapter on "Plants and Animals" is not, perhaps, so fully treated as other parts of the book, and also there are a few slight inaccuracies, probably resulting from the difficulty of finding exact equivalents for the German words in the English translation. Whether the name "manna" is correctly applied to the sap of the Calabrian flowering ashes (p. 114) is a point on which we are not competent to pass judgment; it should, however, be mentioned that "manna of the desert" has been considered to be a lichen. When the fruit of the olive is described as green, brown, or red (p. 116) the latter term hardly appears suitable. On p. 120 the name "gorse" is applied to *Genista hispanica*, a plant which, indeed, often takes the place of our English Ulex in Italy, but can hardly be properly called "gorse."

Again, it is doubtless probable, as stated on p. 122, that fishermen often apply the term "frutta di mare" to shell fish generally, but correctly speaking this is the name of the edible echinus. The large cuttlefish or octopus is too characteristic an article of food at Naples to be omitted from the list, and the Agoni and large trout of the Lombardy lakes ought to receive some mention.

FIG. 1. Arco naturale in Capri. From Prof. Deecke's "Italy."

We pass on to the chapter on "Political Institutions," where it is particularly interesting to see what a German thinks of the slipshod way things are done in a free country like Italy. Prof. Deecke strongly condemns the abuses resulting from political liberty and local government as practised in that country; for example, he says (p. 253):—

"The successful working of a liberal constitution and self government presupposes a conscientiousness and disinterestedness among the officials. There is little of these qualities to be seen in Italy. The honorary posts are looked upon as a kind of milch-

[1] "Italy, a Popular Account of the Country, its People, and its Institutions (including Malta and Sardinia)." By Prof. W. Deecke. Translated by H. A. Nesbitt, M.A. Pp. xii+485; illustrated. (London: Swan Sonnenschein and Co., Ltd.; New York: The Macmillan Co., 1904.)

cow which must be milked with all one's force when one is at the helm. In addition to this there is the want of scruple as regards public money, which, according to a very general view, exists in order to be appropriated to any plausible pretext or to be secured for one's family or friends. . . ."

The author also condemns the wasteful system which exists in municipal bodies of embarking on costly enterprises, which are discontinued after the next municipal election when another party comes into power. In this way the money of the ratepayers is squandered away with no return. In regard to the confiscation of the monasteries, the following sentences may be quoted:—

"These regulations, however, have been applied in the half and half manner characteristic of Italy." "The vast ecclesiastical possessions seized by the State were sold or squandered in the course of a few years." "Thus the enormous source of income which might have proved a blessing to thousands and created a small class of landed proprietors has failed to bestow the expected benefit on the country."

On p. 279 we are told, "The Building Societies are almost a public calamity." "The hideous new quarter near the railway station at Naples, on the Vomero at the same town, and in the Campus Martius at Rome are the best proofs of the results of carrying on business in this manner."

Speaking of universities, Prof. Deecke makes the following remarks, which are equally applicable to our English system:—"There is another difference as compared with Germany, namely, that the Professor appointed to hold a course of lectures is not allowed to take a general survey of his subject or to handle it fully, but has to dispose of a prescribed section of the subject in the three hours a week, so that at the final examination questions can be set within this narrow circle. The instruction given at the Universities naturally suffers, and still more the scientific training of the students, which can only be described as unsatisfactory."

The chapter on art, language and science contains a list of the principal learned academies of Italy.

In connection with music, the author remarks:—"The music of Wagner, poor in melody and difficult to understand, has not become naturalised in Italy."

As illustrating more fully the wide and varied range of the subjects treated, we may instance the statement that there are ten times as many murders in Italy as in Germany, the regulations limiting the number of barrel-organs in Naples, the number of pedlars, the method of smelting sulphur, the statistics of Italians abroad, observations of terrestrial magnetism, the superstition according to which cats' tails are docked, a portrait of Garibaldi and a plan of the harbour of Genoa, photographs of Roman cattle, and descriptions of Italian cheese.

The section on topography might be very well studied by anyone contemplating a tour in Italy. It gives an excellent account of the features worth noticing in different districts, and it includes the Maltese group as well. It is well illustrated. But for that matter the whole book would well repay reading before or after visiting Italy. The average tourist contents himself when visiting a new country with seeing the principal churches and picture galleries, usually conducted by a guide, but to visit a country properly a wider survey should be taken, and a book like the present consulted. To the writer this book brings back the most pleasant reminiscences of bygone travels in Italy; to the reader who has stayed at home it presents as graphic a picture as any book can present of everything that is Italian.

G. H. BRYAN.

DISEASE-PROOF POTATOES?

THE recently established National Potato Society has as one of its many objects the discovery of a "disease-proof" potato. Even if it only succeeds in throwing some light on the relative immunity of some varieties, and on the causes of that comparative exemption, it will do some good. Next to wheat, there is no crop more important in this country, and whilst wheat-growing seems to be getting more and more unprofitable, the culture of potatoes is extending so much that it is evident that the growers must find some good reason for the increased production. The enormous importations from Germany, Holland, and other countries should serve as a stimulus to our farmers, for it is obvious that, excepting in the comparative cheapness of labour, those countries possess no special advantages over our own in the matter of potato-growing.

In dealing with the question of the potato disease, by which we mean the rotting caused by the fungus *Phytopthora infestans*, there are two principal subjects of inquiry: first, the life-history of the fungus; second, the "constitution," if we may use so vague a term, of the potato plant.

Neither of these subjects can be thoroughly investigated by the average potato grower. All important as they are, they lie outside the range of his capabilities. It is to our research stations or to individual experimenters that we must look for guidance. Even now the life-history of the fungus is imperfectly known. We do not know *for certain* what becomes of it in the winter, nor why it suddenly bursts into activity under certain atmospheric conditions. We do not know for certain whether it can pass any portion of its life on some other plant under another guise. We do not know for certain if a resting spore is formed, and our knowledge of the mycelium during the winter is, for the most part, conjectural rather than real. Here, then, are subjects for inquiry at once of the deepest physiological importance and of the greatest practical value.

As to the so-called disease-resisting varieties, also, further information is wanted, and this the practical man might supply. A visitor to the recent display of potatoes at the Crystal Palace, seeing the innumerable varieties there exhibited, might well wonder whether they all "supplied a want," and it was consolatory to the casual observer to hear even experts acknowledge the impossibility in some cases of discriminating one variety from another by the tubers alone. Had it been possible to show the haulms, the foliage, and the flowers and fruits with the tubers, as was, in fact, done in one or two cases, some points of distinction might have been forthcoming.

But although there is often a close resemblance between the tubers of one variety and those of another, and although it frequently happens that tubers of quite different shapes may occur on the same plant, yet it does not appear, from our present knowledge, that this similarity on the one hand, or this diversity on the other, is associated with any structural change which shall indicate either immunity from disease or increased susceptibility to its attacks. In the case of potatoes, certain varieties, like Sutton's Discovery, are unusually robust, producing haulms almost woody in their character, and these are found to be less susceptible to disease than are others of softer, more juicy consistence, which are more easily penetrated by the fungus hyphæ. Differences of this character, dependent on increased vigour of growth, are recognised by the growers, but we are not aware that microscopists have as yet made any researches into the structure of the potato foliage with special reference to its immunity from, or susceptibility to, disease. It

is certainly desirable that such investigations should be made, although, in view of the investigations on various species of Bromus and their liability to disease made by Marshall Ward, Salmon, and others, it is doubtful whether mere microscopic investigation of the internal economy will furnish more valuable results than comparative macroscopical study of the haulm and foliage. Great physiological differences may, on the one hand, exist in conjunction with uniformity of structure, and, on the other hand, great external differences may exist without appreciable physiological diversity.

Some improved method of investigating the nature and construction of the protoplasm seems to be required, and when this is obtained our knowledge of the relation of function to structure will of necessity be much enhanced. At present the three most efficient means of preventing or combating the disease are the production of immune varieties, the use of sulphate of copper in the form of Bordeaux mixture, and the adoption of "high-moulding," by means of which access of the fungus spores to the tubers is at least in part prevented.

NOTES.

We regret to announce that Dr. Selim Lemström died at Helsingfors on October 2, in the sixty-sixth year of his age. Dr. Lemström devoted much attention to experimental investigations on the uses of electricity in stimulating the growth of cereals, vegetables, and other plants.

As already noted in these columns, a distinguished party of French physicians and surgeons has during the past week paid a visit to London in order to become acquainted with our medical schools and hospitals and to study their methods and administration. About 150 gentlemen availed themselves of the opportunity, amongst others M. Lucas Championnière, Prof. Poirier, Prof. Marie, Prof. Netter, M. Louis Martin, M. Huchard, M. Triboulet, president of the French committee, and Dr. Sillonville, secretary. An English committee, with Sir W. Broadbent as president, Sir T. Barlow and Dr. Dundas Grant as treasurers, and Drs. Dawson Williams and Jobson Horne as secretaries, made arrangements for the reception and entertainment of the visitors. Visits were paid to the hospitals, general and special, the physiological laboratories of the University of London, University and King's Colleges, the Lister Institute, the Royal College of Surgeons, cancer research laboratories, the County Council laboratories at Claybury, the London School of Tropical Medicine, and to the Islington Infirmary. The visitors expressed themselves as specially pleased with the order and neatness, the decorations, &c., and the home-like comfort of the wards of our hospitals. During the visit they were the guests of the editors of the *Lancet*, Dr. and Mrs. Dundas Grant, the Dean of the Faculty of Medicine of the University of London and Mrs. Butlin, and on Wednesday evening, October 12, they were entertained at a farewell banquet at the Hotel Cecil, at which Sir W. Broadbent presided. The chairman, in proposing the health of the King, alluded to His Majesty's interest in hospitals and medical work. The other toasts were the President of the French Republic, and "Welcome and *Au revoir*," proposed by the chairman; our guests, by Dr. George Ogilvie, responded to by M. Championnière and Prof. Huchard; and the Faculty of Medicine of Paris, by Dr. Pye-Smith, responded to by Prof. Poirier, Prof. Chauffard, and M. Triboulet. The visit has been a great success, and should prove a benefit to both nations.

REUTER reports that the commander of the *Neptune* Scientific Research Expedition to Hudson Bay and the northern waters has returned to Ottawa with several interesting mementoes of the Franklin Expedition.

MR. H. MARTIN LEAKE, of Christ's College, Cambridge, has been appointed economic botanist to the Government of the United Provinces, India, and proceeds at once to the botanic gardens, Saharanpur, N.W.P.

A CONFERENCE of members of the Museums Association and others interested will be held at Warrington on Saturday afternoon, October 29, for the purpose of discussing subjects of common interest to those concerned in the work of museums, art galleries, and kindred institutions.

THE *Electrician* announces that a congress for the purpose of discussing the production and application of Röntgen rays will be held in Berlin on April 30, 1905. The occasion is the tenth anniversary of the discovery, and Prof. Röntgen will be present as the guest of honour.

A COURSE of twelve Swiney lectures on geology will be commenced by Dr. J. S. Flett at the Victoria and Albert Museum, South Kensington, on Monday, November 7. The subject of the lectures will be "Geology—the Record and its Interpretation." Admission to the course is free.

THE King has consented to give his patronage to the Sanitary Institute, which is carrying on a large work in teaching and examining in hygiene and sanitary science, both in the United Kingdom and in other parts of the Empire.

AT the opening meeting of the new session of the Royal Geographical Society, to be held at the Albert Hall on November 7, Captain Robert F. Scott will deal with the leading features of the National Antarctic Expedition. At subsequent meetings Lieut. Royds will deal with the meteorology of the expedition, Mr. Ferrar with the geology, Dr. Wilson with the zoology, and Mr. Bernacchi with the terrestrial magnetism.

THE inaugural meeting of the Association of Economic Biologists will be held at the rooms of the Linnean Society, Burlington House, on Tuesday, November 8, at 3 p.m. All who signify to Mr. W. E. Collinge, the University, Birmingham, their intention of becoming members before October 31 will constitute the list of original members.

WE learn from a note in the Isle of Man *Times* that within the last few days the large pond at the biological station and fish hatchery, Port Erin, has been in great part emptied for the purpose of examining the condition of the stock of fish of spawning size and the state of the bottom of the pond. Out of 180 large adult plaice which had been, at various times since the autumn of 1903, deposited therein, 168 were safely transferred to the lower supply tank. The condition of these fish was all that could be desired; they were thick, strong, and well fed; many were very large. There were also very many young plaice which were hatched at the station last Easter from parents in captivity—the large fish alluded to, and so have been under artificial conditions—made as natural as possible—during the whole of their existence. These young plaice, four to five months old, were from one to four inches long (the large variation in size is noteworthy), active, and well nourished. Some hundreds were picked out for experiment in rearing in small wooden tanks lately fitted up. There were also found some shrimps, some young of the cod tribe, and a small shoal of young herring (whitebait size). All these must have passed through the pumps from the sea, probably in a larval condition. The young plaice examined were found to be feeding mainly on Copepoda.

It is announced in the *Times* that the Secretary of State for India has appointed an expert committee to assist in and supervise the preparation of an abridged and revised edition of the "Dictionary of Indian Economic Products," by Sir George Watt, the editor of the original work, which was issued in seven octavo volumes, with index, between 1889 and 1893. The new edition will be compressed into two volumes, and care will be taken to give the latest figures and information available in respect to the products described, and to their commercial development. Special facilities have been afforded for Sir George Watt to carry on the work of revision at Kew, and Sir W. Thiselton-Dyer, director of the Royal Botanic Gardens there, is chairman of the committee, the other members being Mr. T. W. Holderness, secretary of the Revenue and Statistics Department, India Office; Prof. Wyndham R. Dunstan, director of the Imperial Institute; and Mr. J. S. Gamble, late of the Indian Forest Department.

A second conference of local authorities, owners of foreshore, and others interested in the defence of the coast against the encroachment of the sea in the counties of Norfolk and Suffolk was held at the Guildhall, Norwich, on October 15, for the purpose of considering the report of the committee appointed by the previous conference. Dr. H. B. Walker, mayor of Lowestoft, presided. The report stated that the Government had been asked to adopt promptly such measures as would preserve the sea coasts from waste and provide a more equitable adjustment of the financial burden which now pressed exclusively upon the immediate frontagers. Mr. Nicholson (town clerk of Lowestoft) said that the Board of Trade had declined to appoint an engineer to make inquiries. A resolution was adopted in favour of communicating with other authorities in Great Britain whose districts abut upon and are liable to erosion by the sea, and with members of Parliament representing such districts, to ascertain how far they would cooperate in an application to the Government to accede to the recommendations contained in the report.

It is reported that the Antarctic relief ship *Morning* has brought home a considerable collection of natural history specimens which will supplement those obtained by the *Discovery*. A considerable amount of dredging was accomplished on the *Morning*, so that the collection consists chiefly of marine invertebrates. As she is an Admiralty ship, all the specimens collected will doubtless be handed over to the British (Natural History) Museum, where the *Discovery* collections have already been received.

In the *Irish Naturalist* for October Mr. D. R. P. Beresford records the discovery in Ireland of a second nest of the Continental wasp, *Vespa rufa austriaca*; the first was found in 1902.

In his report for 1903 (issued in the *Circulars* of the Royal Botanic Garden) the Government entomologist for Ceylon refers with satisfaction to the appreciation of the efforts of his department to aid cultivators in freeing their plantations from the attacks of noxious insects. The report deals largely with those affecting the tea-plant.

The contents of part i. of the second volume of the quarterly issue of the *Smithsonian Miscellaneous Collections* include a continuation of Messrs. Ulrich and Bassler's revision of the Palæozoic Bryozoa; a paper by Miss E. Wood on Devonian crinoids, with descriptions of new genera and species; and a review of the triton and frog-shells by Mr. W. H. Dall, in which several new subgeneric names are proposed.

The Society for the Protection of Birds has issued as a leaflet an abbreviation of an admirable article by Mr. W. P. Pycraft on the manufacture and sale of the so-called "osprey" plumes, which recently appeared in *Knowledge and Scientific News*. In the October number of *Bird Notes and News* the society directs attention to the marked decrease in the number of swallows visiting this country and the Continent during the last few years. The scarcity is attributed to the capture of these birds for their plumage and for the table, and it is suggested that extensive netting must take place at both migrations, though where this occurs has not been ascertained.

According to the report of the Manchester Museum for 1903–4, it appears that the most important acquisition received by the museum during the period under review is the Cosmo Melville herbarium, which was presented by the chairman of the committee. The contents of this collection, stated to be the only private one of which the limits extend beyond the Palæarctic region, are estimated to number more than 40,000 species. It is incidentally mentioned that the skin of Napoleon's Arab charger "Marengo," which is reported to have been lately discovered in a cellar at the Louvre, was formerly in the Manchester Museum. The skeleton is, we believe, in the United Service Museum.

The latest of the series of handbooks to the contents of the Horniman Museum at Forest Hill, issued by the London County Council, relates to the fresh-water aquariums and vivariums. In these receptacles are exhibited a large number of the common British invertebrates, together with a selection of fishes, reptiles, and amphibians. The descriptions of the various species grouped are written, as a rule, in language which can be well understood by the ordinary reader; we may point out, however, that if it is necessary to explain a term like "Porifera" it is equally necessary to do the same in the case of one like "unicellular" (p. 4), the meaning of which, we venture to think, will not be comprehended by 1 per cent. of the visitors to the museum.

In the October issue of the *Journal of Conchology* Mr. A. J. Jukes-Browne refers to the dissatisfaction which exists among many naturalists on account of the sweeping changes proposed in zoological nomenclature by a strict and slavish adherence to the rule of priority. He points out that no less than a dozen familiar names of molluscan genera would have to be changed if those used in a certain obscure work be admitted. The evil is a very real one, and we refer to two points in connection with it. In the first place we notice that in the main only systematic naturalists adopt the proposed changes, anatomists, physiologists, &c., adhering to the old names; this at once introduces a dual system of nomenclature, which is much to be deprecated. Secondly, it may be admitted that to specialists the changes in nomenclature in their own particular groups are not very serious, as they ought to be able to keep abreast of them; but to "all-round" naturalists such changes are very serious indeed. An authoritative conference on the subject is urgently needed.

In the *Revue générale des Sciences* (September 30) M. Ernest Fourneau describes the chemical constitution of the chief local anæsthetics, such as cocaine, eucaine, &c., and discusses the nature of the chemical groups and their arrangement on which analgesic action seems to depend.

We have received Mr. W. Martindale's price list of drugs, chemicals, surgical instruments, &c. The catalogue

of drugs, chemicals, and microscopical stains seems to be very complete, and we note that several pages are devoted to X-ray apparatus.

IN the *Bulletin* of the Johns Hopkins Hospital for September (xv., No. 162) Dr. Howard Kelly describes an ingenious instrument, the piezometer, for measuring degrees of resistance, *e.g.* rigidity of the abdominal wall or the limits of a tumour. Reviews of books and some medical and medico-historical articles complete this excellent number.

IN the *Bulletin international de l'Académie des Sciences de Cracovie* (No. 7, July, 1904) M. Nitsch describes some experiments on rabies in rabbits, and states that the earliest symptoms of infection are movement of the jaws and grinding of the teeth. M. Maziarski discusses the relation of the nucleus to the cytoplasm, and M. Kowalewski describes a new species of tape-worm, *Tatria biremis*, found by him in the intestine of *Podiceps auritus*.

THE Liverpool School of Tropical Medicine has issued an important series of reports on trypanosomiasis by Drs. Dutton, Todd, and Christy, which seem to establish conclusively that sleeping sickness is trypanosomiasis, although there are severe and even fatal cases of the latter in which the somnolence is not observed. In one of the expeditions of the school a blood-sucking larva of nocturnal habits was found to be abundant in many districts of the Congo.

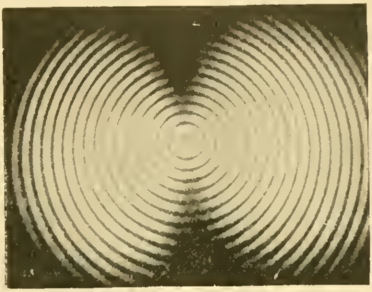
IN the October number of the *Journal of Hygiene* (vol. iv., No. 4) Dr. Boycott discusses the diagnosis of ankylostoma infection with special reference to the examination of the blood, Dr. Todd describes experiments on the preparation of dysenteric toxin and antitoxin, and Dr. Castellani details researches on the etiology of dysentery in Ceylon. The Swedish Antarctic Expedition forms the subject of an article by Dr. Ekelof, the medical member of the expedition, in which he discusses its medical aspects.

AN interesting report by Drs. Jobling and Woolley on Texas fever of cattle in the Philippine Islands is published by the Bureau of Government Laboratories, Manila (1904, No. 14). Some imported American cattle, after inoculation for rinderpest with the blood of native animals, rapidly died with all the symptoms of Texas fever. Investigation proved that Texas fever was endemic among the native cattle, which, however, had acquired an immunity and suffered but little from the disease. The species of tick in the islands was found by Mr. Banks, Government entomologist, to be the Australian variety (*Boophilus australis*).

THE Meteorological Department of the Transvaal (Mr. R. T. A. Innes, director) has issued its administration report for the year ending June 30, 1904. Such of the instruments ordered from this country as had then arrived there had been distributed, and continuous records of some elements would be available from July 1, 1904. Rain gauges were considered to be the most important for immediate erection, and nearly 200 voluntary observers had been supplied with these instruments. All the observations made in the colony will be published in an annual volume. Telegraphic or telephonic weather reports are received daily from twenty-nine stations, and telegrams exchanged with other colonies. The staff is at present much too small for the important work in hand.

PART iii. of the new monthly journal *Le Radium* contains a summary by Prof. Turpain of the present methods of producing high frequency currents, an account by M. M. Moulin of the *n*-rays and the methods used in their study, and an article by Dr. A. Darier on the physiological effects of the radiations from radio-active substances.

BY slightly modifying Pocklington's method of observation, M. H. Dufet has succeeded in making measurements of the rotatory power of biaxial crystals in the direction of the optic axes. The results are described in the October part of the *Journal de Physique*. With the apparatus employed it becomes possible to make observations with much thicker plates than have hitherto been used, and in this way to observe a large number of turns of the isochromatic spirals instead of only their commencement. The paper is illustrated by photographs, and the accompanying figure represents the rings and spirals for the violet mercury



line λ 4358 in the case of the slightly birefringent substance rhamnose. The plate used was cut normally to the stronger axis, and had a thickness of 0·27 mm. The rotation along the symmetrical optic axes of crystalline *d*-tartaric acid has a value of $-114°$ per cm.; it is a striking fact that the rotatory dispersion of solid tartaric acid is normal seeing that in aqueous solution the dextro-rotation of the acid undergoes very anomalous changes with variation of the wave-length. All the biaxial substances studied which were found to show rotatory polarisation in the solid state are capable of existing in enantiomorphous hemihedral forms.

AN interesting paper by T. Godlewski on the dissociation of electrolytes in alcoholic solution appears in the *Bulletin* of the Cracow Academy of Sciences (1904, No. 6). The well known dilution law of Ostwald is satisfied by all the eight acids which have been examined. The order in which the acids appear, when arranged according to the magnitude of their electrolytic dissociation constants, is different from that which holds for aqueous solutions of the acids.

A VERY sensitive method of testing for minute traces of gold is described by J. Donau in the *Sitzungsberichte* of the Vienna Academy of Sciences (vol. cxiii. p. 180). A silk or woollen fibre, previously treated with a solution of tannin or a solution containing pyrogallol and stannous chloride, is immersed in the acidified solution to be examined for gold. If present, the latter is precipitated in the colloidal form on the fibre, and imparts to it a red coloration which is observed by examining the fibre under the microscope. With a silk fibre, mordanted with pyrogallol and stannous chloride, 2×10^{-9} gram of gold can thus be detected.

SOME interesting observations on aqueous solutions of magnesium oxalate are communicated by Kohlrausch and Mylius in the *Sitzungsberichte* of the Prussian Academy of Sciences (1904, p. 1223). By dissolving magnesium hydroxide in aqueous oxalic acid, it is possible to obtain

solutions which contain three hundred times as much magnesium oxalate as that present in the saturated solution of the hydrated salt. Electrical measurements show that the equivalent conductivity decreases at an abnormally high rate as the concentration increases. This and other phenomena furnish strong evidence in support of the view that polymerised molecules are present in the solution in considerable proportion.

A SECOND edition of Mr. Borchardt's "Arithmetical Examples," to which twenty-four pages of new exercises, oral and otherwise, have been added, has been published by Messrs. Rivingtons.

A "GEOMETRICAL Political Economy," by Mr. H. Cunynghame, C.B., is about to be published by the Oxford University Press. The work is an elementary treatise on the method of explaining some of the theories of pure economic science by means of diagrams.

THE October issue of the *Popular Science Monthly* is devoted entirely to the Cambridge meeting of the British Association. Dr. Pritchett, president of the Massachusetts Institute of Technology, contributes "A Traveller's View of the British Association Meeting," and in addition are included the presidential addresses of the Prime Minister, Prof. Horace Lamb, Mr. W. Bateson, Mr. Francis Darwin, Mr. Henry Balfour, Mr. Douglas Freshfield, Prof. C. S. Sherrington, and the Hon. Charles A. Parsons.

OUR ASTRONOMICAL COLUMN.

ENCKE'S COMET.—The absence of further observations of Encke's comet has caused some doubt to be expressed as to the correctness of Herr Kopff's conclusion regarding the identity of the object which he obtained on his photograph of September 11.

In the *Astronomische Nachrichten*, No. 3970, the same observer states that he has obtained confirmatory evidence which places the identity beyond doubt, although the comet is still extremely faint and diffuse. On a photograph exposed on September 17, at 13h. 29.2m. (Heidelberg M.T.), the same object appeared in the following position:—

$$\text{R.A.} = 1\text{h. } 40{\cdot}6\text{m., dec.} = +26^\circ\ 14'.$$

On comparing this position, and the one determined in the first observation (September 11), with the interpolated values obtained from the ephemeris published by MM. Ocoulitsch and Kaminsky, it is seen that the ephemeris requires the following approximate corrections:—

$$-0.7\text{m. and } -6'{\cdot}0.$$

Herr P. Gotz, of Heidelberg, was unable to find the comet on September 6 with a 6-inch telescope.

STRUCTURE OF THE OXYGEN BANDS IN THE SOLAR SPECTRUM.—In the September number of the *Astrophysical Journal* Mr. O. C. Lester, of the Sloane Physical Laboratory, Yale University, discusses the results recently obtained by him in a research as to the nature of the oxygen bands in the solar spectrum, of which the B group is a typical example.

The purpose of the research was to investigate the relations existing between the lines of each band and between the several bands, including in the latter two bands above a which do not appear to have been discussed previously.

The results may be summarised as follows:—(1) More accurate measures of the wave-lengths of the lines in groups A, B, and a have been made, the a' band has been measured for the first time, and a new group (a'') at λ 5377.2 has been discovered and its lines measured. (2) It has been shown that the oxygen absorption spectrum consists of two distinct series of bands, instead of one, which occur in pairs similarly to the series of lines in a band. (3) Deslandre's first law concerning the distribution of lines in a spectral band, viz. $N = a + bn^2$ (where N = the vibration frequency number, a and b are constants, and n takes on all integral values from 0 to n), is shown to be inadequate to represent the line series of the several bands. A modification of this formula suggested by Mr. Lester is

$$N = a + kn + c^{-1}n^2,$$

and this represents the series within the limits of observational errors; c and k are constants which are different for each series, although the differences are but small.

RECURRENT MARKINGS ON JUPITER.—From the inspection of several thousand drawings of Jupiter made during the last half-century, Mr. Denning has arrived at the conclusion that "features exhibiting various peculiarities of appearance and rates of motion are common to certain latitudes and break out from time to time, enduring for certain unknown intervals, then disappearing to be replaced by similar phenomena." Some exceptional outbreaks, no doubt, only take place at long intervals, whilst the evidences of others remain visible for long periods.

Mr. Denning suggests that if the old drawings could be collected and suitably discussed, considerable light might be thrown on the physical changes which are ever taking place. The value of this discussion must, in a measure, depend upon the continuity of the observations, and it is suggested that, as Jupiter is now being continuously observed and delineated, there will in a few years be ample material for such a discussion.

In the meantime Mr. Denning suggests that further insight into the wonderful atmospheric phenomena of the planet might be obtained from a study of the large number of drawings made by Schwabe between 1830 and 1860, and the 300 or 400, or more, made by Schmidt between 1843 and 1880 (the *Observatory*, October, 1904).

COMPARISON OF THE INTENSITIES OF PHOTOGRAPHIC STELLAR IMAGES.—The second chapter of the "Instructions to Variable Star Observers," of which the first chapter was summarised in these columns on September 15, is published in the October number of the *Bulletin de la Société astronomique de France*. Variable star observers will find many points of interest and instruction in the present chapter, which deals with the details of obtaining suitable photographs, and afterwards comparing and reducing the plates.

OBSERVATIONS IN THE SOUTHERN HEMISPHERE.—The Lick Observatory expedition to the southern hemisphere installed its apparatus at Santiago de Chile during the southern winter of 1903, and commenced observations on September 11 (1903).

A detailed description of the instruments in use, the observations and results, is promised for a later publication, but in the meantime Prof. W. H. Wright records several important results obtained with a powerful three-prism spectroscope attached to a Cassegrainian reflector of 94 cm. aperture, in No. 2, vol. xx., of the *Astrophysical Journal*.

The stars β Doradus, w Velorum, l Carinæ, κ Pavonis, and τ Sagittarii, have been found to have variable radial velocities.

Observations of α Centauri have also been made, and indicate an average difference between the radial velocities of the two components of about 5.17 km. One probable explanation as to the cause of this difference is that it is due to the relative orbital motion of the two components, and if this is true the parallax of the system may be determined, because the visual orbit of the pair is already well known. Dr. Palmer made the computation, and obtained the following results:—

$$\pi = 0{\cdot}76''$$
$$a = 3{\cdot}46 \times 10^9 \text{ km.}$$
$$m_1 + m_2 = 1{\cdot}9.$$

a = mean distance between components in kilometres, m_1 and m_2 = the respective masses of α_1 and α_2 Centauri in terms of the sun's mass.

The relative masses of the components, as previously determined, is about 51 : 49 in favour of the brighter. The spectrum of the latter is of the solar type, whilst in that of the fainter the iron lines are more pronounced and the calcium absorption is exceedingly heavy.

THE CLASSIFICATION OF STARS ACCORDING TO THEIR TEMPERATURE AND CHEMISTRY.

I.

ALTHOUGH the observations made by Fraunhofer in 1814 first indicated that the spectra of stars were not all of the same character, it was the more systematic observations of Rutherfurd and Secchi fifty years later which revealed the fact that the different varieties of stellar spectra were, generally speaking, associated with stars of different colours. The stars with fluted spectra, for instance, were generally found to be red; those resembling the sun in having abundant metallic lines were yellowish; while those in which the chief absorption was due to hydrogen were white. Closely following these observations came Zöllner's suggestion that the spectra might indicate the relative ages of the stars, and that the yellow and red stars were older and cooler than the white ones, thus giving birth to the now generally accepted view that the different kinds of stellar spectra represent different temperature stages in the evolution of more or less similar masses of matter. More direct evidence as to temperature differences was brought forward shortly after by Ångström, who directed attention to the probability that the flutings characteristic of the red stars originated in chemical compounds, and pointed out that the occurrence of flutings in such a star as Betelgeuse might be taken as an indication that the temperature of the star was sufficiently reduced to permit the formation of chemical combinations. Subsequent researches have shown that all flutings do not proceed from compounds, but the fact remains that in laboratory experiments flutings are only produced by relatively cool vapours and gases, and their presence in the spectrum of a star may therefore be still accepted as evidence of greatly reduced temperature. The broad distinction between the spectra of cool and hot stars was thus early recognised, but it remained to establish the sequence of temperature in the stars characterised by line spectra.

It was next pointed out by Sir Norman Lockyer in 1873[1] that the spectrum of the sun was intermediate between the more complex fluted spectrum of the red stars and the simpler line spectrum of the white ones, and further that the great development of the blue end of the spectrum in the white stars, as contrasted with stars like the sun, afforded strong presumptive evidence that the white stars were the hotter. Experiments had, in fact, shown that the continuous absorption exerted by certain gases was restricted to the most refrangible part of the spectrum when the density was low, and advanced gradually into the visible spectrum as the pressure was increased. Utilising this criterion, it thus appeared that the hotter a star the simpler was its spectrum, and it was pointed out also that the metallic elements seemed to make their appearance in the order of their atomic weights. As a working hypothesis, founded primarily on results obtained in solar inquiries, it was suggested that in the atmospheres of the sun and stars various degrees of dissociation were at work, so that in some cases the atoms which compose what at terrestrial temperatures we distinguish as metals, metalloids, and compounds, were prevented from coming together. Hence "the so-called elements not present in the reversing layer of a star will be in course of formation in the coronal atmosphere, and in course of destruction as their vapour densities carry them down; and their absorptions will not only be small in consequence of the reduced pressure in that region, but what absorption there is will probably be limited wholly or in great part to the invisible violet end of the spectrum."

Secchi's classification was, of course, made quite independently of such considerations as to temperature; but being based to a great extent on the colours of the stars associated with the different spectra, the numerical sequence of his four well known types is more or less in accordance with the probable temperature gradation.

Vogel[2] was the first to propose a classification professedly depending upon the supposition that the spectrum is indicative of the phase of development which a star has reached, and making use of the condition of the blue end of the spectrum as a guide to the temperature conditions. In stars of his class i. the more refrangible portions of the spectrum are of conspicuous intensity, in class ii. the blue and violet are weaker, while in class iii., which includes Secchi's third and fourth types, this part of the spectrum is described as being strikingly feeble. This is, indeed, the principal feature which is common to the several subdivisions of each of the three classes, and, apart from such possible resemblance, it is difficult to understand, for example, how stars so widely different as Arcturus and the bright line stars of the Wolf-Rayet group could have been brought together in the same class. Thus, although the idea underlying the classification was that of decreasing temperature in passing from the first to the third class, there was no adequate attempt to define the successive positions of the various subclasses on the descending scale of temperature.

[2] *Ast. Nach.*, vol. lxxxiv. (1874), p. 113.

Another idea was put forward in 1887 by Sir Norman Lockyer in connection with the meteoritic hypothesis.[1] Hitherto the generally accepted view as to stellar evolution had started with the assumption that all the stars were intensely hot to begin with, and that all further development was brought about by reduction of temperature; but it was objected that all bodies in the universe cannot be finished suns in the ordinary sense, and that the old view took no account of the processes of manufacture from nebula to sun. It was then suggested that the progress of stellar development was from comparatively cool nebulæ, through uncondensed "stars" of rising temperature, to the hottest stars, with a subsequent decline, through stars like the sun, to planetary conditions. On this modified basis a new classification was proposed in which seven groups were found sufficient to include the data depending on the visual observations, which were then practically all that were available. Some such arrangement of the stars in two series is, in fact, demanded by thermodynamical principles, since a mass of gas condensing under the influence of gravitation must continue to rise in temperature so long as it remains in a condition approaching that of a perfect gas, and Prof. Darwin has shown that a condensing swarm of meteorites would behave in a similar manner.

The magnificent success which soon after attended Prof. Pickering's photographic application of Fraunhofer's method of studying stellar spectra by means of an objective prism, and the subsequent use of the same form of instrument by Sir Norman Lockyer and others, provided data for a far more searching inquiry into the processes of stellar development. Conclusions as to the relative temperatures of the stars could now be more certainly drawn from the extension of their spectra towards the ultra-violet, as shown by the photographs, and the chemical changes accompanying the variation of temperature from star to star could be much more accurately observed.

In a discussion of the photographic spectra of 171 of the brighter stars, Sir Norman Lockyer[2] again found it necessary to arrange the stars in an ascending and a descending temperature series, as was previously the case when dealing with the visual observations, and the general sequence of events demanded by the meteoritic hypothesis was therefore so far confirmed. The classification into seven groups was still retained, but various subgroups were introduced in order to include the finer shades of difference revealed by the photographs.

At this stage of the inquiry many of the stellar lines, especially in the case of the hotter stars, had not been identified with terrestrial spectra, and further progress resulted rather from laboratory than from observatory work. Sir William Ramsay's discovery of terrestrial helium permitted a complete study of the spectrum of that element, and provided a most satisfactory explanation of many of the previously unknown lines appearing in the spectra of some of the white stars, and other lines usually associated in the stars with those of helium were subsequently traced to oxygen, nitrogen, carbon, and silicium.

But there was still another great class of outstanding lines, occurring in such stars as Sirius and α Cygni, for which chemical origins could not be certainly assigned on current principles. Continuing his researches, dating from

[1] Roy. Soc. *Proc.*, vol. xliii. p. 117.

[2] *Phil. Trans.*, vol. clxxxvi. A 1893), pp. 675-726.

1879, Sir Norman Lockyer[1] made the important discovery that several of these "unknown" stellar lines were coincident with lines of iron which were enhanced in brightness in passing from the arc to the spark spectrum. What is meant precisely by "enhanced lines" may be gathered from Fig. 1, and the first idea of their relation to stellar spectra is well brought out in Fig. 2.

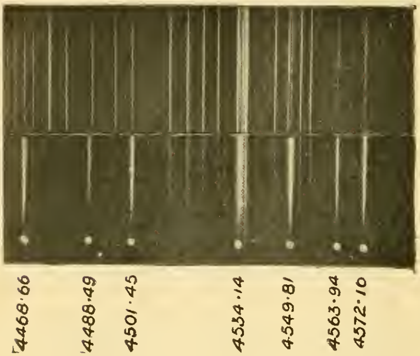

FIG. 1.—Illustrating enhanced lines of titanium; (1) arc, (2) spark.

The laboratory experiments suggested that in a space heated to the temperature of the hottest spark, and shielded from the effects of a lower temperature, the spectrum of iron would consist of these enhanced lines alone, and the outcome of the investigation was, in fact, to show that this condition is realised in the stars which are judged to be very hot by the extension of their spectra into the violet. Thus in α Orionis the continuous spectrum in the violet is feeble, and the arc lines and flutings appear without the enhanced lines; in α Cygni the violet radiation is more intense, and the enhanced lines are relatively much stronger than the arc lines; while in Rigel, with still stronger violet radiation, the enhanced lines appear in the absence of the arc lines. At a still higher stage, represented in the diagram by γ Orionis, the metallic lines have disappeared altogether, and are replaced by lines chiefly due to gases.

In a subsequent paper[2] it was shown that similar results were obtained in the case of other elements, and the presence or absence of enhanced lines, or their intensities as compared with those of the arc lines, appeared to afford a ready means of arranging stars at certain stages in order of temperature independently of a special study of the violet radiation. Adopting this mode of bringing together stars of approximately the same mean temperature, it was found, as before, that at each stage the stars were divisible into two groups, and that these groups naturally fell into two series, in each of which there was an almost unbroken sequence of changes in the line spectra. As determined in this way, stars of one series differ from those of the other at the same stage of heat:—"(1) in the greater continuous absorption in the violet or ultra-violet, (2) in the generally greater intensity and breadth of the metallic lines, (3) in the smaller thickness of the hydrogen lines, (4) in the greater thickness of the helium lines at those stages in which they are visible." The differences indicated in (2) and (3) are well illustrated by the comparison of the spectra of Sirius and α Cygni given in Fig. 3.

[1] Roy. Soc. *Proc.*, vol. lx. p. 475 (1896). [2] *Ibid*, vol. lxi., pp. 148–209 (1897).

It is to be noted that while the *relative* intensities of the arc and enhanced lines of the same metal are the same in both stars, thus indicating probable near equality of temperature, the metallic lines generally are weaker in Sirius than in α Cygni, while the lines of hydrogen behave in an exactly opposite manner.

The differences between the two series were explained by supposing, as before, that one of them comprises stars of increasing temperature and the other those which are becoming cooler. On the meteoritic hypothesis, stars of the first series would still be in the state of uncondensed swarms, and the greater thickness of effective absorbing vapours would account for the increased continuous absorption at the violet end of the spectrum, as well as for the greater thickness of the metallic lines, as compared with those stars in which a photosphere has been formed.

In 1899, in view of the fruitful results of the continued investigation of enhanced lines in relation to the stars, Sir Norman Lockyer[1] concluded that the time had arrived for a complete revision of the nomenclature of the stellar groups, and a more extensive definition of their chemical peculiarities. This new classification, in a slightly revised form, is fully stated and applied to the spectra of 470 of the brighter stars in a recent publication of the Solar Physics Committee.[2] On account of divergences of opinion among those engaged in these investigations, the same type of spectrum was referred to differently numbered groups in the various classifications which had been previously proposed, and to avoid the confusion to which this gave rise the use of numbers was entirely dispensed with. The idea underlying the new nomenclature cannot be better stated than in the words of the author, namely:—"As we know beyond all question that a series of geological strata from the most ancient to the most recent brings us in presence of different organic forms, of which the most recent are the most complex, it is natural to suppose that the many sharp changes of spectra observed in a series of stars from the highest temperature to the lowest, brings us in presence of a series of chemical forms which become more complex as the temperature is reduced. Hence we can in the stars study the actual facts relating to the workings of inorganic evolution on lines parallel to those which have already been made available in the case of organic evolution. If then we regard the typical stars as the equivalents of the typical strata, such as the Cambrian, Silurian, &c., it is convenient that the form of the words used to define them should be common to both." An adjectival form ending in *ian* was therefore suggested.

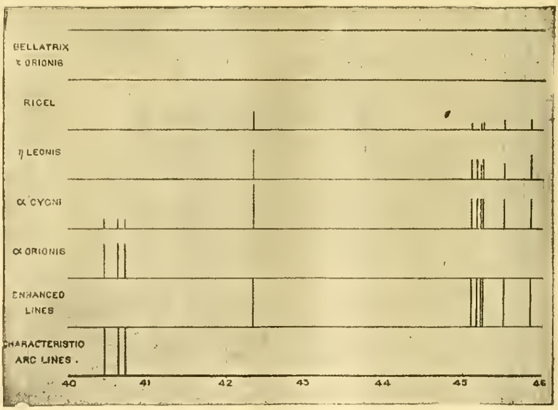

FIG. 2.—Illustrating the gradual replacement of arc lines of iron by enhanced lines in stars of increasing temperature.

[1] Roy. Soc. *Proc.*, vol. lxv. p. 186.
[2] "Catalogue of 470 of the Brighter Stars, classified according to their Chemistry." (London: H.M. Stationery Office, 1902.)

Generally, if the typical star is the brightest in the constellation to which it belongs, the Arabic name is used as a root; if the typical star be not the brightest, the name of the constellation is used in a similar manner. Thus we have *Antarian* from Antares, *Alnitamian* from Alnitam, *Taurian* from ζ Tauri, *Piscian* from 19 Piscium, and so on. In this way the names given to the various groups have very definite associations, and will doubtless be found much more convenient than the old confusing numbers and letters, even for the mere sorting of spectra into similar groups.

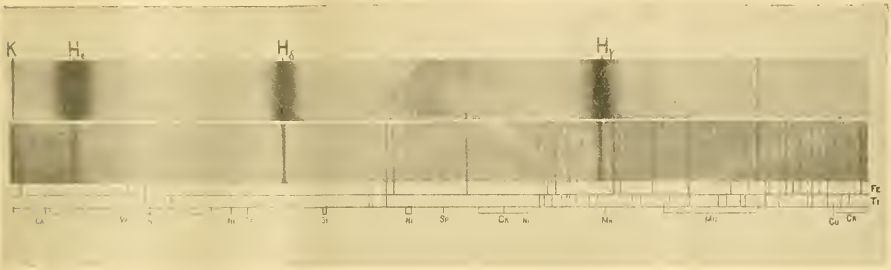

FIG. 3.—Spectra of (1) Sirius (decreasing temperature) compared with that of (2) α Cygni (increasing temperature). The chemical origins indicated are those depending upon coincidences with enhanced lines.

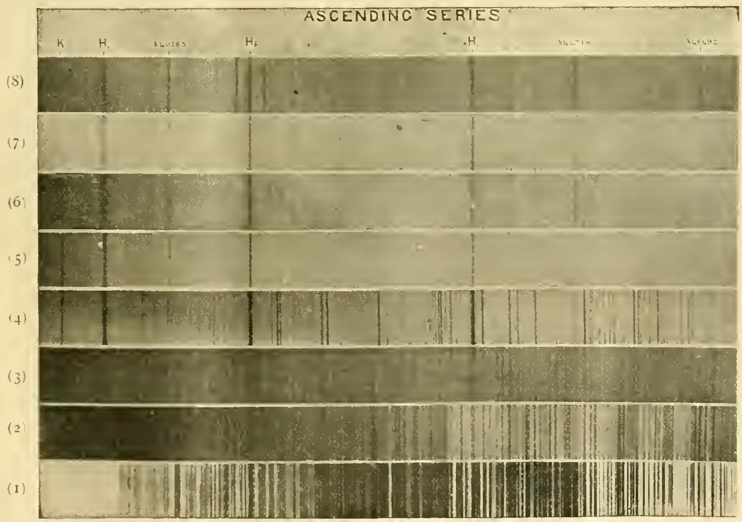

FIG. 4.—Stars of increasing temperature:—(1) α Orionis (Antarian); (2) α Tauri (Aldebarian); (3) α Persei (Polarian); (4) α Cygni (Cygnian); (5) β Orionis (Rigelian); (6) ζ Tauri (Taurian); (7) γ Orionis (Crucian); (8) ε Orionis (Alnitamian).

Bearing in mind the important distinction to be drawn between enhanced lines and the ordinary arc lines of a metal, a new term was found necessary for the proper chemical definition of several of the groups. When a substance is represented by lines which have their greatest development in the arc spectrum its ordinary name suffices; but when its presence is manifested by enhanced lines the prefix "*proto*" is added, the idea being that a substance reduced to the state in which it gives such lines is subjected to some sort of molecular simplification resulting from the dissociating effects of increased temperature. In the case of hydrogen, the proto-lines have not yet been even partially produced in laboratory experiments, but that they are really due to hydrogen is sufficiently demonstrated by the "series" connection of their wave-lengths with the wave-lengths of the more familiar lines of that element. Silicium exhibits four distinct line spectra under different conditions, and it has been found convenient to refer to these in numbered groups. It would be out of place here to reproduce all the minute details of the new classification, but referring only to the most characteristic lines of the various stellar groups, the classification may be shortly stated as follows, the prefix "p" signifying "proto":—

Argonian (γ Argûs).—H, p H.

Alnitamian (ε Orionis).—H, He, λ4649, Si IV.

Proto-metallic lines relatively thick, hydrogen relatively thin.	Proto-metallic lines relatively thin, hydrogen relatively thick.
Crucian (α Crucis).—H, He, Ast, O, N, C.	*Achernian* (α Eridani).—Same as Crucian.
Taurian (ζ Tauri).—H, He, p Mg, Ast.	*Algolian* (β Persei).—H, p Mg, p Ca, He, Si II.
Rigelian (β Orionis).—H, p Ca, p Mg, He, Si II.	*Markabian* (α Pegasi).—H, p Ca, p Mg, Si II.
Cygnian (α Cygni).—H, p Ca, p Mg, p Fe, Si II., p Ti, p Cr.	*Sirian* (α Canis Maj.).—H, p Ca, p Mg, p Fe, Si II.
Polarian (α Urs. Min.).—p Ca, p Ti, H, p Mg, p Fe, Ca, Fe, Mn, Si I.	*Procyonian* (α Canis Min.).—Same as Polarian.
Aldebarian (α Tauri).—p Ca, Fe, Ca, Mn, p Sr, H, Si I.	*Arcturian* (α Boötis).—Same as Aldebarian (includes the Sun).
Antarian (α Scorpionis).—Flutings of manganese,[1] and many metallic lines.	*Piscian* (19 Piscium).—Flutings of carbon and many metallic lines.
[Nebulæ.]	[Dark Stars.]

[1] Many of the flutings have since been shown to be due to titanium [Fowler, Roy. Soc. *Proc.*, vol. lxxiii. p. 219 (1904)]. The flutings are most strongly developed in the less refrangible parts of the spectrum, and are not seen in the spectrum of Betelgeuse reproduced in Fig. 4.

Examples illustrating most of the groups are given in Figs. 4 and 5, from negatives taken by Sir Norman Lockyer and his assistants at the Solar Physics Observatory. These bring out very clearly the gradual simplification of the spectrum in the first series as the temperature rises, and the increasing complexity in the second series as the temperature falls. On the dissociation hypothesis, we have first to deal chiefly with relatively cool metallic vapours, which, as the temperature rises, are brought by *dissociation* to the proto-metallic stage, and finally to the gaseous condition represented by hydrogen and helium; then, through subsequent cooling, *association* begins and produces somewhat similar changes in inverse order.

A. FOWLER.

RECENT IMPROVEMENTS IN THE DIFFRACTION PROCESS OF COLOUR-PHOTOGRAPHY.[1]

THE fundamental principles of the diffraction process of colour-photography will be found in my earlier papers on the subject.[2] In brief, the method consists in preparing by photographic means a picture in which the areas which are to appear coloured are represented by diffraction gratings of various spacings. A grating ruled on glass, when combined with a convex lens and directed towards a lamp flame or other source of light, forms diffraction spectra in the focal plane of the lens. If the pupil of the eye is brought into the red portion of one of these spectra, we perceive the entire surface of the grating illuminated in red light, since every portion sends red light, and red light only, into the eye. If a second grating with closer ruling is substituted for the first, the eye remaining fixed in position, the spectra will occupy different positions, and if the pupil of the eye occupies, say, the green region of one of them, this grating will appear green. If the two gratings are placed side by side, and overlapping one another, the one will appear red, the other green, while the overlapping region, since it sends both red and green light to the eye, appears yellow (secondary yellow). If a third grating of still finer spacing is now placed before the lens, partly overlapping the other two, it will appear illuminated in blue-violet light, and the overlapping portions will be coloured purple, white, and bluish-green.

We may in this way obtain a large variety of colour with only three rulings, and since the intensity of the light depends on the distinctness with which the lines are ruled or photographed, light and shadow can be obtained solely by the presence of the diffracting lines. The portions of the plate on which they are absent send no light to the eye, and appear black.

A full description of the method by which photographs showing the colours of the original object were prepared will be found in the papers above referred to.

The earlier experiments were made with very imperfect gratings, the periodic errors of which caused the pictures to show vertical bands of colour. During the past winter I have ruled gratings of various description on one of the Rowland engines, and continued the experiments of five years ago.

This machine was designed to rule 14,438 lines to the inch, but by employing larger cams, which cause the pawl to skip a specified number of teeth, it may be made to rule at the rate of 7219, 4812, 3609, and so on. Calculations showed that gratings ruled on this machine with cams which advanced the toothed rim of the large wheel five, six, and seven teeth respectively would be suitable, that is, would have the relative spacings necessary to produce white when they were superposed.

To illustrate the principle of the colour synthesis, a glass plate was ruled with the three spacings, the ruled squares overlapping as shown in Fig. 1*a*. The areas appeared coloured as indicated when the plate was placed in front

[1] Paper read before Section A of the British Association at the Cambridge meeting by Prof. R. W. Wood.

[2] Wood, "Application of the Diffraction Grating to Colour-photography" (*Phil. Mag.*, April, 1899); "Diffraction Process of Colour-photography," (NATURE, vol. lx. p. 199, 1899).

of the viewing lens. The white area in the centre was of good quality, though not quite so bright as in the photographic gratings, for the reason that the three sets of rulings were rather more than the glass surface would take without breaking down between the lines. Photographic copies of this multiple ruling have been made, and will probably prove useful in demonstrating colour synthesis.

The appearance of two overlapping rulings under the microscope is shown in Fig. 1*b*.

It would appear at first sight as if a ruling of this description would be incapable of giving distinct spectra, and we should certainly not expect it to give merely the superposed spectra of the two gratings.

As a matter of fact, secondary spectra are produced, though they are usually so faint that they give no trouble. In some cases, however, owing to some peculiarity of the form of the groove, the photographic copies when superposed do not give the expected colour. For example, in one exceptionally pronounced case, the superposition of the red and violet gratings gave, instead of purple, a brilliant yellow-green.

The origin of the secondary spectra can be seen in the following way. If the red and violet gratings are superposed with the lines mutually perpendicular, and a lamp is viewed through the combination, the spectra appear as in

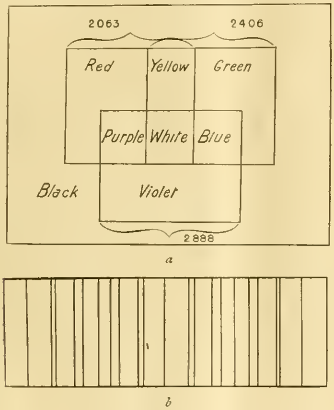

FIG. 1.

Fig. 2, the secondary spectra being usually much fainter than the principal ones. If, now, one of the gratings is slowly rotated through a right angle, the spectra will gradually wheel around into a straight line, and the secondary spectra will be found to fall *between* the principal spectra. In the particular case alluded to above, the secondary spectra for some reason or other were brighter than the principal, and it was found that the yellow-green of one of them fell at the point where the red and violet of two of the principal spectra coincided. This accounted for the abnormal colour which appeared in this case. It is very seldom, however, that these abnormal colours appear in the pictures.

A set of gratings for the production of colour photographs was ruled on this machine, and results far superior to any that had ever been obtained before were immediately secured. A few of the pictures were of such excellence as to compare favourably with the results obtained in the Kromshop. The method of preparing the pictures was essentially as I have described in previous papers.

The diffraction process has also been successfully combined with the Joly process. To accomplish this it was necessary to rule the three sets of lines in bands corresponding to the width of the red, green, and blue lines of the Joly screen. Calculation showed that if 12 lines were ruled with the 5-tooth cam, 10 with the 6-tooth, and 9 with the 5-tooth, the spaces would be about right.

Various schemes for making a ruling of this description were considered, but no satisfactory automatic device appeared to be possible, since the period of the bands on the Joly screen could not be exactly duplicated by any combination of cams.

The following simple device was finally hit upon. The engine was equipped with the 7-tooth cam, and a small stepped piece of brass mounted under the lever which operated the pawl, which, by preventing the complete descent of the lever, caused an advance of only 6 teeth or 5 teeth according to its position. The Joly screen was mounted on the table of the engine under a microscope, and the transit of the coloured lines across the × hair in the eye-piece observed, the rate of the ruling being changed at the proper moment by sliding the stepped piece of brass into the proper position, which was done by means of a short brass rod. The ruling of the grating occupied twelve hours, during which time I was obliged to sit with my eye constantly at the microscope, for the change of rate occurred about every half minute. Two very satisfactory gratings were prepared in this way, one corresponding to the Joly screen and the other to one of the screens ruled on the machine of the McDonough Co., of Chicago.

These gratings when placed in the viewing apparatus appeared white and very brilliant, and were easily duplicated by photography.

They were used in the following way:—

A positive on glass, made from a Joly negative, was flowed with a thin solution of gelatin sensitised with

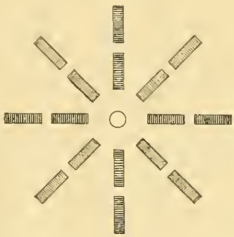

FIG. 2.

bichromate of potash, and allowed to dry. The triple ruled grating was then placed with its ruled surface in contact with the sensitive film, and held before the lens of the viewing apparatus. The appearance of the picture was now precisely similar to the appearance when a Joly colour screen was used, and the lines could be brought into register at once, when the picture appeared in its natural colours. A ten-second exposure to the light of the arc recorded the grating lines on the film, and the plate was then dipped into warm water and dried. The colours of the picture prepared in this way were fully equal, if not superior, to those obtained with the Joly viewing screen. There is the added advantage that the colour lines and picture lines are on one and the same film, consequently there is no liability of the lines to get out of register. Moreover, the picture can be duplicated by contact printing on glass sensitised with chrom-gelatin. These prints are, of course, quite transparent until they are placed in the viewing apparatus, when the coloured picture at once appears.

By this means the trichromatic screen, which in the Joly process must be mounted with every picture, is done away with, and a picture obtained which can be easily duplicated. To offset the advantages gained we have, however, the disadvantage that the pictures require the viewing apparatus, and show the same obtrusive lines as the original Joly pictures. The triple diffraction screen could easily be ruled with its colour elements much closer together, but we should gain nothing in this way until some method of taking a negative with narrower colour elements is devised.

The pictures made by the old method with three separate

gratings can, I believe, be very much improved, as soon as some better method of printing gratings is devised. I have worked exclusively with chrom-gelatin, and it is by no means easy to get a film of such uniform thickness that the print made on it appears uniformly illuminated.

During the past summer I made some experiments with Prof. Lippmann, of Paris, on copying gratings by means of the plates which he uses in his process of colour-photography. These plates are much more sensitive than chrom-gelatin plates, are orthochromatic, and yield gratings of great brilliancy and uniformity. Whether they are capable of receiving two or more impressions remains to be seen. If they are it will probably be possible to form a diffraction colour-photograph directly in the camera, in the manner suggested in one of my earlier papers.

Moreover, if the triple ruling can be transferred in any way to the Joly taking screen, it is obvious that the *negative* taken by means of it in the camera will, when placed in the viewing apparatus, appear as a positive in natural colours; we can thus obtain our coloured positive at once in the camera, and make as many duplicates from it as we please by contact printing.

THE AGRICULTURAL EDUCATION CONFERENCE AT GLOUCESTER.

UNDER the auspices of the Gloucestershire County Council, a conference on agricultural education was held at the Shire Hall, Gloucester, on October 15. There was a large attendance not only of those locally interested in either education or agriculture, but also of delegates from many of the other counties. After a few preliminary remarks from the chairman, Sir John Dorington, Lord Onslow opened the proceedings, and explained the work his department was charged with in regard to education. He justified the retention of that work by the Board of Agriculture instead of allowing it to be merged in the general educational system administered by the Board of Education, on the plea that agriculture in England was so far from being the leading industry that the specialised education it required would get scant attention were there not his own department peculiarly interested in fostering it. He claimed that the constant and sympathetic communication between the two departments secured more favourable results than could be acquired under the Board of Education exclusively. The work of the Board of Agriculture was confined to assisting the collegiate centres under which the greater part of the country was now grouped; there was, however, a large blank on the educational map, for the whole of the west country, including Gloucestershire itself, had no centre of university rank from which agricultural instruction emanated. He trusted that the present conference would pave the way towards remedying the need he had indicated.

Sir William Hart-Dyke, to whom the first paper, on higher agricultural education, had been entrusted, was unable to be present; his paper, of which an abstract was read, warned the meeting of the difficulty that now confronted all counties in the matter of higher education because of the great draft on their funds for the future training of elementary schoolmasters.

A paper by Prof. Middleton, of Cambridge University, next dealt with the proper function of experimental plots in local agricultural education; Prof. Percival, of Reading, who followed, dealt with the ideal course of instruction in an agricultural college. The current courses, he maintained, were far too scientific; chemistry, botany and kindred sciences should be reduced to a minimum in favour of work on the farm, a thoroughly popular programme which appealed to the "practical men" in the room.

Lord Monteagle then opened the second part of the proceedings, on the education of the small farmer, with an account of the way the Irish Board of Agriculture had gone to work.

In Ireland the central authority administered the larger part of the funds, contributing five-ninths of the cost of any work, and securing four-ninths from the local authority; thus the organisation proceeded more evenly over the whole country than in England, where the initiative rests with the local authority. Next, they had proceeded in Ireland on the principle of establishing no institution until they had created a demand for it by means of pioneer lecturing and demonstrations. Lastly, in Ireland they believed that the industrial organisation of the farmers must go hand in hand with their education.

Prof. Wallace, of Edinburgh, who followed, dwelt on the necessity of beginning an agricultural training at an early age, so far as practical work on the farm went, leaving the true technical instruction to come when the lad had matured. Mr. Frederick Verney also dwelt on the harm that was being done to country children by keeping them at unsuitable school subjects until they had lost all taste for farming pursuits; the present system of elementary education contributed both to the depopulation of the country and the overcrowding of the towns.

Mr. H. Hobhouse, M.P., spoke on the value of attaching agricultural sides to the ordinary country grammar schools; the training would not be technical, but scientific with an agricultural bias.

After lunch Mr. Morant expressed his pleasure at the opportunity the conference afforded him of learning the feelings of the great agricultural community towards the educational system of the country. He assured the meeting that the Board of Education was wholly anxious to assist, provided the men who represented agriculture on such occasions would make their views precise, and, instead of grumbling at large, would indicate exactly what worked harshly or harmfully in the present arrangements controlled by the Board of Education.

A paper by Sir C. Dyke Acland was then read in his absence; it dealt with the education of the labourer, and was, like so many that followed, a plea for more intelligent teaching in our elementary schools, and for a more flexible system which would partially liberate boys at an earlier age for light work on the farm. Mr. G. Lambert, M.P., and Mr. Martin F. Sutton emphasised this point of view, and, like Mr. Acland, they agreed that in the main rural labour difficulties had been caused by keeping the rate of wages too low, with consequent loss of efficiency.

The last section of the conference, on the education of the teacher and expert, was opened by Mr. A. D. Hall, who pleaded for a more rigorous training which should include some experience in farming for the teacher of agriculture, and some work at research for the man who dealt with agricultural science. Canon Steward, principal of the Salisbury Training College, discussed more generally the education of the elementary schoolmaster and mistress in country districts, and finally, Mr. R. P. Ward gave an account of the way the teachers were being trained in Cheshire.

In the discussion which followed most of the speakers urged the substitution of winter schools or of evening continuation schools for the compulsory attendance of country boys at school up to the age of fourteen; for farming purposes a boy ought to begin light work on the farm at the age of twelve at latest, though his education should go on much later than it does now.

The conference was noteworthy not only for the quality of the papers read, but for the advance they showed in the direction of organisation on those submitted to previous conferences. It was made clear that there are several different classes to be provided for; the large farmer's son or future land agent wants a different equipment from that of the small holder; the farmer himself must be reached by an entirely different method; the labourer, again, has to be treated separately. At Gloucester the various speakers defined clearly their aim and their method; in former gatherings of the same nature the speakers seemed to consider there was only one kind of worker engaged in agriculture.

THE SPREAD OF PLAGUE.[1]

IN accordance with our views on the origin of epidemics it is necessary to believe that the plague which appeared in Bombay in the autumn of 1896 was derived from some previously infected locality. Two such localities have been

[1] Substance of a paper read before the Section of Physiology at the Cambridge meeting of the British Association on August 19 by Dr. E. H. Hankin.

suggested. The most obvious suggestion is to the effect that it was derived from Hong Kong, which town had been the seat of a serious epidemic in 1894, and which in 1896 remained still infected. An alternative suggestion was put forward in the report of the German Plague Commission to the effect that it was derived from Garhwal. The suggestion was to some extent substantiated by the fact mentioned in the report in question that two thousand fakirs from Garhwal had arrived in Bombay on their way to a pilgrimage at Nassik shortly before the appearance of the disease. Plague is endemic in Garhwal (a district in the Himalaya Mountains), and this locality is therefore a possible source of infection. By conversation with a fakir who had attended the Nassik festival, Mr. Hankin learnt that the Garhwal fakirs only visit western India on occasions when the Nassik festival is being held. This festival is held regularly at twelve-yearly intervals.

It occurred to Mr. Hankin that if Garhwal was the source of the Bombay plague, by means of fakirs, it might also be the source of previous epidemics of plague in western India. On counting backwards from 1896 by twelve-yearly intervals, one arrives at 1836, the date of the Pali plague, and at 1812, the date of the Gujerat plague. That is to say, of the eight occasions on which these fakirs visited western India during the nineteenth century, on no less than three an outbreak of plague appeared. This fact may be regarded as strongly substantiating the suggestion of the German Plague Commission as to the origin of the Bombay outbreak. Further, it is stated by Forbes that the Pali plague originated in a village a few miles distant from the town of Pali shortly after the arrival of some wandering fakirs, and that it was preceded by a mortality among the rats. It was pointed out that these three plagues of western India had certain characters in common in which they differed from the majority of plagues in other parts of the world. First, they were characterised by their greater intensity and persistence; secondly, during the greater part of their course, at all events, they showed more virulence in villages than in towns; thirdly, they spread over the affected country, like a wave, from village to village, and showed but little tendency to travel along trade routes; fourthly, in each of the outbreaks the pneumonic form of the disease was frequently observed. The fact that these outbreaks resembled each other, and differed in general from outbreaks elsewhere, in the above characters, accords with the idea that they have a common origin. One apparent exception, however, which is of great importance must be described. This is the black death. So far as evidence goes, this outbreak was distinguished by each of the characters that have been ascribed to Indian plagues. In order, therefore, to be able to hold that Indian plague is of Garhwal origin, it is necessary to show that the black death may possibly have been derived from the same source.

The black death is known to have been imported into Europe from the town of Caffa, in the Crimea, where the Tartar army had been besieging some Italian merchants. According to an Arab historian, Aboel Mahasin, the plague was brought to the Tartar army from Tartary, where it was present in the year 1346, if not earlier. At that period, trade in horses and merchandise existed between India and Tartary. It is therefore necessary to investigate whether a Nassik festival occurred shortly before that time, and whether it was accompanied by an outbreak of pestilence. At first sight a study of Indian history appeared to negative the suggestion. It is stated, however, in Elphinstone's "History of India" that a rebellion broke out in Ma'bar in 1341, and that the army sent to suppress it was destroyed by plague. It appeared desirable to investigate this statement in detail. Counting back by twelve-yearly intervals, we arrive at 1344 as the year of a Nassik festival. In view of the great antiquity of Indian religious festivals, we are safe in assuming that in that year a number of fakirs emerged from Garhwal on their way to the sacred shrine. Ma'bar is situated on the Coromandel coast, on the Madras side of India, and one would expect that the army of the Emperor of Delhi would not march anywhere near to Nassik. But a contemporary history dealing with the conquest of Ma'bar, some thirty-five years previously, describes minutely the route then followed by the army. It appears to have lain through, or near, Nassik, and that the soldiers must have marched along the same route as the fakirs for all the first part of their journey. It is further recorded that when the army was destroyed by pestilence the Emperor himself was attacked, and that when suffering from the disease he halted at Deogiri, a town close to Nassik. It appears from a contemporary history that the army originally sent in 1341 was insufficient for its purpose, that the Emperor returned for reinforcements at a time when a famine was raging in Delhi, and that it was these reinforcements that were destroyed by the pestilence. The date of the famine is given as 1344. This is also given as the date at which the campaign terminated, and at which the rebels recovered their independence. Thus we have evidence that a plague broke out near Nassik in the year 1344, at a time when Garhwal fakirs were present, and it is obvious that this plague may have been carried to Tartary in time to have been the precursor of the black death, which is first known to have been present there in the year 1346. Other suggestions as to the origin of the black death, as, for instance, that it came from China, or from the supposed endemic area in Mesopotamia, or from the then existing endemic area of the Levant, if not contradicted by known facts, are at least unsupported by any positive evidence.

Prof. G. S. Woodhead asked whether it was known to what the pneumonic form of plague was due. Was it due to extra virulence or to the climatic conditions?

Sir Edward Candy asked if the outbreaks of plague in 1812 and 1836 spread and continued in the same manner as that of 1896, which re-appeared for some time after with every return of cold weather. It was noteworthy that the plague of 1896 took hold of the country up to the Punjaub, but missed out Calcutta and Madras.

In the course of his reply, Mr. Hankin pointed out that it was a remarkable fact that the pneumonic form of the disease showed but little tendency to spread as such by direct infection from person to person. Mr. Hankin had found that the plague virus lost its virulence by passages through rats. It was possible that it would also lose its virulence by passages through human beings, and that the true nidus of the disease in which it could retain or regain its virulence was to be found in some other living organism, as, for example, some species of flea. With regard to the important point raised by Sir Edward Candy as to the spread of plague, Mr. Hankin stated that it was a necessary corollary of his theory that the present outbreak of plague in India had not established itself in any other part of the world. It was probable that plague was carried from Hong Kong to Noumea, to Australia, to Madagascar, thence to South Africa, Oporto, and other localities. The present pandemic of plague was essentially a disease of sea-ports, in the first instance, and then of towns. It but rarely established itself in villages, and then always rapidly died out. In this and in other characters it showed itself distinctly different from the Indian form of the disease.

INVESTIGATIONS ON THE NUTRITION OF MAN.[1]

PROF. W. O. ATWATER, Middletown, Connecticut, chief of nutrition investigators of the United States Department of Agriculture, gave an account of the inquiry regarding the food and nutrition of man which is carried out in the United States by authority of Congress. The work is done by cooperation between the Department of Agriculture and a large number of universities, experiment stations, and other organisations from Maine to California. The headquarters is at Wesleyan University, Middletown, Connecticut, where the speaker, who is in charge of the work, is situated. The Federal Government devotes 20,000 dollars (4000*l.*) a year to the enterprise. This is used mainly as aid to research, and is supplemented by grants of money and other aid from State Governments and other sources. The inquiry has three aspects, one very practical, another more purely scientific, and a third educational.

On the practical side studies are made of the composition, the digestibility, and the nutritive values of food materials

[1] Abstract of an address before the Sections of Physiology and Economics at the Cambridge meeting of the British Association on August 23.

commonly used in the United States. This is done by chemical analyses and by actual experiments with men. Investigations are also made of the kinds, amounts, and costs of the food consumed by people of different classes and occupations in different parts of the country. The results throw valuable light upon the physiological, hygienic, and economic phases of the subject. At the same time experiments are made on various collateral topics, and thus information of the greatest usefulness is being acquired.

The more abstract scientific researches have to do with the transformations of matter and energy in the body, and consequently with the fundamental laws of nutrition. The experiments are made with men by use of the respiration calorimeter, an apparatus which serves to measure the changes which take place in the body with different diets and under different conditions, as, for instance, with physical or mental work or of rest. One very interesting result is the demonstration that the law of the conservation of energy obtains in the living body. Such purely scientific research is difficult and costly, but the speaker insisted earnestly upon its fundamental importance. These experiments show very clearly how the demands of the body for energy, for warmth, and work decide the needs for food. Taken in connection with the practical inquiries, they reveal much that was previously unknown regarding the uses of food and the adaptation of diet to health, purse, and welfare.

Numerous illustrations were given of the results of these inquiries. The average man on average diet digests and utilises about 96 per cent. of the material and 91 per cent. of the energy of his food, the rest being rejected in the excretory products; but the proportions thus utilised vary with the person, and still more with the food. The investigations bring out these differences in much detail.

The question of the nutritive values of bread made from ordinary white flour as compared with the whole wheat meal or brown flour, such as is used to make "brown bread," was considered. Chemical analysis shows that the bran which is removed in making the white flour contains considerable quantities of nitrogenous materials, and also of mineral matters, such as phosphates. A natural inference is that when the miller removes the bran he takes out the most valuable part of the flour. But the analysis in the chemical laboratory is not the same as that in the human body. The digestive apparatus of man has not the power to utilise the bran, consequently, when we eat the meal from the whole wheat we digest the part which makes the white flour and reject most of the ingredients of the bran. Cattle and sheep can digest the bran; the miller is therefore right in selling the bran for fodder for stock, and the white flour bread for man. This last statement perhaps requires a slight qualification. A large number of experiments with healthy men show that the nitrogenous ingredients of the bran escape digestion when made into bread, so that 1 lb. of white flour furnishes more digestible material than 1 lb. of the whole wheat meal; but it may be that the body obtains more phosphates from the whole wheat. This last question is still under investigation. The present probability, however, is that the chief value of the bran is as a stimulant to digestion in some cases where peristaltic action or the secretion of digestive juices is enfeebled.

While Prof. Atwater could hardly adopt the vegetarian theory of diet, he believed that the idea of the needs of large amounts of meat is often greatly exaggerated.

The investigations emphasise the great importance of a liberal diet for people engaged in muscular labour. They make it clear that in many cases the food of the poor is inadequate for normal nourishment, and must remain so until they have larger incomes or cheaper food.

The investigations also bring out clearly the reasons why people with sedentary occupations need less food than those with more physical exercise. Mental labour differs from muscular labour in requiring much less material and energy for its support. In general, people with sedentary occupations have the larger, and those whose labour is manual the smaller, incomes. Thus it comes about that the well-to-do are apt to be over-fed and the poor under-fed.

The application of these principles to some of the economic questions of the day was emphasised. High value was placed upon the inquiries of Mr. Rowntree regarding the conditions of living of the labouring classes in York. Other investigations in England and Scotland were referred to, and the statements of Mr. Charles Booth, in his monumental work on "Life and Labour in London," regarding the need of such an inquiry in Great Britain were quoted with approval.

"Half the struggle of life is a struggle for food"; half the wages of the bread-winner are spent on the food for himself and his family. Little regard is paid to the relation between the real nutritive value of food and its cost. The poor man's money is worst spent in the market, the poor man's food is worst cooked and served at home; here it is emphatically true that "To him that hath, shall be given, and from him that hath not, shall be taken away even that which he hath."

The importance of proper diet as an aid to temperance reform was emphasised. In countless cases in the United States, and he presumed the same was true in England, the home diet of the labouring classes is not what it should be, and the cooking and the serving of the food are the opposite of attractive. It is not strange that the people take to drink. One place to work against the evil of alcohol is at the table.

The educational aspect of the subject was also dwelt upon. The Federal and State Governments which support these inquiries, and the institutions and individuals who carry them on, lay great stress upon the distribution of the results among the people at large. Not only are the details printed in scientific memoirs, but the practical outcome is condensed in pamphlets and leaflets which the Government prints literally by the million, and distributes gratuitously. Copies of these publications were shown. Schools, from the lower grades to the universities, are introducing the subject into their curricula, and leading educators are coming to recognise that when such themes are treated in the true scientific spirit as revelations of natural law, and their significance and their connection with life and thought are explained, they are valuable both for mental discipline and for daily use. It is not a lowering, but a broadening, of the ideal of education which thus makes these subjects in the best sense humanistic.

In closing, Prof. Atwater urged the importance of such inquiries. He showed how they were already being actively pursued in the different countries of the world, in Europe, in Japan, and in the United States, and suggested that the time had come for the development of the science of the comparative nutrition of mankind.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following appointments are announced: Prof. Marshall Ward, F.R.S., to be a member of the general board of studies; Dr. W. E. Dixon to be assistant to the Downing professor of medicine; Mr. P. V. Bevan to be demonstrator, and Mr. C. Chittock to be assistant demonstrator, of experimental physics; Mr. J. J. Lister, F.R.S., to occupy the university table at the Plymouth Marine Biological Laboratory; Mr. J. W. Clark to be an additional manager of the Balfour Fund.

MR. H. M. MACDONALD, F.R.S., has been appointed professor of mathematics in the University of Aberdeen.

THE death is announced of Mr. Alonzo B. Cornell, who was the founder of Cornell University, and gave special attention to the development of teaching of scientific subjects at the university.

A COURSE of ten lectures on "The Chemistry of Proteids," by Dr. S. B. Schryver, was commenced on Wednesday, October 19, in the physiological theatre, University College, London, and will be continued on following Wednesdays at 5 p.m. The lectures are open to all internal students of the university, and also to medical men on presentation of their cards.

IT is reported, says *Science*, that about 60,000*l*. is left to public institutions by Mrs. Elizabeth Green Kelly, including 20,000*l*. to the University of Chicago. We learn from the same source that the will of Mrs. Sarah B. Potter, of Boston, contains public bequests aggregating more than

200,000*l*., including 30,000*l*. to the Boston Medical Library and 10,000*l*. to Harvard University. It is also announced that the increased appropriations for Miami University by the Legislature of the State of Ohio at its last session have rendered it possible to enlarge the science hall, given by Senator Brice, to about three times its present capacity. The new Brice Hall will be occupied by the departments of chemistry, physics, and biology of the Liberal Arts College, and by the natural history department of the State Normal School. The University of Southern California, at Los Angeles, is also to be extended by a new building to cost 20,000*l*. It will be devoted to the science departments.

AN attempt is being made to establish an association of teachers of science, art, and technology who are engaged in teaching at London institutions. It is hoped that the new association may become ultimately a national body. It has been agreed at meetings already held that the principal aims and objects of the association should be the general advancement of technical education; the interchange of ideas regarding methods of teaching technical subjects; the promotion and safeguarding of the professional interests of the members of the association in such matters as tenure, pensions, and registration; to lay the views of the association before educational authorities and before the public; and to enable the members to cooperate as a body with other scientific and educational associations. Arrangements have been made for a general meeting to be held on October 22 at the Birkbeck College, Chancery Lane, at 3.30. All London teachers of science, art, and technology, other than those employed in secondary schools, are invited to be present. Fuller particulars may be obtained from Mr. J. Wilson, head of the chemical department, Battersea Polytechnic, who is acting as temporary honorary secretary.

THE annual report of the Glasgow and West of Scotland Technical College, recently adopted by the governors of the institution, shows that the first section of the new buildings has proceeded satisfactorily. The main structure is nearly completed, and the internal equipment is advanced sufficiently to permit of the occupation of a few rooms during the present session. It does not seem possible to proceed immediately with the erection of the second section. The subscriptions to the building fund amount to 186,525*l*.; the cost of the first section will be 140,000*l*., and to this must be added 44,654*l*., the cost of the site. The second section will cost at least 60,000*l*., and the governors appeal for further contributions to enable them to erect the whole of the buildings. It is estimated that the equipment of the first section will mean an expenditure of 40,000*l*. Conditional upon a new fund of this amount being raised for the purpose, the Carnegie University Trust promised a grant of 5000*l*. A second grant of 5000*l*. from the Education Department and other subscriptions have been placed to the credit of the fund, which now stands at 18,135*l*. The governors hope that they will soon be placed in a position to claim the grant conditionally promised by the trust. It is worthy of note that the total number of individual students reaches 5333, of whom 489 are adult day students, 4212 evening students, and 632 pupils of Allan Glen's School.

AN article on the selection of Rhodes scholars in connection with the Rhodes Scholarship Bequest was contributed to the *Times* of October 13 by Dr. G. R. Parkin. It appears that during the present month about seventy-five men, the first large group of scholars selected, enter on residence at Oxford University. Canada, Australia, South Africa, New Zealand, Newfoundland, Bermuda, and Jamaica, within the Empire, and, outside the Empire, Germany and the United States, with the exception of a few States where no suitable candidate was found, will have their representatives. In 1905 a larger number will probably be selected; in 1906 scholars will be chosen only from colonies of the Empire and from Germany, to which annual scholarships are assigned, whereas each of the United States has only two scholarships in three years. Thus in 1906 the full number—about 190 in all—provided for under the bequest will be in residence. It is interesting to note that the men sent as scholars are selected, where practicable, from colleges or universities rather than from secondary schools. It has been decided that throughout the United States generally only those candidates shall be eligible who have done at least two years' work at a recognised degree-granting university or college. In cases where the committee of any State expressly asks leave to appoint from secondary schools this leave is granted. The limits of eligible age were placed between nineteen and twenty-five. The public interest taken in the organisation of the scheme of award has been most striking. It will probably take some time to complete a system of selection which is beyond criticism, but a fair beginning seems to have been made in giving practical effect to the conception of the testator.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, October 5.—Prof. E. B. Poulton, F.R.S., president, in the chair.—Mr. G. H. **Verrall** exhibited specimens of (*a*) *Callicera yerburyi*, Verr., a Syrphid new to science, taken this year in Scotland by Colonel J. W. Yerbury, and (*b*) *C. aenea*, F., the other British species of the genus, together with three European species of Callicera, *C. macquatii*, *C. spinolae*, and *C. porrii*.—Mr. H. St. J. **Donisthorpe** exhibited *Tetropium fuscum*, L. (♂ and ♀), and *Abdera 4-fasciata*, Curt., taken by him at Market Bosworth, Leicestershire.—The Rev. F. D. **Morice** exhibited cells constructed by two wasps, *Polistes gallicus* and *Eumenes coarctatus*, found by him in the Balearic Islands.—Mr. A. J. **Chitty** exhibited specimens of the earwig *Apterygida media* (*albipennis*), found originally by Westwood, and hitherto recorded only from Norfolk. He had taken the species at Huntingfield and Charing, Kent, this year.—Mr. W. J. **Lucas** exhibited a living specimen of *Labidura riparia*, ♂, from the shore near Christchurch, Hants, kept alive for more than a month, and fed upon fruit, meat, &c.—Prof. Hudson **Beare** exhibited on behalf of Mr. C. J. C. Poole specimens of *Aulonium sulcatum*, Oliv., a beetle new to the British fauna.—Mr. W. **Dannatt** exhibited a specimen of *Papilio homerus* from the Blue Mountains, Jamaica, and three new butterflies, *Chloríppe godmani*, from Venezuela, *Delias hempeli*, from Gilolo, and *Monethe johnstoni*, from British Guiana.—Dr. T. A. **Chapman** exhibited for Mr. Hugh Main a teratological specimen of *Arctia caja*, bred this year. Immediately below the costa the left hind wing divided into three layers, each of which was apparently a normal wing so far as form, colour, and markings went, but which, when the insect was alive, were so closely applied to each other as to look like one normal wing, until they were separated.—Mr. F. **Merrifield** exhibited pod-like galls found on a terebinthine shrub in the limestone region of Auvergne, apparently those of *Pemphigus cornicularius*.—Mr. Norman **Joy** exhibited the black variety of *Bledius taurus*, Germ., taken at Wells, Norfolk, August, 1904; *Bledius femoralis*, Gyll, from Wokingham, Berks, a species that has not been taken in the British Isles for more than fifty years; *Polydrucsus sericens*, from Hampshire; *Neuraphes carinatus*, Mul., from Bradfield, near Reading; a small form of *Dyschirius politus*, Dej., taken at Bridlington and at Wokingham; and a Rhizotrogus (? species), taken in some numbers near Streatley, Berks.—Dr. F. A. **Dixey** exhibited some preparations of the scent of male Pierine butterflies, and read a note descriptive of the same.—Mr. H. J. **Turner** exhibited living examples of the larva of *Phorodesma smaragdaria* from the Essex marshes. He also contributed notes on the life-histories, and living larvæ and cases, of several Coleophorids, among them *C. vibicella*, a species which, although generally distributed on the Continent, has only been recorded from a few English localities.—Mr. G. J. **Arrow** read a paper on sound production in the lamellicorn beetles.—Prof. C. **Aurivillius** communicated a paper on new species of African Striphnapterygidæ, Notdontidæ, and Chrysapalonidæ in the British Museum.—Mr. A. H. **Swinton** communicated a paper on the droughts and weather, and insect increase and migration.—Mr. E. Ernest **Green** communicated a paper on some new mosquitoes from Ceylon, by Frederick V. Theobald.

MANCHESTER.

Literary and Philosophical Society, October 4.—Prof. W. Boyd Dawkins, F.R.S., president, in the chair.—Mr. Charles **Bailey** exhibited some specimens of *Sisymbrium strictissimum*, L., which had been sent him by Mr. James E. McDonald, of Stockport, as occurring at Heaton Mersey, where it had been established for the last fifteen years. He remarked that this genus, apart from the aboriginal species, was already represented in Lancashire and Cheshire by two aliens, *S. polyceratium* at Birkenhead, and *S. pannonicum* at St. Anne's-on-the-Sea and elsewhere. *S. strictissimum* is, therefore, a third colonist of this genus which has obtained a permanent footing in our flora.—Prof. W. Boyd **Dawkins,** F.R.S., directed attention to a new cause of folding of the rock other than that which has been long recognised by geologists as ultimately due to the folding of the outer layers of the earth as they follow the contracting nucleus. The deep cuts made through valleys to make watertight barriers in the construction of reservoirs revealed the fact that the bottom of the valleys, wherever it was formed of shales and thin sandstones, was more or less folded and contorted. These folds and contortions caused the shales to let the water through with more or less freedom, and he had been called in repeatedly to advise as to how far it was necessary to carry the puddle trenches down below the valley bottom. He found, as a matter of experience, that these folds were superficial, and if the sinking were made to a sufficient depth below the bottom of the valley they disappeared altogether. It was therefore obvious that they were not due to deep-seated movements of compression resulting from the contraction of the earth. They are due to the relaxation of pressure caused by the removal of the rock by denudation from the area of the valley, and are analogous in every particular to "the creep" in coal workings, caused by the excavation of coal, by which the surrounding strata crush down into the area of relaxed pressure and ultimately fill it up. This may be studied in any coal pit where there is a superincumbent pressure, say, of more than 1000 feet. The two following illustrations of folding and faulting by relaxation of pressure are presented by the puddle trench of the Langsett reservoir belonging to the Sheffield Corporation, and by the two reservoirs now under construction on the head waters of the Derwent by the Derwent Water Board. In the first of these the foldings in question at the bottom of the valley in the shale under the first grit are strongly marked at the surface. These folds gradually disappear, and are based upon a hard black unmoved shale offering a good foundation about 60 feet below the bottom of the valley. This is in the valley of the little Don. The thickness of rock removed from the bottom of the valley amounted to no less than something like 8000 feet of Coal-measures and Millstone Grit. In the case of the Derwent, in which the folding is much more marked and is accompanied by faulting, the thickness of rock removed amounted to at least 9700 feet (7200 feet of Coal-measures, 2000 feet of Millstone Grit, and at least 500 feet of Yoredale). In this the movement had not extended beyond a depth of 90 feet. In the case of the Derwent reservoir lower down the river there are two systems of folding and faulting which do not penetrate beyond 60 feet from the surface. At that point a good foundation is found for the puddle trench of the embankment.

PARIS.

Academy of Sciences, October 10.—M. Mascart in the chair.—The discontinuity of the external work of muscles compared with the discontinuity of their internal work from the point of view of the energy expenditure of the contraction: A. **Chauveau.** The results of two sets of experiments are given graphically.—On Perrot's experiment: Louis **Maillard.** A preliminary account of some qualitative results is given. In the first set of experiments twelve succeeded out of twenty-one. In a second set, in which greater precautions were taken to ensure the stability of the receiver, and to avoid currents of air and temperature changes, thirty-one out of thirty-three experiments were successful.—Colour photographs obtained by the interference method without using the mercury mirror: E. **Rothé.** A careful examination of some photographs taken by Lippmann's method led to the conclusion that it ought to be possible, by prolonged exposure, to obtain photographs in colour by the reflection of light on the air-gelatine surface only, and this has been proved experimentally. The method presents the advantages of being applicable in any apparatus without the use of special material.—On the temperatures of transformation of steels: Georges **Charpy** and Louis **Grenet.** Three methods were applied to each sample, making use of the electrical resistance, the expansion, and the thermoelectric power. It was found that the thermoelectric and dilatometric methods show no well marked correlation except for the softer steels. On the other hand, the results furnished by the electrical resistance and dilatometric methods agree closely qualitatively and even quantitatively within the limits of experimental error.—Substituted derivatives of phenyldiazoaminobenzene: Léo **Vignon** and M. **Simonet.** The preparation and properties of several substitution derivatives of phenyldiazoaminobenzene are described. These substances are easily prepared by the interaction of the substituted diazoanilines with diphenylamine, and possess the general properties of the diazoamines, being usually unstable.—The influence of castration on the physique: Eugène **Pittard.**—Culture of a trypanosome of the frog: A. **Billet.**—On some Hæmoflagellæ of marine Teleostea: C. **Lebailly.**—New geological observations on underground sheets of water in the Brenner district: Pierre **Termier.**

CONTENTS.

THURSDAY, OCTOBER 27, 1904.

HALLER'S COMPARATIVE ANATOMY.

Lehrbuch der vergleichenden Anatomie. By B. Haller. Pp. viii+914. Erste Lief., pp. vi+424, price 8 marks; Zweite Lief., pp. viii+425 to 914, price 12 marks; illustrated. (Jena: Gustav Fischer, 1904.)

IN his preface the author explains that his aim in writing this book was to produce a modern work on the lines of the second or last edition of Gegenbaur's "Grundriss der vergleichenden Anatomie," which was published twenty-four years ago. The book deals in a concise manner with the structure of all animals from the Protozoa to the highest Vertebrata. The character and mode of treatment of the subject will be sufficiently described by the statement that the author closely follows in Gegenbaur's footsteps. For his material he has drawn very largely from Gegenbaur's recent "Vergleichende Anatomie der Wirbelthiere" (1898 and 1901); but as he devotes much more space almost half the book—to the Invertebrata than is given to this branch of the subject in the latter work, he has freely used the facts and illustrations found in the great treatises of A. Lang and Korschelt and Heider in compiling the first part.

The whole book, with the exception of the part dealing with the structure of the brain of vertebrates, concerning which the author has published some original memoirs ("Morphologisches Jahrbuch," 1898 and 1900), is obviously a compilation, and not from the original writings, but from such books (themselves of necessity largely compilations) as have already been mentioned. The result is what one would naturally expect. The book reproduces many of the mistakes of the works from which it is derived, and adds not a few misinterpretations which do not occur in these; the information is not up to date. The author is, for example, unaware of J. P. Hill's discovery of a placenta in the Marsupialia, and is apparently ignorant of Willey's work on Balanoglossus; the descriptions are disjointed and difficult to understand, such as would be written by one who has no adequate practical acquaintance with the facts, or has not digested the mass of pabulum with which he is dealing. Anyone who has had occasion to make use of the last edition of Gegenbaur's "Vergleichende Anatomie" knows to how great a degree this work fails to reach the high level of the first edition, which was written when the author was in his prime. In the last edition Gegenbaur relied in too many cases upon the immature work of young contributors to the "Morphologisches Jahrbuch" in preference to more trustworthy researches published elsewhere. All such faults are reproduced in Haller's book.

The attempt to cover so vast a field as the entire animal kingdom is such a colossal undertaking in the present state of knowledge that one hesitates before hastily passing judgment on the work as a whole. In such circumstances the reviewer naturally turns for an estimate to those parts of the book in which the author might claim to write as an expert. The portion dealing with the brain of the Vertebrata is almost entirely original.

The difficulty of understanding the author's meaning which characterises the greater part of the book is greatly increased in the case of the nervous system by his frequent abuse of terms and the needless invention of new names for structures which already have designations familiar to all anatomists. But, in addition, his account of the brain is so studded with inaccuracies that the mere enumeration of them would fill the whole space devoted to this review. It is sufficient to quote only a few from among many others equally astounding. While he correctly locates the caudal limit of the forebrain on the dorsal side at the posterior commissure, he places it on the ventral side at the junction between the mid- and hind-brain, which he calls "sulcus interencephalicus" (p. 623 and elsewhere). In reptiles, birds, and mammals he calls the paraterminal body (which in mammals becomes converted into the septum lucidum and the precommissural area) by the name "gyrus fornicatus"—a term which is employed by all other anatomists to designate a strip of neopallium above the corpus callosum (pp. 633 and 638 *inter alia*). To add to the confusion, he labels the fascia dentata in a marsupial brain "gyrus fornicatus" (p. 640). In figures of the brains of reptiles, birds, and a mammal (rabbit), he labels as "sulcus coronarius" furrows which are certainly not homologous the one with the other; and even in the mammal it is not the "coronary" but the "lateral" sulcus on which he has placed the label. On p. 638 he refers to the hippocampus as "part of the occipital lobe," and on the preceding page he states that the occipital lobe is separated from the frontal lobe in Echidna by the Sylvian fissure; by the latter term he refers to a furrow (*p*, Fig. 629), which resembles the Sylvian fissure neither in form nor in position. But the most erroneous and hopelessly muddled parts of his account of the brain are his numerous references to the cerebral commissures. He seems to imagine that the "fimbria" and "fornix" (names applied by anatomists to different parts of the *same* series of hippocampal fibres) are independent structures, and he refers to the fornix-commissure by the term "fimbria-commissure," and applies the former term in one place to a part of the anterior commissure, which has no connection whatever with the fornix, and in another place to the corpus callosum! To this amazing confusion he adds the further error of attributing to Phascolomys a corpus callosum like that of Erinaceus, and representing an utterly different state of affairs in Didelphys, whereas all marsupials lack a true corpus callosum.

His spelling of many terms is somewhat peculiar. As examples I might quote "thalam*o*cephalon" (p. 636), "rhin*o*cephalon" (p. 638), "t*h*ela" (p. 637), and "corpus callos*i*" (in several places).

If we judge the whole work by the part to which the author has devoted his chief attention no condemnation of it can be considered too harsh. It is confused, inaccurate, and difficult to understand.

The book has one great redeeming feature in its numerous illustrations. They are, on the whole, well

chosen, clearly and yet artistically drawn, and excellently reproduced. The sources from which they were derived are indicated in some cases only, although a number of the unacknowledged figures will be familiar to the readers of zoological literature.

There is an unduly large number of misprints in the book, especially in the lettering and the inscriptions of the various figures. There is no bibliography.

G. E. S.

LIQUID CRYSTALS.

Flüssige Kristalle: sowie Plastizität von Kristallen im Allgemeinen, Molekulare Umlagerungen und Aggregatzustandänderungen. By Dr. O. Lehmann. Pp. vi+264; atlas of 39 photographic plates. (Leipzig: W. Engelmann, 1904.) Price *1l.* net.

WHATEVER may be the ultimate conclusion of physicists concerning the explanation of the interesting phenomena described by the author of this volume under the term "liquid crystals," and however diverse may be the views entertained as to their bearing on current molecular theories, there can be no difference of opinion as to the value of the work before us, in which the description of these phenomena is so clearly set forth and so fully illustrated.

It was in 1889 that Dr. Otto Lehmann, the professor of physics in the Technical High School of Karlsruhe, and the author of many memoirs dealing with the application of microscopical methods to physical research, first suggested the use of this term "liquid crystals." The acceptance of the term by physicists and crystallographers has not been by any means universal or unqualified, and in certain quarters it has been received with something like ridicule. The general attitude which, with our present knowledge of the subject, it may be wise to preserve was well expressed by Prof. Miers in an article upon the subject which he contributed to *Science Progress* of January, 1897:—

"It will be wise to retain the names crystal and crystalline in their old significations, rather than to extend them so as to include the birefringent liquids whose existence has been established by Lehmann. It may be that these remarkable drops are examples of liquid matter in which particles while free to move are compelled to preserve the same orientation, and differ in this respect from ordinary liquids. But whether this peculiarity of structure, whatever may be its nature, is really analogous to that of solid crystals is a question in which it will be better not to commit ourselves to an answer by applying the same name to both until more is known about the structure both of liquids and solids."

It is not probable that the present volume will materially affect the cautious verdict pronounced by Prof. Miers, seven years ago, on behalf of crystallographers and physicists, for although many new and interesting observations are added to those announced in Prof. O. Lehmann's earlier memoirs, there is nothing in the work before us which can be regarded as supplying absolutely conclusive or crucial evidence on the subject.

In his original memoir Dr. O. Lehmann was able to confirm the observations of Reinitzer and of Gattermann that certain organic compounds possess two melting points, and he showed that, at temperatures between these two melting points, the substances, though possessing the freedom of motion of liquids, affect polarised light like crystals, and, like crystals, exhibit the phenomenon of dichroism.

In the treatise under review the list of organic compounds exhibiting these remarkable properties is considerably augmented, though all the newly described substances are closely allied in their chemical nature to those previously known. Dr. O. Lehmann proposes to divide them into two classes—"Fliessende Krystalle," in which between the two melting points the crystal retains something of its original form, modified by the rounding of the edges and angles, though two of them brought into contact have sufficient mobility to enable them to unite; and true "Flüssige Krystalle," in which, although the original crystal form is wholly lost and the substance forms rounded and very mobile drops, the double refracting and other optical properties of the crystal are nevertheless retained. It is, however, admitted by Lehmann that the distinction between these two classes of substances is neither very definite nor of fundamental character.

It is impossible in the space at our command, even if such a course were desirable, to enter upon the discussion of the physical relations of solids and liquids which the author bases on his observations. On many points he arrives at conclusions in marked opposition to those maintained by Butschli, Nernst, Ostwald, and other physicists.

By the aid of the beautiful photographs, so admirably reproduced in the plates, and the numerous diagrammatic figures in the text, the reader will find it possible to follow and understand the very interesting observations of the author. The value of the photographs would certainly have been increased if, in every case, the degree of magnification had been indicated; and a detailed description of the plates with a good index would have added to the value of this very important treatise.

THE TESTING OF STEELS.

Relations between the Effects of Stresses Slowly Applied and of Stresses Suddenly Applied in the Case of Iron and Steel. Comparative Tests with Notched and Plain Bars. By Pierre Breuil. Pp. vii+152+23 plates. *Jour.* Iron and Steel Inst. Supplement, vol. lxv. (London: Iron and Steel Institute, 1904.)

CONSIDERATION of the subject of tests and testing should be approached with a very open mind, not only because it is the common meeting ground of the engineer and the metallurgist, but because it is a difficult subject of compromise, where the selected method is practically never ideal. Steel is necessarily as often submitted to tests which it is hoped will give a measure of its qualities as to those stresses to which it will be exposed in practice. The latter is the practical ideal test short of behaviour in actual use, which is seldom feasible, as often the finish of the test would require to be left to another generation. Thus the real purpose of tyres or rails is to wear well without breaking; nevertheless, they are often tested

to destruction by a falling weight, and the material invariably so in tension.

Again, some members of a girder are in tension, others in compression, while practically all are passed on the measure of their qualities given by the tensile test. For a certain elastic limit and maximum stress the highest elongation and reduction in area are assumed to indicate the toughest steel. For materials where great toughness is of paramount importance, the tensile, cold bending, and even quenched bending are typical tests, and on the whole they have served well; but in perhaps one case out of many thousands mild steel snaps in use without elongation after satisfying all ordinary tests for ductility. Cases such as these, which, though rare, may entail great loss of life or, as in the case of certain parts of vessels of war, might mean disaster to a whole crew, have probably been the exciting cause which has set men on the search for some means of detecting these rare cases where the risk would justify the extra expense.

It is evident that this case of one in thousands cannot be touched by experiments on (to quote the author) "no less than five tons of various kinds of specially manufactured metal," for that particular one must be found by the real test of failure in ordinary use and experiments made on it. The author's unconditional advocacy of the plain tensile and bending tests, and scornful reference to the others, indicates either that he is happy in a paradise which need not be specified or that many eminent practical and scientific engineers and metallurgists are at the present day unnecessarily anxious. No one would advocate the abolition of the tensile tests, as they are required for the engineer's calculations, and are generally a sufficient guarantee of trustworthiness. The sole contention is that in certain special cases something more is necessary.

The reviewer has been engaged during the last two years with Prof. Arnold on this very matter, subjecting steels known to have failed in use to Arnold's alternating stress and other tests with a view to find a practical system which will eliminate those possessing this curious brittleness. Two steels, one the best modern make of boiler plate, the other a steel which gave passable tensile tests and bent close double without a sign of distress, yet broke during the official hydraulic tests, gave very different results under the special alternating stress test. These statements having reference to facts, no study of comparative tests on specially manufactured steels can strike at the root of the matter. Although to certain mechanical testers and men of figures the variations in some of the results from the newer methods may look somewhat formidable when presented as percentages, the fact remains that these tests have picked out dangerous steels which had satisfactorily passed tensile and bending tests. Therefore some such new system of testing claims the special attention of the designer of high-speed and other work where large issues, and possibly loss of life, would be involved by the failure of a member.

This volume is the Carnegie gold medal thesis for the year, and deals with experiments on tensile tests, on plain and on notched bars, slowly applied. Many figures are given on the effect of size and form of notch. Plain and nicked bends slowly applied and as impact tests are also considered, but excuse is made that the subject is so large that it could not be adequately dealt with. The present writer is firmly convinced that it would count more for real solid progress if the Carnegie scholars were encouraged to take a smaller field and explore it more thoroughly, for to a steel metallurgist a brief paper embodying definite and concrete results is far more valuable than a voluminous and indefinite thesis. It is worthy of note that the 0·7 per cent. and 0·4 per cent. carbon steels contained 0·34 per cent. and 0·22 per cent. silicon respectively, amounts that would debar their acceptance under British specifications, not on account of the tensile tests, but because of their suspected greater liability to break under vibration.

A. McW.

CHEMISTRY OF THE PROTEIDS.

Chemie der Eiweisskörper. By Dr. Otto Cohnheim. Zweite Auflage. Pp. xii + 313. (Brunswick: Vieweg und Sohn, 1904.) Price 8.50 marks.

ALTHOUGH only four years have elapsed since the first edition of this work appeared, the great advances made in our knowledge of the chemistry of the proteids have necessitated a considerable revision of the book. The author, however, has found it possible to avoid any enlargement of the work by altering the order of subjects treated, and by stating the facts more concisely than in the previous edition. Some of the alterations in arrangement appear somewhat difficult to justify. Thus, for example, in the earlier edition the physical characters were dealt with prior to the consideration of the more purely chemical properties of the proteids, while in this edition the order is reversed. As the first edition has been already reviewed in Nature, only a brief account of the chief additions to the second will be necessary.

Perhaps the most important recent additions to our knowledge have consisted in the more complete separation and identification of the products of the hydrolytic decomposition of the proteids. Dr. Cohnheim gives an excellent account of the results obtained in this field by E. Fischer and his pupils by means of the method of fractional distillation under reduced pressure of the ethyl esters of the amino-acids. This method has secured a much more complete separation of the amino-acids than any methods previously employed, although the results obtained are still far from quantitative. By its use E. Fischer has been able to prove that certain amino-acids, namely, α-amino-valerianic and α-amino-β-oxypropionic acids, are much more widely distributed products of proteid hydrolysis than has been hitherto supposed. Fischer has also succeeded in separating two acids, namely, α-pyrrolidincarboxylic and oxy-α-pyrrolidincarboxylic acids, which were hitherto unknown as products of the decompositions of proteids. The latter acid was isolated from the residue remaining after distilling off the esters of the amino-acids. A full account is also given of recent work on the more complete chemical characterisation of the amino-acids, including the separation of several into optically active isomers.

The isolation and determination of the probable constitution of tryptophane by Hopkins and Cole, and that of oxyphenylæthylamine by Langstein and Emerson, may also be mentioned as some of the most important additions to our knowledge of the products of the hydrolysis of the proteids by the action of trypsin. Dr. Cohnheim appears to have omitted to mention the discovery of the latter substance.

Our knowledge of the chemistry of the diamino-acids and other basic products of hydrolysis has not been so markedly increased. The constitution of histidin has not yet been determined, although the evidence so far obtained points to it being a pyrimidine derivative. The discovery by Herzog that it gives the biuret reaction is of much importance in view of the fact that this test has been used to distinguish between the more complex products of proteolysis which still retain proteid characters and the simpler chemical bodies resulting from more complete decomposition.

The tables compiled by Dr. Cohnheim which give the nature and quantity of the products of hydrolysis of various proteids and albuminoids form a very useful addition to the book.

The third chapter of the general part of the work gives an interesting account of the chief views held with regard to the constitution of the proteids. The most interesting advance in this field is due to E. Fischer, who has shown that the amino-acids possess in a marked degree the power of reacting with one another to form more complex bodies. The prototype of these substances—glycylglycin—results from the union of two molecules of glycin with the elimination of the elements of water, the amine group of the one molecule reacting with the carboxylic group of the other to form an amide. By extending this synthesis Fischer has succeeded in preparing compounds of three or more molecules of various amino-acids to form compounds which he terms polypeptides. Some of the more complex polypeptides resemble peptones in many of their chemical properties.

In the special part of the work the section on the proteids of plants has been much extended. The section on nucleoproteids gives a good account of recent work elucidating the constitution of the pyrimidine derivatives, uracil, thymin, and cytosin. Considerable additions, embodying the work of Nencki and Zaleski, and of Küster on the decomposition of hæmatin, have also been made to the chapter on the blood pigments.

The second edition of the work well maintains the high standard for completeness and accuracy secured by the first one.

OUR BOOK SHELF.

Elements of General Radio-Therapy for Practitioners. By Dr. Leopold Freund, Vienna. Translated by Dr. G. H. Lancashire. Pp. xix+538; illustrated. (New York and London: Rebman, Ltd., 1904.) Price 21*s*. net.

Dr. Freund is so well known to English workers in electrotherapeutics that any work written by him will be welcome. To his earliest writings the profession is largely indebted for the first experimental work in radio-therapy, and the results were sufficient to indicate the possibilities of X-rays in therapeutic work as well as in diagnosis. The work before us shows that Dr. Freund has based his experimental research upon a thoroughly scientific knowledge of what has been done by others as well as by himself, and consequently all workers with X-rays will feel indebted to him for his book and gratefully acknowledge this.

In his preface Dr. Freund states that he has attempted to bring the essential features of a recent form of treatment before the notice of a larger circle of medical men, that he has tried in a comprehensive way to explain the technique, the indications for treatment and the results to be expected, while at the same time tabulating and arranging the fundamental physical laws so as to explain the physiological effects. That he has succeeded no one will doubt who reads the work, and that the views of others have not been forgotten is made evident by the fact that he quotes more than eight hundred writers upon the subject. The author admits that this branch of science can hardly be said to be more than in its infancy, that there are gaps in our knowledge to be filled in and errors to be corrected; but notwithstanding the doubt expressed in some quarters we have already achieved brilliant theoretical and practical results which lead him to hope that radio-therapy will obtain an acknowledged place among our methods of treatment. In support of this view he says one need only refer to the undeniable and astonishing results already achieved in skin disease.

After a short but expressive introduction referring to the physical aspect of the question, Dr. Freund divides the work into five sections. The first deals with the elements of electricity, and this section should be useful to medical practitioners who are desirous of obtaining the acquaintance with physics necessary to understand this special branch of surgery. The second part treats fully of high-frequency currents, the third section is devoted to X-rays, the fourth to Becquerel rays, and the fifth to treatment with heat and light rays.

A careful perusal of the different chapters will convince anyone that Dr. Freund has fully succeeded in his aims; and that the text-book under notice will become a popular one is certain. That it will be regarded as one of the standard works on the subject no one can doubt.

English workers are largely indebted to Dr. Lancashire for his excellent translation of the work, and to Mr. Clarence A. Wright for his notes on instrumentation published in connection with the English edition, which are introduced at the end of the book.

The whole is clearly and scientifically written. There are one hundred and seven illustrations taken from the original text, and the author, translator, and publisher are to be congratulated upon the success of their efforts.

Physiography. An Introduction to the Study of Nature. By T. H. Huxley. Revised and partly re-written by Prof. R. A. Gregory. Pp. xi+423; with 301 illustrations. (London: Macmillan and Co., Ltd., 1904.) Price 4*s*. 6*d*.

The task of revising and bringing up to date Huxley's inspiring text-book of physiography was one not to be lightly undertaken, but it could not well have been placed in better hands than those of Prof. Gregory. In spite of the many fine qualities of the original volume, and of the author's belief that its methods could be adapted with little difficulty to any locality by an intelligent teacher, it can scarcely be questioned that the usefulness of the book was somewhat restricted by its special reference to the Thames and its basin.

In its new form, however, the book no longer specially appeals to those who dwell in this neighbourhood, but is equally applicable to any river basin.

While the value of the book is undoubtedly much enhanced by the judicious additions which have been made to the text, the most notable feature of the new edition is the abundance of excellent illustrations. The majority of these are from actual photographs, and depict a great variety of natural objects and phenomena, among which are clouds, glaciers, volcanoes, earthquakes, and geological structures. This unique collection of photographs, each of which is of real value, makes the book of quite exceptional interest, and it is pleasant to learn that many of the pictures have been generously contributed out of regard for the memory of Huxley. The scope of the subject, as here set forth, is such as to make it the natural complement of the "nature-study" which refers chiefly to the various forms of life. That is to say, it is regarded entirely as an introductory subject, dealing with inanimate nature; and it may be remarked that it does not unduly encroach on the domains of physics, chemistry, or astronomy. We are glad to note that instructions for practical work, which is obviously essential to make the study of the greatest educational value, are in course of preparation. Meanwhile, the present book will be heartily welcomed as a clear, attractive, and trustworthy introduction to the study of science. A. F.

Die Theorie der Direkten Anpassung und ihre Bedeutung für das Anpassungs- und Deszendenzproblem. Versuch einer methodologischen Kritik des Erklärungsprinzipes und der botanischen Tatsachen des Lamarckismus. By Dr. Carl Detto. Pp. 214; mit 17 Abbildungen im Text. (Jena: Gustav Fischer, 1904). Price 4 marks.

Of two well-known tenets of Lamarckism, the inheritance of acquired characters, and the power of "direct adaptation" on the part of the individual organism, the consideration of the former is relegated to a few pages at the end of the present work, which is mainly concerned in combating the latter. This pro-Darwinian book is, in fact, occupied in an endeavour to prove that individual organisms possess no mysterious and inexplicable power of adjusting themselves to their surroundings, and that from this point of view the theoretical basis of Lamarckism is unsatisfactory. The first two chapters largely deal with psychological considerations, terminology, and definitions. The third chapter quotes and considers the views of Lamarck, H. Spencer, Eimer, Warming, von Wettstein, and others, so far as they relate to "direct adaptation." The fourth chapter (pp. 81–188) is devoted to the discussion of the facts and phenomena that are usually cited as demonstrating the power of direct adaptability on the part of individual organisms, and to alternative explanations of these. It is this chapter that will appeal most to the busy botanist, who, after ascertaining the meaning of the two new terms "œcologism" and "œcogenesis," may find it advisable to commence the book at this point. The following selected headings suffice to illustrate the kind of subjects dealt with:—methods of interpretation of the facts of "direct adaptation"; direct adaptation in bacteria, fungi (including a discussion of a biological species of Uredineæ), and Euglena; physiological adaptation among highly organised plants (races produced by nutrition, climatic adaptation in respect to duration); structural adaptations among highly organised plants (œcological convergence of types; parallel variation in xerophytes, hydrophytes, halophytes; shade-leaves).

The Photographic Reference Book. Edited by J. McIntosh. Second edition. Pp. 344. (London: Iliffe and Sons, Ltd., 1904.) Price 1s. 6d. net.

The first edition of this book was chiefly compiled by using the columns devoted to answers to correspondents of *Photography* as a basis, the work being undertaken by Messrs. W. A. Watts and Henry Sturmey. In the present issue the material has been largely rewritten and much new matter added, so that the book may be considered as practically a new one. The editor has, however, confined himself to the original object for which the book was written, namely, a worker's handbook, and as such the reader will find that the present volume is a handy and useful *vade mecum*. The great point about a work of this character, if it is to be useful, is the facility with which any information that is desired can be found and correctly given. Both these desiderata are here, for a capital index supplies the former and the paragraphs under the different headings complete the latter. Many subjects were chosen at random, and in each case the facts required were easily found and fully given. As a book of reference this issue should be the companion of many photographers.

Transactions of the South African Philosophical Society. Vol. xiii. Part i. Pp. 1–293; plates 1–4 (43–46 of the whole series). Descriptive Catalogue of the Coleoptera of South Africa (Lucanidæ and Scarabæidæ). By L. Péringuey. (Cape Town, 1904.)

An exceedingly valuable synopsis of South African Coleoptera, chiefly by Mr. Péringuey, the worthy successor of Mr. Trimen in the South African Museum, is at present being published in the above named *Transactions*. Vol. xii. was devoted to the descriptive catalogue of Lucanidæ and Scarabæidæ, and vol. xiii., a goodly instalment of which now lies before us, continues the subject. It includes the subfamilies Sericinæ (tribes Sericini and Ablaberini) and Melolonthinæ (tribes Pachypodini, Sparrmannini, and the first four groups of the Melolonthini). Many of the species figured are very handsome, resembling in miniature the magnificent Goliath beetles of the west coast of Africa. The work is too highly technical for detailed notice here, but the excellent tables and descriptions of genera and species will render it very useful to students of South African Coleoptera. We hope in time to possess equally elaborate works on the insects of all the British colonies. W. F. K.

Toning Bromides and Lantern Slides. By C. Winthrope Somerville, F.R.P.S. Pp. 72. (London: Dawbarn and Ward, Ltd., 1904.) Price 1s. net.

This is a collection of formulæ for many methods, practically, perhaps, all the methods in use, for toning "bromide" prints. Lantern slides do not appear to be mentioned in the text, and it can hardly be supposed that all the processes given are available for them, as, for example, the "hypo and alum, or 'boiling' process." Perhaps in future editions this part of the subject will receive more attention. The author is enthusiastically in favour of the choice of bromide printing rather than the other methods of photographic printing available. To him it is "the ideal of the present day." He actually compares it with platinum and carbon printing to the disadvantage of these for fineness of result, and claims for it an equal permanency. Of course many will not agree with the author in this, but it is an advantage to have the formulæ preferred by one who thoroughly believes that the process treated of is altogether the best, and to have the results of his experience.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Further Discovery of Dodos' Bones.

SINCE the astonishing discovery, in 1865, of innumerable bones of the dodo in the peat of the Mare aux Songes by Mr. George Clark, of Mahébourg, in Mauritius (*Ibis*, 1866, pp. 141–146), whereby Prof. Owen was enabled to describe the greater part of the skeleton of that remarkable bird (*Trans.* Zool. Soc., vi. pp. 49–80), and the subsequent researches at the same place of Mr. Sauzier in 1889, the results of which, when worked out by Sir Edward Newton and Dr. Gadow (*Trans.* Zool. Soc., xiii. pp. 281–302), almost wholly completed our knowledge of its osteology—besides affording evidence of the former existence of other contemporary species now extinct—nothing more has been recorded on the subject.[1] It was therefore with great interest that, just five years ago, October, 1899, I received a letter from M. E. Thirioux informing me of his having found, in the preceding month of August, some remains of at least two dodos in a small, partly collapsed cave, about 800 feet above the sea, and about two miles and a half from Port Louis. Encouraged by this success M. Thirioux continued his operations, a matter of some difficulty, not to say danger, from time to time, and was good enough to keep me acquainted with many of the results, sending me photographs of the bones which he was fortunate in disinterring from the soil. They were not all dodos' bones, but some belonged to other extirpated forms of birds—as the brevipennate parrot (Lophopsittacus), the "Poule Rouge" (Aphanapteryx), and the coot—and reptiles—as Didosaurus and one or more of the land tortoises—all of which are very imperfectly known, while some of the small dodo bones are of great rarity, and at least one of them (the pygostyle) had not been seen before. From that time until very recently M. Thirioux has been continuing his researches, and has consequently formed a very considerable collection, which he now writes to me he has disposed of to the Museum of Mauritius, and I can but express the fervent hope that some competent person may be found to work it out and publish a memoir on it which will be a worthy successor to those that I have already mentioned. ALFRED NEWTON.

Cambridge, October 20.

The Forest-pig of Central Africa.

THERE are two good mounted specimens of the forest-pig in the Museum of the Congo Free State at Tervueren, near Brussels, where I had the pleasure of examining them in July last. M. A. Dubois, conservator of the Royal Museum of Natural History at Brussels, told me that he intended to describe the animal in conjunction with Dr. Matschie, of Berlin, but I am not aware that their description has yet been published, so that I hope the forest-pig may remain known by the excellent name Hylochœrus, proposed for it by Mr. Thomas.

As regards the "third mysterious animal" of the Congo Forest alluded to by Sir Harry Johnston in his letter on this subject (NATURE, p. 601), I have little doubt that it was the fine antelope of the genus Tragelaphus, lately described by Mr. Thomas as *Boocephalus euryceros isaacsoni* (*Ann. Nat. Hist.* (7), v. p. 310, and *Proc.* Zool. Soc., 1902, ii. p. 319). The first pair of horns of this species was obtained by Mr. F. J. Jackson in 1897 (see *Proc.* Zool. Soc., 1897, p. 455), but it is only recently that the perfect specimen which now adorns the mammal gallery of the British Museum was procured.

The "abnormally developed horns of the cow eland" referred to by Sir Harry Johnston have nothing to do with this antelope. They will be found fully described and figured in the "Book of Antelopes" (vol. iv. p. 209).

P. L. SCLATER.

[1] Some reputed dodos' bones, said to have been found in a cavern (*Proc.* Zool. Soc., 1885, p. 719), turned out to be turkeys' (*op. cit.*, 1890, p. 402).

Average Number of Kinsfolk in each Degree.

THE letter you forward to me from Prof. G. H. Bryan gives an opportunity of discussing the question somewhat more thoroughly than space allowed in my brief memoir of September 29.

The writer says:—"Is Dr. Galton's deduction of $d-\frac{1}{2}$ correct? I should have thought that if a parent had d male and d female children, each female child would have $d-1$ sisters and d brothers."

The objection holds good only on the erroneous supposition that each and every family of $2d$ children consists of d boys and d girls; it does not hold good on my supposition that each such family contains *on the average* d boys and d girls. The inclusion of the omitted word introduces a new set of considerations. They depend on the variety of the possible forms of combination of boys and girls in $2d$ children, which are $2d+1$ in number, and on the frequency of each of these forms, which is given by the $d+1$ terms of the binomial expansion of $(1+1)^{2d}$. The exact character of the process concerned is clearly appreciated by thoroughly working out some particular case, say that of $d=2\frac{1}{2}$, where the number of children, $2d$, in each family will be 5. There are then 6 possible combinations of boys and girls, forming 6 different classes, shown in the first three lines of the table.

(1)	Classes	I.	II.	III.	IV.	V.	VI.	
(2)	Boys in each family	5	4	3	2	1	0	
(3)	Girls in each family	0	1	2	3	4	5	
(4)	Sisters in each family ...	—	—	2	6	12	20	Totals
(5)	No. of families in each class	1	5	10	10	5	1	32
(6)	Girls in all the families ..	—	5	20	30	20	5	80
(7)	Sisters in all the families...	—	—	20	60	60	20	160

In line (4) is shown the number of sisters in any *one* family of each of these classes ($n.(n-1)$ sisters to n girls). Thus in each family in class vi. there are 5 girls, consequently $5\times4=20$ sisters, in class v. there are 4 girls, and $4\times3=12$ sisters, and so on. The total number of combinations of boys and girls in a family of 5 children $=2^5=32$, which are distributed into six classes according to the familiar binomial fashion as above; these are shown in line (5). Multiplying each entry in (5) with that in the same column in (3) we obtain line (6), which shows that the total number of girls in the 32 families is 80 ($=2\frac{1}{2}\times16$, as it should be). Multiplying similarly the entries in (5) by those in (4) we obtain line (7), which shows that the 80 girls have between them 160 sisters; consequently each girl has on the average 2 sisters. This is identical with my $d-\frac{1}{2}$.

I have made similar calculations for values of $d=1$, $1\frac{1}{2}$, 2, $2\frac{1}{2}$ (above), and 3. In each case the result is that a girl has on the average $d-\frac{1}{2}$ sisters. It may therefore be assumed that the reasoning by which I originally arrived at that deduction is correct.

Before concluding, I should like to direct attention to a slip of the pen in the last line but one of my memoir, which somehow escaped correction; the term $d=5$ should have been $2d=5$. The context corrects the mistake, which may nevertheless puzzle the reader for a while.

FRANCIS GALTON.

Mendel's Law.

IN his letter of last week detailing his most interesting experiments on cross-bred maize, Mr. R. H. Lock makes the following statement:—"I see from the published account of a recent discussion at the Cambridge meeting of the British Association that the facts of Mendelian segregation are still disputed by the biometric school of evolutionists." Now it is easy to make a general statement about some vaguely defined group of men, and I have no right to speak for biometricians as a body. But as inventor of the term *biometry*, I may perhaps be allowed to say what I understand by it as a science, and to restate what I said with some emphasis at the Cambridge meeting. Biometry is only the application of exact statistical methods to the problems of biology. It is no more pledged to one hypo-

thesis of heredity than to another, but it must be hostile to all treatment which uses statistics without observing the laws of statistical science. The criticism which has been published in *Biometrika* upon Mendelian work has attacked its too frequent want of method and of logic, and I think no one can have read recent literature without seeing that the criticism has been effective in its aim. Even Prof. Tschermak now allows a large influence to ancestry, although he asserts that the offspring are not distributed "in the proportions of Galton and Pearson." As I have never distributed the offspring in *fixed* proportions, I may perhaps be content with the admission.

I have headed my letter "Mendel's Law," but the difficulty is to know what is understood by this term. Mr. Lock reproves me in his "Studies in Plant Breeding in the Tropics" because I distinguished a theory of the pure gamete from pure Mendelianism, for I thought, and still think, Mendel himself considered "dominance" an essential part of his system. Another Mendelian protagonist, Prof. Castle, in his last paper writes:—"The basic principles of Mendel's law are two, the principle of dominance and the principle of segregation." Which view is the correct one? If Mendel's law be limited to its earliest form, then it may cover Mendel's own observations and Mr. Lock's maize, but there are many other cases of segregation which it does not cover. So far as I am aware, the only attempt to carry out any form of Mendelianism to its logical conclusion was produced by one biometrician at the suggestion of a second. I refer to my memoir in the *Phil. Trans.*—"A Generalised Theory of Alternative Inheritance with Special References to Mendel's Laws." Even then we did not succeed in making the fundamental hypotheses wide enough to cover the case of man, but we did show—what must be obvious on consideration—that a *description* by modern statistical methods of actual observations need not, as such, be itself opposed to any physiological hypothesis. Out of Mendelianism came on analysis the condemned "law of regression" and the diminishing correlations of the "ancestral law" whenever a population springing from hybrids mated at random.

One might at least have hoped that this result would have demonstrated how idle it is to contrast a school of "Mendelians" with one of "Ancestrians." It is, I fear, however, vain for the biometrician to try and right himself with the non-mathematically trained biologist. Notwithstanding that in every generation dealt with in my memoir the fundamental idea of Mendel is accepted and the recrossing of the parental forms with each member of the generation occurs and is treated as giving its Mendelian result, Mr. Lock in his "Studies in Plant Breeding" states that I entirely ignore Mendel's demonstration of the truth of his hypothesis by the process of recrossing with the parental form. The only ignoration seems to be one on Mr. Lock's part of what lies behind the mathematical symbols. What, then, is the Mendel's law for which Mr. Lock provides a "crucial experiment"? The mere fact of segregation? Two grey-eyed human parents will produce blue- and brown-eyed children; this has been long known, and is equally crucial. The segregation of *recessives* in certain cases in the proportion of a quarter? This is a fact, but, accepting the fact, is it needful to accept Mendel's theory to describe it? For Mr. Lock's maize, as for mice, we may fairly ask where the other homozygote is before we accept the experiments even as complete cases of the old simple Mendelianism. But Mr. Lock tells us that not even in 1900 did Mendelians suppose Mendel's law to hold good for all characters in all species. The experiment is therefore clearly not "crucial" for heredity at large. It is of interest, great interest, as adding to the number of things in which a Mendelian proportion of 1 in 4 holds for recessives. Will anyone explain why the absence of colour bulks at present so largely in the characters for which this proportion holds? There must be some physiological ground for it.

Karl Pearson.

The Formation of Polonium from Radium.

The idea has for some time been afloat that the polonium found in radio-active minerals is a product of the radium that they contain. I have recently made an experiment which seems to afford considerable evidence that this is the case. Some radium salt of quite low activity (barely sufficient to produce fluorescence), which has been in my possession four years or more, was dissolved in water, and some cupric chloride added. The solution was precipitated with sulphuretted hydrogen (the copper served to give a manageable quantity of precipitate).

The sulphide was very active. It was dissolved in nitric acid, and a plate of bismuth immersed in the solution, in order to collect polonium, after Marckwald. This plate became intensely active, giving α rays only. The activity was sufficient to light up a blende screen. The rays showed diminished penetrating power the further they had penetrated; their initial penetrating power was exactly the same as that of the rays of the polonium from pitchblende.

I think it will be agreed that the activity of this bismuth plate may be regarded as due to polonium. Its activity has not yet diminished. The question remains, was this polonium part of the original mineral, or has it been generated since? It is difficult to believe that the radiferous barium could have been freed from copper, bismuth, and the other metals in pitchblende, without being freed from polonium too.

I am making fresh experiments to see whether the formation of polonium can be traced in a radium solution initially quite free from it.

Terling Place, Witham, Essex.

Misuse of Words and Phrases.

Unfortunately a good style of writing English is not a strong point among men of science, especially mathematicians. The chief defects may, I think, be classed under three heads. First, grammatical errors, such as *Bessel functions, the Faraday effect, an uniform density* instead of *Bessel's functions, Faraday's effect* and *a uniform density*. Secondly, the use of uncouth, inelegant, and inaccurate phrases, such as *coal-stuff-gas, stretch-squeeze ratio, non-singular cubic or quartic curve*. Thirdly, a vague, obscure and slovenly mode of constructing sentences, whereby the author envelops his meaning in a cloud of mystery instead of enlightening the understanding of his readers. In fact, the sentences of some authors are so inartistically worded as to produce the impression that they labour under the delusion that a vague and obscure style of writing is evidence of profundity, whilst a clear and lucid one betokens shallowness.

The English language is by no means an easy one to write clearly and concisely, which is due to various causes, amongst which may be mentioned the absence of declensions. In Latin the nouns to which two pronouns respectively refer are always known if (as frequently happens) their genders are different; but in English considerable care is often required in the arrangement of a sentence so as to avoid ambiguity.

As regards the choice of language, there are two cardinal rules to be observed. In the first place, words are to be construed according to their natural and literal meaning unless there is something in the context to show that they are used in an artificial or secondary sense; secondly, lucidity and brevity ought always to be aimed at, and circumlocution and verbosity avoided.

October 22. A. B. Basset.

The British Association and Referees.

The correspondence in Nature some time ago respecting referees induces me to send you the following singular example of their unbusiness-like ways in the hope that greater care may be exercised in the future.

I submitted a radium paper to Section B for the Southport meeting. It was accepted; the usual proof was printed, revised by me and returned. *At* Southport it was decided by a joint committee of Sections A and B that the radium papers held by the latter should be handed over to Section A. This was done. It appears that my paper, now in new hands, was submitted to a referee and condemned. At the close of the meeting I was informed of the fact by the assistant general secretary. In the meantime, however, in reply to my personal inquiries, I had become acquainted with the state of things, and ventured partly to express my views on radio-activity at the discussion in Section A. In the sub-

sequent report of this discussion in your Journal these views were suppressed. The abstract of the rejected paper was printed in the annual report of the British Association, just issued, among the Section B papers, from the officers of which section I had received uniform courtesy and consideration throughout the transaction.

Now such a joint resolution as I have mentioned ought to have precluded any referee from rejecting a paper which had already been approved, and I have to suggest that a by-law be framed to render an occurrence of this kind impossible in the future. WILLIAM ACKROYD.

Striped Hawk-moths in Sligo.

THERE has been a letter or two in recent numbers of NATURE on the finding of rare moths in England. It may be of interest to the writers to know that in the middle of last September there was caught in the town of Sligo a specimen of the striped hawk-moth. It was captured in the printing office of the *Sligo Independent*, its great bulk first attracting attention and then its beautiful markings. I know but very little about insects, the honey bee excepted, but I carefully compared the living object with a description and coloured plate in a work on Lepidoptera, and have no doubt but that it was the very thing your correspondents are making so much ado about. It is now preserved in a little collection of Mr. Irvine (Ratcliffe Street), but the gorgeous colouring has all gone, and the striping is barely traceable. I have been told that another exactly similar moth was found last year a few miles from Sligo along the sea coast.

I never noticed one of these insects before, but if it be such a rarity in the British Isles as your correspondents seem to hold, it is easy enough to account for its presence in the present instance. Sligo is a sea-port town, and in August last a cargo of timber from, I was told, South America was discharged. Most likely the eggs came over in the timber and were here hatched out.

THE SIMPLON TUNNEL.

AS the Simplon Tunnel is rapidly approaching completion, natural curiosity is aroused as to the extent to which the accuracy of the alignment has been attained. This is a riddle which can only be answered when the last metre of rock has been removed and the two headings unite.

It was hoped that this international meeting of Switzerland and Italy, under Mont Leone, would take place in October, but in consequence of unexpected difficulties which occurred early in September, it is probable that the actual junction will not occur so soon.

The setting out of the centre line of the tunnel is done every month by the company and contractors, but, in addition to this, the work is checked several times in the year by the Government engineers. On these occasions the work in the tunnel is entirely suspended, so as to ensure that the atmosphere for the entire length shall be bright and clear. A small slit of light is thrown into the tunnel by means of a powerful lamp, and by the aid of theodolites this is taken right up to the working face. It is anticipated that when the actual meeting occurs the error in level will be nil, and that the error in direction will be under eighteen inches.

As our readers know already, the length of the tunnel will be $12\frac{1}{4}$ miles, all of which has been penetrated with the exception of a short distance of about 260 yards near the middle. The work consists of two single line tunnels 50 feet apart, axis to axis, and the object of having two tunnels in place of one has been fully justified by later experience, and for the following reasons. The ventilation is much more efficient, one tunnel being used as an "intake" for fresh air, which is blown in by powerful high-speed fans working with a water-gauge of nearly 9 inches, the other being the outlet; in case of derailment of a train occurring it cannot possibly run into a train in the opposite direction; when repairs are required one tunnel can be closed for a time, the traffic being conducted in the other; and finally, which is most important, the crushing weight of the material overhead is much more easily dealt with than it would be in a double line tunnel. When it is remembered that the overlying rocks extend to a height of 7005 feet, and that the workmen are at the enormous distance of nearly $1\frac{1}{2}$ miles below the surface, or 50 per cent. more than man has ever been heretofore, it will be realised that not only is the pressure enormous, but the heat is also great; in fact, the pressure which has been encountered is so great that in one place the arching, consisting of granite blocks, is 2 metres in thickness. The tunnel is arched throughout, as it was deemed advisable that no risk should be incurred of even a

FIG. 1.—The Great Spring, 12,000 gallons per minute.

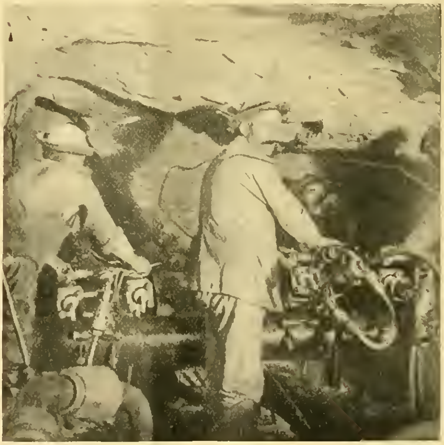

FIG. 2.—The Brandt drill at work at the "face." Daily progress 18 feet. Size of heading 10 feet × 6 feet.

small fragment of rock falling on to the permanent way.

In order that the present condition of the work may be better understood, a longitudinal section along the line of the tunnel is given, drawn to a small scale; and, with a view to illustrate the facts better, the gradient is very considerably exaggerated.

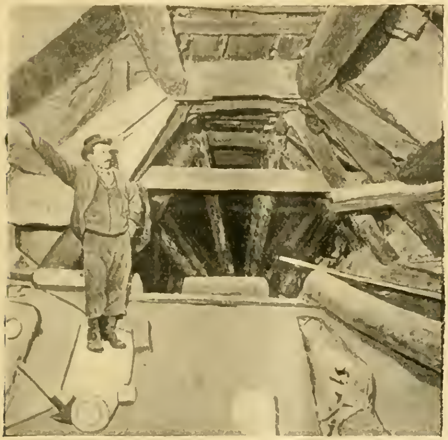

FIG. 3.—The timbering of the tunnel—six miles from the entrance.

It will be noticed that the gradient rises from each end of the tunnel towards the middle, the object of which has been to provide efficient drainage from the face, and it is an instance of the prudence which has been exemplified throughout the entire work that this system was adopted from the commencement. In driving a heading forward under a mountain, it is a matter of very common occurrence that springs of water are encountered; consequently, on the ascending gradient, the water flows away by gravity from the workmen; but should the work be carried out on a descending gradient, then the water accumulates where the men are working, not only causing them inconvenience and delay, but requiring to be pumped out over the highest point of the rails. In order to prevent delay, this was done for some considerable distance; but in consequence of a hot spring being encountered at the "face" on the Swiss side it was deemed necessary to withdraw the workmen, and the tunnel between points A and B has become filled with hot water.

At each end of the tunnel—Brigue at the north portal, and Iselle at the south or Italian entrance—a large and well equipped installation is provided for carrying on the works, and each of these is provided with machinery of sufficient capacity and power to serve for half the distance, that is, to the summit of the tunnel at A.

The work of actual perforation at Brigue and Iselle began in August, 1898, by hand, and by Brandt drill in December, 1898. When, however, the advance from the Italian entrance had reached a point between 15 and 16 kilometres, the great spring of 12,000 gallons per minute was encountered. This caused a delay of several months, thus throwing back the progress very considerably. In the meantime, the advance from Brigue proceeded rapidly, the summit A being reached in the month of December, 1903. Then arose the question, as already explained, in order to save time, of driving the tunnel downhill in order to meet the workmen coming up from Italy.

Meanwhile, the work on the Italian side has been pushed forward until the distance remaining to be pierced, as already mentioned, is only some 260 yards; but a serious difficulty has arisen, for again a hot spring has been encountered, and the temperature of the rock in the advance gallery is 108° F.

The system adopted for dealing with hot springs is very ingenious—and at the same time very simple. It was at first proposed to conduct the hot water out of the tunnel through pipes, but the simpler and more efficient method, which was adopted, is to play a jet of cold water into the fissure from which the hot water is escaping, and thus to cool it down to such a degree that the workmen are not seriously incommoded; they are then able to continue the drilling and blasting.

A channel or canal is being excavated at one side of the tunnel to carry the hot water from the spring to the outside, and this will be covered over with non-conducting material to prevent the heat rising into the tunnel.

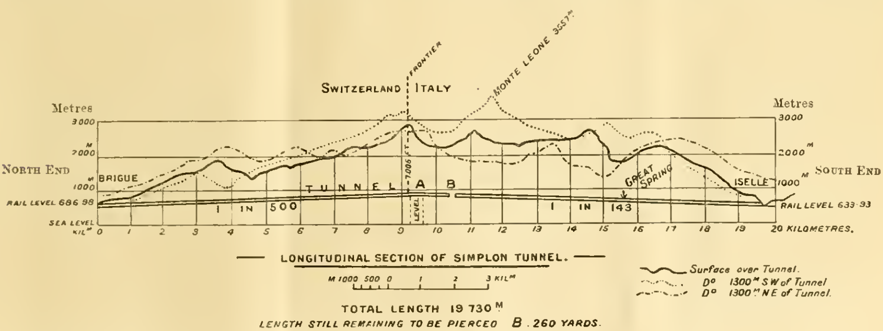

FIG. 4.—Longitudinal section of Simplon Tunnel.

The question arises from whence this great heat comes, for although observations made in various wells and borings in all parts of the world give an approximate figure of 1° F. rise in temperature for each 70 feet of vertical depth, this is insufficient to account for

what has been encountered, and one is driven to the conclusion that some portion of the thermal result is due to the internal heat of the earth arising from volcanic agency.

The energy and skill of those in control, amongst whom are Colonel Locher, Herrs Brandau, Pressel, Kager, Sulzer, and many others, are surmounting these difficulties, and it is anticipated that without any very great delay the junction of the headings will be effected.

Certainly no tunnelling operations in any part of the world have been exposed to such vicissitudes and difficulties, and when the arching of the tunnel is fully completed little will be left to show how hardly earned has been the victory over physical obstructions.

It is expected that within three months of the piercement trains will be running, and the railway will prove to be a most important link in the line of communication between Rome, Genoa, and Milan with Lausanne, Berne, and mid-Europe. FRANCIS FOX.

WATER-DROPPERS AND RADIUM COLLECTORS.

IT is more than forty years since Lord Kelvin commenced a new era in measurements of atmospheric electric potential by devising the water-dropper. Though marking a great advance, and simple in its construction, the water-dropper has not increased the happiness of those responsible for the conduct of self-recording meteorological instruments. It has weaknesses which it takes some time to discover, and which, when undetected, may lead to serious error. Some of the earlier forms had their water reservoirs so constructed that the pressure under which the jet issued varied considerably with the time since the reservoir was filled. Punctuality in filling the reservoir had in this case the disadvantage of accentuating a subsidiary diurnal variation not due to nature. The misdirected attention of spiders, variations of moisture, and other meteorological conditions, produce changes of insulation in the water tank; choking of the jet occasionally happens through impurities in the water, and in severe winters there may be complete stoppage through freezing of the jet. As this major catastrophe usually occurs at night, it generally entails a considerable loss of trace.

The idea of replacing the water jet by some radio-active substance presented itself pretty soon after the announcement of Becquerel's discoveries. The report of the International Meteorological Committee, which met at Southport in 1903, contains a note by Prof. Paulsen on his early use of a radio-active powder. This was spread on filter paper resting on a disc of copper, a thin covering plate of aluminium serving as a protection against rain. In this form the apparatus was used in Iceland in 1899–1900. M. La Cour modified this form by mixing the powder with caoutchouc into a paste, which was spread on a disc of copper, while a thin copper grating was pressed down on the top of the paste before it was quite dry. This form was used with satisfactory results in Finland in 1900–1. After wetting by rain, however, its efficiency was temporarily lessened. The same report also describes an instrument which M. Moureaux had had in use for some time at Parc St. Maur Observatory, Paris. It employs as collector chloride of radium in a shallow copper vessel, over which is soldered a plate of aluminium 0·1 mm. thick to keep out rain. Chloride possessing 5000 times the activity of uranium was not sensitive enough, but chloride with 30,000 times the activity of uranium gave good results. M. Moureaux so arranged matters that he could at pleasure record the electric potential, practically at a fixed point, either by the radium collector or a water jet. In this way he obtained an electrogram, successive portions of which were obtained in immediate sequence by the two collectors. Unless the times of the change had been indicated, one could not have told by inspection of the curve—which is reproduced in the report—which collector was being used. When M. Moureaux's note was written the radium had been in use for several months with satisfactory results. A foot-note, however, of later date, mentions that some months later the radium was found to have produced a number of minute holes in the aluminium, and that it was intended to dispense with the aluminium and protect the radium against rain by coatings of varnish. It was further hoped that this would admit of the use of cheaper chloride of less radio-activity.

The employment of radium is thus hardly out of the experimental stage, and any one adopting it at present would be well advised to check the action from time to time by recourse to a water jet. It would also be desirable to make sure before final adoption that the radium does not itself modify the potential which it is desired to record, more especially in calm weather. Whatever the final outcome may be, it is at least satisfactory that M. Moureaux's experiments showed agreement between the water jet and the radium collector when both were upon their good behaviour.

C. CHREE.

NOTES.

THE friends of Prof. G. Carey Foster, F.R.S., are taking the occasion of his recent retirement from the principalship of University College, London, as an opportunity of showing their appreciation of him by promoting a fund with the object of having his portrait painted for presentation to the council of the college, and a replica for presentation to Mrs. Foster. The president of the movement is the Right Hon. Lord Reay, G.C.S.I., and the vice-presidents are Sir Norman Lockyer, K.C.B., Sir Oliver Lodge, and Sir Arthur Rücker. Further information with regard to the scheme may be obtained from the secretaries of the fund, University College, Gower Street, W.C.

THE death is announced at Hamburg, on September 27, of Dr. H. Kortum, professor of mathematics at the technical college at Bonn.

THE Naples Academy of Physical and Mathematical Sciences offers prizes of 500 francs to the authors of the best papers in Latin, French, or Italian on the two following subjects: the processes of formation of urea in the animal organism, and the evolution of the ovaric ovum in the Selacii. The essays are to be sent in anonymously, bearing a motto, on or before June 30, 1905. The Padua Society of Encouragement offers, to Italian subjects only, two prizes of 5000 francs for an essay on the present state of the problem of electric traction on railways, and for a new method of diagnosing the disease of pellagra previous to its development. This competition closes on June 30, 1906.

A PETITION has been presented to His Majesty in Council asking for the grant of a charter of incorporation to the South African Philosophical Society under the name of "The Royal Society of South Africa."

MR. WILFRED MARK WEBB has accepted the honorary secretaryship of the Selborne Society.

THE death is announced of Dr. Tillaux, professor of surgery in the University of Paris, president of the Academy of Medicine, and Grand Officer of the Legion of Honour.

Dr. Doyen is stated by the Paris correspondent of the *Daily Chronicle* to have succeeded in isolating a micro-organism in cancer, and to have prepared a curative serum for the disease. It is proposed to institute a committee to investigate Dr. Doyen's claims and reputed cures.

An appeal to the Danish people was issued at Copenhagen on October 18 for contributions to defray the cost of a monument to the late Prof. Niels Finsen, the discoverer of the light cure, and also for the establishment of a fund to be devoted to scientific and humanitarian purposes in accordance with his wishes.

According to the *Daily Chronicle* of October 17, a specimen of the water-warbler (*Acrocephalus aquaticus*) has been taken at Clay-next-the-Sea, Norfolk. Up to the year 1894, at any rate, only three specimens of this warbler were definitely known to have been taken in Britain, one of these being now in the museum at Dover.

Mr. A. W. Itter informs the *Times* that while an artesian well was being sunk on his property near Aylesbury, at a depth approaching 500 feet, the whole tackle was blown out of the bore-hole, and after a " noise like thunder," lasting for several minutes, natural gas rushed out, and on being ignited burnt with a brilliant light. He states that when he wrote, on October 19, the gas had been issuing for forty-eight hours, and was still pouring out at a pressure of more than 50 lb. to the square inch.

The *Times* correspondent at Copenhagen reports that shocks of earthquake were felt at 11.15 a.m. on October 23 throughout the Scandinavian countries. Disturbances occurred almost simultaneously at Stockholm, Christiania, Gothenburg, the northern part of Jutland, Malmö, and Copenhagen. The severest shock was in the Danish town of Aalborg. The earthquake was felt at Skagen, Frederikshavn, Hjörring, and Brönderslev, and in the Island of Laesö, but no serious damage was done. Telegrams from Christiania show that there was a great panic in the city.

The British Fire Prevention Committee's programme for the new winter session, which has just commenced, includes the preparation and issue of a report on the great Baltimore conflagration. Further reports will be issued on various tests with sprinklers, lamps, and different forms of partitions. Arrangements are also being made for the organisation of branches of the committee in Canada, Australia, and New Zealand. The committee will assist in the preparation of the " International Technical Dictionary," which is being issued by the German Institution of Engineers, so far as technical terms regarding fire prevention are concerned.

Major Powell Cotton is about to start on another African expedition. The object of the journey, which is expected to occupy eighteen months, is to explore the extensive country lying between the Nile and the Zambesi. After investigating the Great Forest and the district to the west of Lake Kivu, the region to the west of Tanganyika will be traversed, and the expedition will then proceed south towards Katauga. Major Cotton expects to come out in British territory in Nyasaland, whence he will travel to the coast by the Zambesi. Every facility will be given to Major Cotton by the Belgian Government, and as he will travel the entire length of the Congo State, there is every reason to hope that much may be added to the knowledge of the natural history of this part of Africa.

A correspondent suggests a means of obviating, in the ordinary form of Atwood's machine, the difficulty that the acceleration of the moving system is not constant, but increases continuously as more and more of the string passes over the pulley to the descending side. He proposes to connect the masses on both sides of the pulley to an endless cord, and so to ensure that the total length of string remains the same throughout.

A report has been received from the members of the sleeping sickness expedition of the Liverpool School of Tropical Medicine. Writing from Lisala, on the Upper Congo, they state that they believe they are leaving the districts where sleeping sickness is rife. Investigations have been made into cattle disease in the Congo Free State, and measures have been devised which, it is hoped, will enable stock to be raised there without difficulty.

It is stated that craw-craw, a common skin affection on the west coast of Africa, has made its appearance in Birmingham. The disease is due to a nematode worm allied to the filaria, and it is reported that Mr. J. D. Whittles, lecturer on dental histology and pathology in the University of Birmingham, has detected the worm in the blood of several persons. Confirmation of this observation will be awaited with interest.

We have received the report of the Glasgow Municipal Commission on the Housing of the Poor. Among the many recommendations contained in it, one suggests that, with the view of encouraging private enterprise to erect suitable, sanitary, and cheap rented houses for the poorer classes, some relaxation of the provisions of the Building Regulations Act should be favourably considered by the corporation under proper safeguards.

In the *Scientific Memoirs of the Government of India* (No. 11) Lieut. Christophers, I.M.S., gives additional particulars respecting the Leishman-Donovan body or parasite (see Nature, vol. lxx. p. 534). He states that the bodies described by Wright in tropical ulcer are indistinguishable from those found in cases of enlarged spleen in Madras. The bodies may occur in the leucocytes in the peripheral blood, but have not been detected in the red blood cells.

The " General Report and Statistics of Mines and Quarries," part ii., for 1903, is in many respects interesting reading. The general death rate from accidents of those employed in coal and metalliferous mines shows a steady decrease, having fallen from an average of about 2·25 per thousand during the years 1873–82 to 1·25 per thousand during the years 1898–1903. On the other hand, in the Cornish mines, and probably elsewhere, the death rate from phthisis among men from twenty-five to forty-five has very greatly increased during the last few years, and is attributable to the use of rock drills, which cause much dust. Reference is also made to the outbreak of ankylostomiasis in the Cornish mines.

From Mr. J. Wheldon, of Great Queen Street, we have received a catalogue of books and papers on invertebrates (other than insects).

In the October number of *Nature Notes* the editor commences a series of papers on the geology of scenery, dealing in this instance with stratification.

According to the annual report for 1903–4, the rate of additions to the industrial section (inclusive of ethnology) of the Indian Museum, Calcutta, is such that it is increasingly difficult to find space for the accommodation of

the new specimens. The superintendent has to report the theft during the year of a quantity of gold jewellery, of which no trace has been discovered.

Zoological papers received from America in our last week's batch include a treatise on Acarina, or mites, by Mr. N. Banks; notes on Hawaiian reptiles, by Mr. R. C. McGregor; on reptiles from Missouri, by Mr. J. Hurter; two molluscan papers by Mr. F. C. Baker, and a third, by Mr. T. L. Casey, on the gastropods of the family Pleurotomatidæ. The first two are published in the *Proceedings* of the U.S. National Museum, the rest in the *Transactions* of the St. Louis Academy.

The *American Naturalist* for July and August contains a report of the proceedings of the first annual meeting of the eastern branch of the American Society of Zoologists, held in Philadelphia in December last. Of its other contents, perhaps the most interesting is a paper, illustrated with a coloured plate, by Mr. M. M. Mayland, on the colour-variation displayed by a small local form of the common marine gastropod *Neritina virginea*, which inhabits "Salt Pool," near Port Henderson, Jamaica, and is also found in a fresh-water stream in the same island. In the one instance the dwarfing is attributed to the extra salinity of the water, in the other to its freshness. The diversity in colour and colour-pattern of both the normal and the dwarf forms is extraordinary, and perhaps unparalleled, but all the variations intergrade.

Mr. H. Ingle, who recently went from the Yorkshire College to take charge of the chemical work of the Transvaal Department of Agriculture, contributes a short paper to the department's Journal on the composition of Transvaal soils. About a dozen typical soils from different parts of the country have been examined by him. He finds that, as compared with English soils, Transvaal soils are somewhat markedly deficient in nitrogen and phosphoric acid, but he very properly points out that their fertility cannot be judged of entirely by European standards. The soils are in reality much better than analyses made in the ordinary way would lead us to suppose. When Dyer's method was employed the proportion of available to total phosphoric acid and potash was found to be high, much higher than is usually the case in this country. As a set-off to the natural poverty of the soils in nitrogen, Mr. Ingle indicates that the receipts of combined nitrogen from the atmosphere are probably higher in South Africa than in England. In February and March of this year, for example, the rainfall collected in Pretoria brought down about 2 lb. combined nitrogen per acre, whereas at Rothamsted the average annual receipts of the soil from this source amount to some $4\frac{3}{4}$ lb. only. In addition to nitrogenous manures, Transvaal soils require compounds supplying phosphoric acid and lime, and of the manures imported basic slag is suggested as likely to be most economical.

As a contribution to the volume which was prepared in honour of Dr. P. Ascherson's seventieth birthday, Dr. Stapf has written a sketch of the distribution of the grasses in South Africa. Two main subdivisions are distinguished, a smaller group of forms extending into the tropics and a larger endemic South African group, which includes subtropical and temperate forms. The tropical and subtropical species are allied to the palæotropic flora of tropical Africa; the temperate element has affinities with some grasses of Asia Minor and Australia, but how and when they have been connected is not obvious. There is an accumulation of temperate grasses, many of them endemic species, in the Cape district, which suggests that the land formerly extended further south.

According to *Circulars* received, the Department of Agriculture in the United States, through the Bureau of Forestry, offers the services of its officers to farmers and landowners as advisers in the matter of tree planting and forest conservation. As for the conditions under which this help is given, preliminary examination is defrayed by the department, but if the undertaking is sufficiently extensive to require a survey and special plans, the owner has to pay actual and necessary expenses; the object is to prove to timber-land owners that conservative methods of lumbering will pay.

In the *Revue Scientifique* of October 1 Prof. A. Thauziès, of Périgueux, resumes the discussion of the question as to the manner in which carrier-pigeons find their way home. In the same journal for March 24, 1900, Mr. de Cyon expressed the opinion that the sense of smell determines the proper direction, and it is to the refutation of this theory that the portion of the professor's article published in the issue before us is devoted. Among other points cited to disprove the olfactory theory is the fact that young pigeons are frequently unable to discover the whereabouts of their dovecot despite the overpowering odour issuing therefrom. In the concluding portion of his *critique*, published in the issue of October 8, Prof. Thauziès discusses the theory that homing pigeons orientate by a "sense of attitude." That is to say, they preserve a sense of direction by the number of times they have turned *en route*. After urging several strong and apparently fatal objections against this theory, Prof. Thauziès suggests that it may nevertheless contain a germ of truth. For the present, however, the "homing instinct" must remain a puzzle.

The current number of the *Annals* of the Royal Botanic Gardens, Peradeniya, contains several papers of interest, and helps to emphasise the necessity for a thorough study of the problems presented by tropical vegetation. A paper by Mr. R. H. Lock is of particular value in this connection. By a careful study of the rate of growth of giant bamboos, Mr. Lock has found that the difference in rate of growth between day and night is due, not to the alternation of light and darkness, but to the change in the conditions of moisture, the air being damper at night. The curve of rate of growth follows that of moisture and rainfall with most surprising closeness. The second part of Mr. Herbert Wright's paper on Diospyros contains figures of the flowers, &c., in this genus, and shows the great need for study of tropical plants in the field as well as in the herbarium. The number also contains a paper by Dr. Svedelius on *Enalus acoroides*, the life-history of which he studied in the straits between Ceylon and India. The floral mechanism shows a very interesting difference from that of Vallisneria, correlated with the fact that Enalus is a marine plant. The male flowers are caught at low water and drawn under as the tide rises, pollination taking place subsequently. Another paper by Mr. R. H. Lock contains a preliminary statement of the results of the first "Mendelian" breeding work carried on in the tropics, and gives a number of interesting results with peas and maize, mentioned in last week's Nature (p. 601).

The report of the Meteorological Commission of Cape Colony for the year 1902 shows that the interest taken in the progress of meteorology by the public is increasing. Rainfall is observed at 500 stations; this number includes 58 second order (barometric) stations and 27 third order (thermometric) stations. The report also contains sum-

maries at a large number of stations in neighbouring colonies and in German South-West Africa. At the request of the Admiralty circulars were issued to all observers at second order stations south of 30° south latitude asking them to take observations at Greenwich noon, in connection with the National Antarctic Expedition.

The U.S. Hydrographic Office has issued a handy pamphlet of instructions, prepared by Mr. J. Page, for the use of the voluntary meteorological observers who contribute information for the U.S. Monthly Pilot Chart; it will also be found very useful for all observers at sea. The number of vessels regularly engaged in its service exceeds 1800, and the list embraces the merchant marine of all nations, all the vessels of the U.S. Navy, and many foreign cruisers. The form of weather-register now in use was adopted in 1888; it provides only for a single daily observation, to be made at Greenwich noon, instead of the old form recommended by the International Maritime Congress held at Brussels in 1853, which provided for observations at several hours. The registers are generally returned by post in a foolscap envelope at the end of each month, and supply the information required for laying down tracks of storms, and for the preparation of mean values for each month, published in the valuable monthly pilot charts, to which notice has frequently been directed in our columns.

An interesting article on the development of the theory of electrolytic dissociation is contributed to the *Popular Science Monthly* (September) by Prof. Svante Arrhenius.

In the *Transactions* of the Academy of Science of St. Louis, Prof. Francis E. Nipher discusses the speed of the trotting horse as a function of the time, and applies the empirical equation $s=a+be^{-kt}$ to connect the speed s with the time t in the problem or problems, of which he gives numerical illustrations.

In a short but suggestive paper contributed to the *Popular Science Monthly* (September), Dr. Allan McLaughlin discusses the problem of Hebrew, Magyar, and Levantine immigration. The first part deals with the persecution of the Jewish race in Europe, and the serious problem which America has to face in the building up of large ghettos in towns like New York by the overflowing stream of immigrants. Of the Magyar race only 27,124 subjects were landed in America in 1903, and these appear to be ideal immigrants but for their tendency to return to Europe. In regard to Levantine races, we are told that "the Greeks are the best of this rather bad lot."

Several interesting papers on radio-activity are contained in recent numbers of the *Atti dei Lincei* (xiii., 3, 4, 5). In the first of these numbers Drs. G. Martinelli and A. Sella give measurements of the radio-activity of the pozzolana from the neighbourhood of Rome. In the next Dr. G. Martinelli describes experiments to ascertain whether the reactions involving loss of weight (according to the theories of Landolt, Sanford, Ray, Heydweiller and others) are accompanied by radio-active phenomena. A figure is given of the apparatus, in which the reactions were produced inside a closed vessel in a dish placed under the electroscope; but though each experiment was continued for two hours no positive results were obtained. Lastly, Messrs. G. Pellini and M. Vaccari discuss the chemical actions produced by radium. They find that there are many chemical reactions produced by light on which radium has no effect, and that, as a general rule, the actions most affected are those provocated by ultra-violet light or Röntgen rays.

We have received a reprint of a paper by Prof. H. Geitel which is published in the *Jahrbuch der Radioaktivität und Elektronik* under the title "Elektrizitätszerstreuung und Radioaktivität." It forms a valuable summary of the development of the study of terrestrial electricity from the time of Coulomb to the present.

In No. 7 of the *Bulletin* of the Royal Academy of Belgium M. H. Gillot publishes an experimental investigation of the properties of mixtures of the sugars and of the polyhydric alcohols. Melting-point curves are given for binary mixtures of saccharose, lactose, glucose, mannitol, and dulcitol, which are of importance because they indicate the non-existence of isomorphism between these substances. On the other hand, the presence of more than one eutectic point in many of the curves probably means that in these cases definite compounds are produced.

A prospectus has been issued by the Berlin Wireless Telegraphy Company, "System Telefunken," which describes the organisation and scope of the company and the character of the apparatus covered by its patents. The company is an amalgamation of Messrs. Siemens and Halske and the Allgemeine Elektricitats-gesellschaft of Berlin, and its system a combination of the Braun-Siemens and the Slaby-Arco systems. The company has already equipped more than fifty German warships with its appliances, and its system has been adopted by the United States Navy. An especial feature of the prospectus, which is excellently illustrated, is the description of a portable apparatus designed for military field service. The transmitter and receiver are arranged so that a variation of several hundred per cent. in the wave-length of the electric waves can be rapidly made; in this manner disturbances caused by the enemy may be eliminated.

Mr. H. J. Glaisher, of Wigmore Street, will shortly publish "X-Rays: their Treatment in Cancer and other Diseases," by Mr. R. J. Cowen.

Prof. Meldola has completed vol. i. of "The Chemical Synthesis of Vital Products and the Inter-relations between Organic Compounds," which is to be published by Mr. Edward Arnold on November 1.

The syllabus of meetings for the session 1904–5 of the Hampstead Scientific Society gives full particulars of the subjects for the general meetings and for the separate meetings of the natural history, photographic, and astronomical sections.

A new edition of Mr. Joseph Y. Bergen's "Elements of Botany" has been published by Messrs. Ginn and Company. A more careful study has been made in this edition of typical cryptogamic forms, and an outline of the ecological classification of plants has been added, as well as chapters on the ecology of leaves and the evolutionary history of plants.

Messrs. Heffer and Sons, Cambridge, have in the press a book by Mr. S. W. Cole entitled "Exercises in Practical Physiological Chemistry." The book, which is written for the use of medical students, is essentially a laboratory book, only those exercises being included which the author has found can be carried through in ordinary class work.

Mr. W. B. Clive has published a revised and rewritten edition of "First Stage Magnetism and Electricity," by Dr. R. H. Jude. The section dealing with electrostatics has been curtailed and simplified, and a more practical

character given to the part on voltaic electricity. Under magnetism a brief account has been included of tubes of force, magnetic flux, permeability, and reluctance.

NEW editions of three standard works on botany have just reached us from Germany. One volume is the third edition of Prof. G. Haberlandt's "Physiologische Pflanzenanatomie" (Leipzig: W. Engelmann), the second edition of which was reviewed in NATURE of March 18, 1897 (vol. lv. p. 457). About sixty pages have been added to the work, and the number of figures has been increased from 235 to 264. Mr. Engelmann has also published the twelfth edition of Prantl's "Lehrbuch der Botanik," revised by Prof. F. Pax. The additional matter has enlarged the book by twenty-two pages, and twenty-five new figures have been included. The fourth revised edition of Prof. A. Engler's "Syllabus der Pflanzenfamilien" has been issued by the firm of Borntraeger Bros., Berlin. The work is a summary of systematic botany, with special reference to medicinal and useful plants, and a survey of kingdoms and regions of flowering plants; it is of particular value to students of special and pharmaceutical botany.

OUR ASTRONOMICAL COLUMN.

A NEW VARIABLE STAR.—A telegram received at the Kiel Centralstelle from Prof. E. C. Pickering, on October 7, states that the object discovered by Mr. Stanley Williams on September 20 is, according to its spectrum, a long period variable star.

On a plate obtained by Herr P. Gotz at Heidelberg on August 8·4 the star was fainter than B.D. $+29°·4653$, which has a magnitude of 9·2 (*Astronomische Nachrichten*, No. 3971).

EPHEMERIS FOR TEMPEL'S SECOND COMET.—In No. 3971 of the *Astronomische Nachrichten* M. J. Coniel publishes a continuation of his daily ephemeris for Tempel's second comet, extending from October 25 to January 1.

Abstracts of the previous portions have already appeared in these columns, and the following is from the present publication:—

Ephemeris 12h. (M.T. Paris).

1904	α app. h. m. s.	δ app. ° ′	log. Δ	$1 : r^2\Delta^2$
Oct. 25	17 25 44	−22 11	0·2584	0·156
,, 29	17 39 37	−22 50	0·2608	0·155
,, 31	17 46 40	−23 8	0·2621	—
Nov. 2	17 53 46	−23 25	0·2634	0·154
,, 4	18 0 57	−23 40	0·2648	—
,, 6	18 8 11	−23 54	0·2662	0·152
,, 8	18 15 29	−24 6	0·2677	—
,, 10	18 22 49	−24 17	0·2692	0·150

Although the comet was unsuccessfully sought during August and September, and, theoretically, its light should commence to diminish towards the end of the present month, the fact that at previous apparitions the light has been sensibly stronger after perihelion than before leads M. Coniel to hope that the object may yet be observed during its present return. As before mentioned in these columns, the feeble light of the comet, combined with its southerly declination, will render it a difficult object for observers in the northern hemisphere.

PHŒBE: SATURN'S NINTH SATELLITE.—The promised extended discussion of the observations of Phœbe by Prof. W. H. Pickering appears in No. 3, vol. liii., of the Harvard College Observatory *Annals*.

The discoverer of the satellite therein describes the first discovery of, and the subsequent searchings for, the object, explaining in detail the examination of the plates and the difficulties experienced in recognising the satellite's image.

Sixty photographs of Saturn have, so far, been obtained with the Bruce telescope, and of these twelve were taken when the planet was moving rapidly, and were therefore useless in locating the satellite's position. Several others were, for various reasons, useless, but the object sought is to be seen on forty-two plates, which are used in the discussion.

After preparing the description of the observations and results for the press, Prof. Pickering received information from Arequipa which considerably modified his ideas of the satellite's orbit. An approximate ephemeris had been sent to Prof. Bailey, at Arequipa, in March of this year, but he was unable to find the image of the satellite in the computed positions. Subsequent research has shown that the motion of this body in its orbit is probably retrograde, an unlooked-for possibility, since the other eight of Saturn's satellites all have direct motions. Consequently Prof. Pickering gives the details of the reductions for both retrograde and direct motion.

The elements, as determined for the case of retrograde motion, are as follow:—

Semi-major axis at a distance of 10 units measures 29′·62. This corresponds to a distance of 0·0862 astronomical unit, or 7,996,000 miles.

Eccentricity	= 0·22
Inclination to ecliptic	= 5°·1
Longitude of ascending node	= 220°
,, ,, perisaturnium ..	= 289°·7
Epoch of perisaturnium ...	= 1900 Mar. 28·0 (G.M.T.)
Period	= 546·5 days.

The inclination of the orbit of Phœbe to that of Saturn is, therefore, 6°·0, and the longitude of the ascending node is 170°·0.

The eccentricity is remarkable as being greater than that of any other satellite or major planet in the solar system.

The brightness of Phœbe is judged as two magnitudes fainter than that of Hyperion, which is assumed to be of the fourteenth magnitude. From photometric considerations the diameter of the satellite is thought to be about 200 miles.

In conclusion, Prof. Pickering gives a table showing the differences between the computed and the observed places of the satellite, and then discusses the deviations and gives an ephemeris for 1904.

FAINT STARS NEAR THE TRAPEZIUM IN THE ORION NEBULA.—The lists of stars in the Orion nebula recently published by Profs. Wolf and Pickering included none of the stars near the Trapezium, because, with the short-focus cameras used in obtaining their plates, the images of the stars in that region were blotted out by the bright nebula.

On the plates obtained by Prof. Ritchey in 1900 and 1901, using the Yerkes 40-inch telescope with a yellow screen placed immediately in front of the plate, these fainter stars are easily seen, therefore Mr. J. A. Parkhurst has measured their coordinates from θ' Orionis, and gives these, together with the magnitudes of the stars, in a list published in the September number of the *Astrophysical Journal*. The list contains forty-two stars, all within two minutes of arc of the trapezium star θ' Orionis, of which twenty-three were observed visually by Bond—these include ten observed photographically by Prof. Pickering—whilst nineteen are presumably catalogued for the first time.

PHOTOGRAPHIC DETERMINATION OF PARALLAX.—Encouraged by the successful photographs obtained by Prof. Ritchey with the Yerkes 40-inch telescope, Mr. Frank Schlesinger tried several exposures with the same instrument for the determination of several stellar parallaxes. The yellow screen used in the former work was found to be unnecessary, and, as it introduced several troublesome errors, it was dispensed with.

The great focal length of the instrument renders errors in measuring the plates much less important than when smaller instruments, such as those used in the production of the astrographic chart, are used, and Mr. Schlesinger computes the probable error for one exposure to be only $\pm 0''·030$.

Among the results obtained there occurs the parallax of the star *Krueger* 60 (R.A. = 22h. 24m., dec. = $+57°$ 10′), which was placed on the working list because Prof. Barnard suggested that it has a large parallax. The result shows that the suggestion is probably correct, and, if confirmed by other measures, it places the star as one of our nearest neighbours, its parallax being $+0''·278$. This value was obtained as the result of measuring eight plates, containing twenty exposures, and using five comparison stars (*Astrophysical Journal*, No. 2, vol. xx.).

THE CLASSIFICATION OF THE STARS ACCORDING TO THEIR TEMPERATURE AND CHEMISTRY.[1]

II.

THE temperature relationships of the various groups in the classification of stars described in the previous article are further illustrated in a diagram which is reproduced in Fig. 6, from which it will be seen that the stars

Highest temperature.

3	Polarian		Procyonian
2	Aldebarian	Metallic Stars	Arcturian
1	Antarian	Stars with fluted spectra	Piscian

FIG. 6.—Temperature relationship of stellar groups.

are arranged in sixteen groups along a temperature curve having its apex in the middle. Apart from the inferences as to low temperature which may be drawn from the occurrence of flutings, it will be remembered that while the evidence for temperature was primarily based on the strength of the continuous radiation in the violet, this detailed arrangement of the stellar groups depended upon the chemical sequence revealed by the successive predominance of metallic, proto-metallic, and "gaseous" lines in the different stars.

This chemical sequence, however, so far as could be judged from the photographs then available, was identical with that derived from the investigation of the violet radiation, thus showing that the apparent chemical differences resulted from changes of temperature. The simplest explanation of the chemical changes is that afforded by the dissociation hypothesis, according to which the step from metallic to proto-metallic vapours is to be regarded as a breaking up of complex molecular groupings into simpler ones still retaining characteristics which permit the parent substance to be distinguished, while the continuation of the process results in the reduction of all substances to the finer forms of hydrogen and helium. The classification of the stars on a temperature basis is therefore of the utmost importance, not only for the indications which it gives as to the processes of stellar evolution, but also on account of the light which it throws on the dissociation hypothesis and the evolution of the chemical elements. Adopting the foregoing temperature sequence of the various stellar groups, this side of the question has already been fully dealt with by Sir Norman Lockyer in his work on "Inorganic Evolution" (Macmillan and Co., Ltd., 1900).

[1] Continued from p. 614

In view of the important issues depending upon the correct determination of relative stellar temperatures, Sir Norman Lockyer has endeavoured to confirm his previous results by another piece of work, of which an account was recently communicated to the Royal Society.[1] The previous conclusions involving the intensity of the violet radiations depended upon photographs taken with optical appliances composed of glass, which has a marked absorption for these rays, and the relative intensities were judged by noting the limits of the spectra in photographs which were of the same intensity in the region about $H\gamma$. Although there was no reason to suppose that the general laws of continuous radiation would be modified in still more refrangible parts of the spectrum, it was possible to test the results further by including this region in the discussion. An instrument which was transparent to the ultra-violet radiations was necessary for this research, and the one devised for the purpose was a prismatic camera having a 2-inch 30° calcite prism mounted in front of a $2\frac{1}{2}$-inch quartz lens of 18 inches focal length (Fig. 7). The prism is so cut that its first face is perpendicular to the optic axis of the crystal, and it is so arranged that the incident rays are normal to this face. All the rays, therefore, pass through the prism parallel to the optic axis, and there is consequently no double refraction.

By this means it became possible to utilise not only the length of the spectrum in the violet, but the relative brightness of the different parts to a greater extent than before.

To make the matter clear, it may be pointed out that the temperatures of most of the stars are too high to permit of their determination from the actual limits of the continuous radiations towards the violet, as might conceivably be done in the case of a red-hot poker, since these limits lie beyond the wave-length for which our atmosphere is transparent. The principle involved in the method employed, however, is clearly indicated by Sir Norman Lockyer in a quotation from Sir George Stokes,[2] the substance of which has been fully borne out by more recent work, namely, that

"When a solid body such as a platinum wire, traversed by a voltaic current, is heated to incandescence, we know that as the temperature increases, not only does the radiation of each particular refrangibility absolutely increase, but the proportion of the radiations of the different refrangibilities is changed, the proportion of the higher to the lower increasing with the temperature."

In the case of stars, the radiation is of course modified by the continuous absorption of the stellar gases and vapours; but, so far as we know, the greater absorption is always associated with reduced temperature[3] and increased density, and regularly diminishes in intensity from the ultra-violet towards the red.

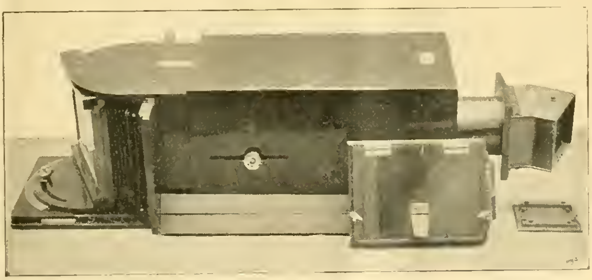

FIG. 7.—Quartz-Calcite Prismatic Camera.

Conclusions as to the temperatures of the stars, as was suggested by Crova in 1878,[4] may therefore be based on

[1] Roy. Soc. *Proc.*, vol. lxxiii. p. 227 (1904).
[2] Roy. Soc. *Proc.*, vol. xxiv p. 353 (1876).
[3] It has been observed that various metals, including iron, produce a continuous absorption at the blue end of the spectrum when reduced to the state of vapour in the relatively cool oxy-hydrogen flame (Lockyer and Roberts-Austen, Roy. Soc. *Proc*, vol. xxiii. p. 344, 1875).
[4] *Comptes rendus*, vol. xvii. p. 981.

the relative intensities of different parts of the continuous spectrum. While this was in reality what had already been done in the case of spectra photographed with glass prisms, the new apparatus permitted comparisons over a much longer range. In each case the limits of the spectra towards the ultra-violet in the photographs are determined by the intensities of the spectra in that region and the duration of the exposures.

To eliminate as far as possible the varying effects of atmospheric absorption, to which the ultra-violet rays are specially sensitive, and the errors which might arise from differences in photographic treatment, each selected pair of stars was photographed on the same plate when the stars had approximately the same altitude, and if any change in the atmospheric conditions were suspected the result was discarded. In each case an attempt was made so to expose the photographs that in every pair the intensity of the spectrum was as nearly as possible the same in both stars in the region between $H\beta$ and $H\gamma$. This condition was very difficult to fulfil in actual practice, owing to the different magnitudes and declinations of the stars compared, and the consequent need for very careful adjustment of the clock rate. The difficulty was further increased on account of the different actinism of the stars in this part of the spectrum. The work, however, has resulted in a series of comparison photographs from which all variable conditions except the natural variations in radiation have, so far as possible, been less extended towards the ultra-violet than that of η Ursæ Majoris, and the maximum intensity is much nearer the red end.

The general result of this research is thus stated:—"Taking the stars assumed to be hottest in the chemical classification, we find that in all cases the relative length of the spectrum is reduced, and the relative intensity of the red is increased, as a lower temperature is reached. That is to say that where two spectra having their intensities about the region $H\beta$–$H\gamma$ equal are compared, we find that in the cooler stars, according to the chemical classification, the emissions in the red preponderate, whilst in the hotter star the ultra-violet is more extended and intense."

In other words, the sequence of the various groups of stars, as determined by this more extended study of the continuous radiations, so far as the investigation has yet been carried, is identical with that previously arrived at from a discussion of the line spectra. It follows, therefore, that the classification which was based upon the chemical differences indicated by the successive appearances of metallic, proto-metallic, and gaseous lines, in all probability reveals also the true temperature sequence of the different varieties of stars.

As pointed out by Sir Norman Lockyer, this result is at variance with that arrived at by Sir William and Lady Huggins. While also basing their conclusions as to relative stellar temperatures on the comparative intensities

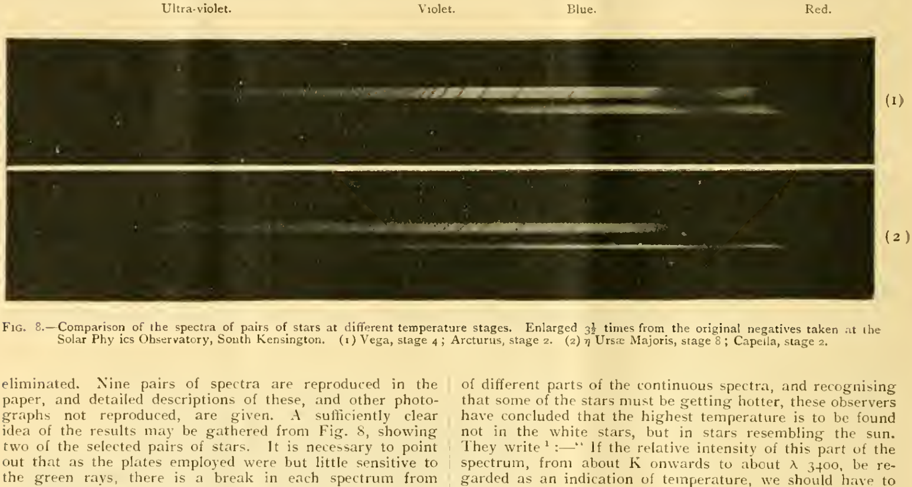

FIG. 8.—Comparison of the spectra of pairs of stars at different temperature stages. Enlarged $3\frac{1}{2}$ times from the original negatives taken at the Solar Phy ics Observatory, South Kensington. (1) Vega, stage 4; Arcturus, stage 2. (2) η Ursæ Majoris, stage 8; Capella, stage 2.

eliminated. Nine pairs of spectra are reproduced in the paper, and detailed descriptions of these, and other photographs not reproduced, are given. A sufficiently clear idea of the results may be gathered from Fig. 8, showing two of the selected pairs of stars. It is necessary to point out that as the plates employed were but little sensitive to the green rays, there is a break in each spectrum from about λ 486 to λ 550, followed on the less refrangible side by a further portion of the spectrum having its centre about "D." The numbered "stages" in the description refer to the ten horizons of mean temperature already shown in Fig. 6, stage 1 corresponding to the fluted spectra of the Antarian and Piscian stars, and stage 10 to the simplified spectra of the γ Argus type.

A glance at the photographs will suffice to show that in the case of each pair the star at the higher stage of temperature, as previously determined from the investigation of the line spectra, has the greater development of the violet end of the spectrum, and that the difference is more marked the greater the temperature difference. In the first example it will be seen that, while the maximum intensity of the spectrum of Vega is in the blue, that of Arcturus is obviously much further towards the red end; the differences at the extremities of the spectrum are also very marked, Vega having the greater extension into the ultra-violet, and a relatively reduced intensity at the red end as compared with Arcturus. Again, in the second pair, in spite of relative over exposure, the spectrum of Capella is notably of different parts of the continuous spectra, and recognising that some of the stars must be getting hotter, these observers have concluded that the highest temperature is to be found not in the white stars, but in stars resembling the sun. They write[1]:—"If the relative intensity of this part of the spectrum, from about K onwards to about λ 3400, be regarded as an indication of temperature, we should have to consider Procyon as at a hotter stage than Vega, and that the highest stage of temperature is reached in the true solar stage, of which Capella is typical. Then a fall of temperature sets in, as is shown in the advancing enfeeblement of this part of the spectrum in Arcturus, Betelgeuse, and Aldebaran." Special stress is laid by these observers on "the rather sudden fall of intensity of the continuous spectrum at about the place of the end of the series of dark hydrogen lines" in such stars as Vega (a feature which is well brought out in the photograph of the spectrum of this star reproduced in Fig. 8), but Sir Norman Lockyer states that this in no way affects his results, and promises another paper dealing with this and similar points. The precautions taken by Sir Norman Lockyer to secure equal treatment for the stars compared would seem to give his results greater weight than those of the other observers, whose photographs appear to have been obtained in the course of more or less routine work on the spectra of individual stars.

It should also be noted that the occurrence of proto-metallic lines has not been accepted as evidence of the

[1] "Atlas of Representative Stellar Spectra," p. 85.

relatively high temperature of a star by some observers, in consequence of the production of these lines in arc spectra under certain special conditions. The recent work of Mr. C. de Watteville[1] on flame spectra in relation to spark spectra obtained with and without self-induction, however, appears to be entirely in harmony with the result derived from stellar inquiries by Sir Norman Lockyer.

At present, then, the evidence available appears to favour the view that the chemical differences indicated in the different groups of stars are due to differences of temperature, and that successively higher stages of heat are indicated by the predominance of metallic, proto-metallic, and gaseous lines. Thus, although further researches on some points are needed, it is very probable that the new classification correctly exhibits the relative temperatures of the various stellar groups, besides giving exhaustive definitions and providing a convenient nomenclature. At the same time, the sequence of phenomena indicated in the classification seems strongly to support the dissociation hypothesis. A. FOWLER.

THE FALKLAND ISLANDS AND THEIR FAUNA.

MR. RUPERT VALLENTIN, who has spent many years in the Falklands, where he has been an assiduous observer and collector of the fauna and flora, contributes an excellent account, illustrated by photographs, of those remote islands to the third part of vol. xlviii. of the *Memoirs* of the Manchester Literary and Philosophical Society, of which his article forms No. 23. The author alludes in the first place to the celebrated stone-rivers, which consist of slowly moving blocks of quartzite between banks of peat. In Mr. Vallentin's opinion the stones forming these "rivers" had approximately attained their present position before the formation of the peat, and the "rivers" have been produced by the denudation of the peat. In every "stone-river" islets of vegetation remain near the margins, these being most luxurious where the denudation has been recent. Where the denudation is of long standing, the sole remnant of the covering of vegetation is a mass of bog-balsam (*Bolax globaria*), as shown in Fig. 1, which, owing to its long tapering root, can obtain nourishment after the soil which supported other plants has been washed away. Very similar "stone-rivers" exist in parts of the Himalaya.

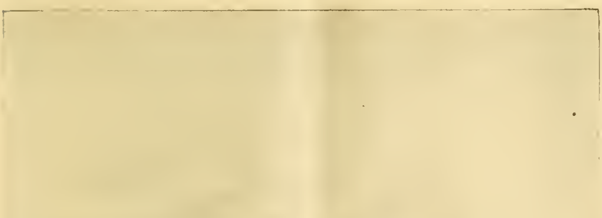

FIG. 1.—A mass of Bog-balsam near the edge of a Stone-river in the Falklands.

Apparently the Falklands are by no means the desolate spots we are often prone to imagine, the vegetation being locally abundant, and the shores of the estuaries and coves on part of West Falkland being fringed with bushes of the attractive Falkland box (*Veronica decurrata*), which has a beautiful and highly scented flower. With the aid of abundant manure, many English vegetables can be grown in sheltered spots.

FIG. 2.—Gentu Penguins on the Falklands. The birds in the background are running to the shore.

With regard to the fauna, the most interesting statement is the one to the effect that, so far as the author could ascertain, the Falkland Island wolf (*Canis antarcticus*) is now completely exterminated. This latest addition to the list of animals extirpated in recent years by human agency is the more to be regretted seeing that this wolf, or fox as it used to be called by the settlers, is an extremely interesting animal from the point of view of geographical distribution, and one that is probably very insufficiently represented in our museums. According to Prof. Huxley's paper on the dentition of the Canidæ, published in the Zoological Society's *Proceedings* for 1880, the Falkland Island wolf is closely allied to the North American coyote, the remarkable feature connected with this resemblance being that there are no true wolves in either Central or South America. The British Museum has one mounted skin of the Antarctic wolf in the exhibition galleries, and there are two skeletons in the store collection. Strychnine poisoning appears to have brought about the extermination of this wolf, the last survivor of which seems to have been killed so long ago as 1876.

Birds form by far the most important portion of the terrestrial vertebrate fauna of the Falklands, and among these penguins, of three species, and "mollymauks," or lesser albatrosses, are numerically the most abundant. Mr.

[1] Roy. Soc. *Proc.*, vol. lxxiv. p. 85 (1904).

Vallentin's article is illustrated by a photograph of a "rookery" of rock-hopper penguins (*Eudyptes chrysocome*), showing the myriads in which these birds congregate on the coasts, and by a second (herewith reproduced) of a much smaller assemblage of gentu penguins (*Pygosceles taeniata*). An interesting fact in connection with the habits of the rock-hoppers is that the smooth surfaces of the hard igneous rock over which these penguins have passed for generations are not only highly polished, but are marked by irregular groovings made by their claws. These scratches are usually about 3 inches in length, and may be as much as a quarter of an inch in depth. Apparently such a polished and striated rock-surface might well be attributed to ice-action. A striking feature about such a rookery is the number of dying and maimed birds to be met with; such injuries appear to have been inflicted by seals or sea-lions. The enormous number in which the "mollymauks" frequent the Falkland and other Antarctic islands may be inferred from the statement that on one occasion a vessel arrived at the main port with a cargo of 10,000 eggs of this species. Mr. Vallentin found these beautiful birds so tame and confiding that they allowed themselves to be stroked by his hand as he admired the softness of their plumage and its spotless condition. How these birds keep themselves clean amid the liquid filth of a rookery is little short of a marvel. R. L.

THE ST. LOUIS INTERNATIONAL ELECTRICAL CONGRESS.

THIS congress, during its five working days, considered about 160 papers on electrical subjects. In fact, so large was the number of papers and so wide the range of subjects of which they treated, that it may be said that there is no branch of electrical science which was not referred to at one time or another during the meetings. Nevertheless, the chief scientific interest in the proceedings centred round a few subjects, namely, units and standards, radio-activity, wireless telegraphy, and the electric arc. Of the engineering papers, those on the alternating current motor, the steam turbine, and high tension transmission attracted most attention. There were also numerous papers on electrochemical and electrotherapeutical subjects, which will not be referred to here.

The joint discussion by Section A, general theory, and Section B, general applications, on units and standards was opened with papers by Prof. Ascoli (systems of electric units), Profs. Carhart and Patterson (absolute value of the E.M.F. of Clark and Weston cells), and Dr. Wolff (international electric units). The subject divided itself into two parts:—(1) the true value of the volt and ampere; (2) which of these should be represented by a material standard, and the nature of that standard. During the discussions the naming of the magnetic units was also considered.

Upon the question of the true value of the volt and ampere there was practical unanimity of opinion that the true value of the volt (10^8 C.G.S. units) is such that the E.M.F. of a standard Clark cell at 15° C. is very much nearer 1·433 volts than 1.434, the present legal value. Profs. Carhart and Patterson, in describing the dynamometer with which they are making a re-determination of the ampere, stated that though the experiments were not sufficiently advanced to give a definite value, the results so far obtained made the E.M.F. of the Clark cell about 1.433 volts, accepting the ohm as correct. In this connection Mr. Trotter's results, mentioned by Dr. Glazebrook, are of great interest. Mr. Trotter has recently made a determination of the E.M.F. of the Clark cell at the Board of Trade laboratory in terms of the standard ampere and standard ohm, and finds the value to be 1·4329 volts at 15° C. It would thus appear that the voltage of a normal Clark cell, determined in terms of our standard ampere and ohm, is nearly 1/10 of 1 per cent. less than the legalised value. The Reichsanstalt take the value of the Clark cell at 1·4328 volts. It is of interest to note that the present legal value of 1·434 appears to be almost exactly correct at 14° C. instead of 15° C.

Mr. Barnes, in his paper on the mechanical equivalent of heat measured by electrical means, which contains a very careful comparison of the results obtained both by the electrical and mechanical methods, takes the Clark cell as 1·43325 volts, and then finds that the "results by the *continuous* electrical method is brought into absolute agreement with the *mean* of the mechanical measurements," and he gives the value of the mechanical equivalent as 4·186 joules in terms of the mean calorie between 0° and 100°.

The standards which are to represent the fundamental electrical units raised quite another set of questions, the main desiderata for these standards being that they should be both permanent and reproducible to a high degree of accuracy. No one appeared anxious to quarrel in any way with the standard mercury ohm, and the agreement of the standards lately made by the National Physical Laboratory, both with one another and with those constructed by the Reichsanstalt, shows that this standard is reproducible to a few parts in 100,000. Accepting the present ohm standard, it is only necessary to legalise a standard for either the ampere or the ohm, as the three units are connected by Ohm's law. Prof. Carhart and Dr. Wolff urged the desirability of defining the volt in terms of a cell, preferably the cadmium cell, and the ampere in terms of the volt and ohm, the advantages being that the standard cell is very generally used in practical measurements both of potential difference and current, and that the cells are reproducible to a high degree of accuracy. Dr. Glazebrook pointed out that the greater simplicity of the chemical changes in the deposition of silver gave promise of its being an even more accurate standard for the ampere.

Prof. Carhart and Mr. Hulett, in their paper on a study of the materials used in standard cells and their preparation, trace the difficulties with cells both of the Clark and Weston (cadmium) type to the mercurous sulphate; they describe an electrolytic method of preparing it, and they strongly emphasise the importance of avoiding hydrolysis of the mercurous sulphate. In a table in the paper they give the results obtained with fourteen cadmium cells made according to their method, from which it appears that the maximum difference between the voltages of individual cells and between the voltages of the cells during the whole seven months that the tests lasted did not exceed 5 parts in 100,000, so that, taking any cell at any time during the tests, its voltage could be depended on to within $\pm 0·03$ millivolt of the mean voltage. Similar excellent results have been obtained by Mr. Smith at the National Physical Laboratory (report to British Association, Cambridge).

In view of the large amount of work which is now being carried out on the preparation of standard cells and the redetermination of the ampere, the general feeling of the meeting seemed to be that international action to correct the error in the volt should be postponed, although one speaker urged that the error of 0.1 per cent. in the volt had become of serious commercial importance in the life tests of incandescent lamps.

Prof. Wolff's paper, which dealt largely with the legal definitions of the fundamental units adopted by various nations, pointed out the great differences which exist, and the necessity of rendering them all uniform.

On the subject of naming the magnetic units there was very little discussion; the question of 4π, of course, came up, and was discreetly left on one side, most of the meeting agreeing with Dr. Kennelly that it is better to let well alone, and that no very great practical advantage would result from the change. The views of the I.E.E. delegates, that if any magnetic units were named they should be those proposed by Dr. Kennelly, viz. the C.G.S. units of magnetic potential (already called the Maxwell at the Paris congress), total magnetic flux, and magnetic reluctance, met with pretty general acceptance. The other proposal made by Dr. Kennelly, namely, to add the prefix "ab" or "abs" to the names of the practical units to form names for the corresponding C.G.S. units in the electromagnetic and electrostatic systems, so that "abvolt" would be the name for the C.G.S. unit of difference of potential in the electromagnetic system, and absampere for the C.G.S. unit of current in the electrostatic system, led to no discussion, the I.E.E. delegates simply expressing their disapproval of this proposal, which made the same prefix have different numerical values according to the name it preceded.

The chamber of Government delegates, to which Great Britain appointed at the last moment Colonel Crompton,

Dr. Glazebrook, and Prof. Perry as delegates, also considered the questions of units and standards, and at the concluding meeting of the congress the announcement was made that the chamber of Government delegates had decided to advise their respective Governments to appoint a permanent international commission, consisting of two members from each Government, to secure uniformity in units and nomenclature, and a second committee to deal with the international standardisation of machines, this latter to act by correspondence.

The most interesting paper on radio-activity was that of Prof. Rutherford, who traced one step further his remarkable disintegration theory of radio-activity. Starting with the radium emanation, he traced its disintegration through three stages, which he called radium A, B, and C, the latter producing by its disintegration α, β, and γ rays. These changes take place fairly rapidly, and the activity dies away approximately following a logarithmic law. There remains behind, however, in the tube which contained the emanation a deposit the activity of which dies away very much more slowly. By dissolving this deposit in sulphuric acid, it can be separated into two parts, the one of which will deposit on a bismuth disc immersed in the liquid, and the second part will remain behind. That which remains behind is found to give out β rays only, and is called by Rutherford radium D, while that which is deposited on the bismuth disc gives α rays only, and he calls it radium E. He also finds that there is another way of separating these two substances, namely, by heating the deposit on platinum to 1000° C., at which temperature the radium E is volatile and driven off. Regarding the rate of decay of the activity of these two substances, Rutherford estimates that the activity of radium D will fall to half value in about forty years, while that of radium E will require only about one year. By a comparison of the properties of radium E with polonium, Rutherford deduced strong arguments in favour of their identity, and he also considered that radio-tellurium was the same. The product radium D is more uncertain, though it may be radio-lead. If these results are confirmed, and it is proved that polonium, radio-tellurium, and radio-lead are all products of the disintegration of the radium atom, a considerable simplification will result, and a step forward in our knowledge of radio-activity has been made.

The papers by Elster and Geitel concerning natural radio-activity of the atmosphere and the earth, and by Prof. McLennan on the radio-activity of mineral oils and natural gases, gave the results of large numbers of tests on the radio-activity of various waters, oils, muds, &c., from different parts of the earth's surface and from different depths, and they go far to show the omnipresence of radio-activity in the crust of the earth, though they are not yet sufficiently advanced to settle the important question as to whether there exists a large number of radio-active minerals in the earth which have not yet been isolated. McLennan deduces from the rate of decay of the emanation the conclusion that the active substances in natural gases, petroleum, spring-water, and mercury are very probably identical with the emanation from radium, and he also mentions that there appears to be present in some samples of crude petroleum an active substance more persistent than the emanation from radium. Is this the radium D and E of Rutherford?

It was unfortunate that, whereas three important papers on the arc were taken together in one section, the same time was selected for Prof. Child to read his arc paper in a different section, so that those interested in arc phenomena could not hear all the papers; added to this, three out of the four arc papers were not in print at the time of the congress, and the acoustical properties of the rooms in which the meetings were held were of the very worst, making it almost impossible to hear the speakers. Prof. Child attempted to explain the phenomena of the arc on a purely ionic basis, which he summarised as follows:—"The current is carried by ions. These ions are produced, first, either within the kathode, because of its high temperature, or at the boundary surface by the impact of the positive ions; second, through the gas by the impact of the atoms on the negative ions at high temperature; and third, at the boundary surface of the anode by the impact of the negative ions." The theory is, however, not very satisfying, as it throws but little light on many important points, more especially the actions going on at the surfaces of contact of the vapour column and electrodes, as he admits. He also does not attempt to explain the extraordinary effect of slight traces of impurities, which is so marked in the case of the carbon arc that the present writer is of the opinion that with perfectly pure carbon electrodes the carbon arc, as we know it, could not exist.

One of the most interesting facts brought out in Prof. Child's paper is the great importance of the temperature of the *kathode*, and, as he says, "the essential condition appears to be that the kathode shall be very hot." Prof. Steinmetz entered very fully into the importance of the kathode, and he described the stream of particles which he considered as issuing from it. The existence of this stream, and Steinmetz's view that the re-lighting of the alternating arc is a disruptive phenomenon, received striking confirmation from Prof. Lombadi's stroboscopic photographs of the arc.

Prof. Steinmetz deduced an equation for the relation between the arc-length, P.D., and current from theoretical reasoning, which took the form $V=a+b(l+c)/\sqrt{A}$, where V is the P.D., A the current, and l the arc-length; he applied this equation to the volt-ampere characteristics of the magnetite arc, but the agreement between the observed and calculated values seemed as if it would have been better if Mrs. Ayrton's form of equation had been adopted. The magnetite arc looks as if it has a large future before it, as its efficiency is high and the rate of consumption of the electrodes extremely slow. In this connection Prof. Steinmetz said that he had obtained an efficiency of 0.15 watt per mean spherical C.P. with a titanium arc, but that it was not in a commercial form yet. Mr. Blondel, in his paper on impregnated arc light carbons and lamps, gave (if the figures were not misquoted in the reading) an equally extraordinary result with his new lamp and carbons, namely, a mean *hemi*spherical C.P. of 4800 for a 500 watt 9 ampere lamp, as against 700 C.P. for an ordinary open arc taking practically the same power.

Dr. Fleming and Dr. de Forest each contributed papers on wireless telegraphy, and Dr. Guthe gave one on coherer action; there was also a highly mathematical paper on the theory by Mr. Stone Stone. Dr. Fleming's paper gave a good general *résumé* of the subject, but contained very little new matter. The chief interest in de Forest's paper centred in the experiments he describes to prove that the action of his electrolytic receiver is due to polarisation, and not to a heating of the electrolyte as alleged by Fessenden. The electrolytic receiver consists essentially of a very small electrode dipping into an electrolyte, the second electrode being large and connected in series with a cell and telephone. Normally, a very small current flows through the receiver, which is greatly increased directly the oscillations pass through it. Dr. de Forest maintains that this is caused by the oscillations destroying the polarisation at the small electrode, and one of the most conclusive statements he makes in favour of this view is that the small electrode must be made the *anode*, and that the receiver is practically inoperative if it is connected to the negative of the local battery. This would certainly not be the case if the action depended on the heating of the electrolyte, which should be independent of the direction of the local battery.

Dr. Guthe treated at length the theory of the action of the coherer, especially from the electronic point of view. The first step is assumed to be an electrostatic attraction between the metallic particles. The electrons are carried over from the negatively charged metal to the other side, and we have a current carried entirely by the electrons. An increase in the electrical energy produces an increase in the number of electrons, *i.e.* the current increases while the difference of potential remains constant. This passage of electricity is accompanied by a pressure at right angles to the flow, which pushes aside the molecules of the dielectric which may have been between the metallic particles, and there remains what may be considered as a continuous metallic conductor. Dr. Guthe further extends this theory by considering the ionisation of the gas or dielectric surrounding the metallic particles. Both Dr. Guthe's and Dr. Fleming's papers contain numerous bibliographic refer-

ences. Dr. Fleming also proposes the name "kumascopes" for all forms of Hertz wave detectors, but it is not a very pleasant sounding term.

Telegraphy over wires was not neglected by the congress, and Dr. Kennelly gave both an excellent theoretical paper on the transmission speed over submarine telegraph cables, and a practical one on high frequency telephonic circuit tests. To test the telephone circuit for effectiveness a known sinusoidal E.M.F. is applied, and the corresponding received current strength is measured; the ratio of these quantities Dr. Kennelly calls the "receiving end impedance" of the circuit at the frequency used (600 ~ in the tests). If this impedance exceeds a certain value, then the circuit will be defective or inoperative. The interesting part of the apparatus is that used for the measurement of the received current; this is accomplished by passing it through a small platinum wire (Fessenden barretter), which it heats, and the change in its resistance is measured.

By this means, using a 3 micron wire, 23 microamperes can be measured, and with a 1·7 micron wire *in vacuo* 3 or 4 microamperes is said to be measurable. For practical tests on telephone switchboards the use of a sensitive reflecting galvanometer, which the above arrangement involves, is not very convenient, so the change in resistance of the platinum wire is observed by putting it in series with a sensitive milliameter and cell. A complete portable apparatus of this kind was described, with which one scale-division change in deflection of the Weston milliameter corresponded to 1·4 milliamperes of superposed alternating current. Curves are given in the paper showing tests of different lengths of cables.

The improvement of telephonic communication by increasing the self-induction of the circuits is receiving considerable attention in the States, and Dr. Hammond Hayes gave some most striking curves illustrating the reduction in attenuation which has been produced by the use of uniformly spaced loading coils on long circuits. The improvement is very much more marked in the case of cables than air wires. The most striking results are those obtained with a standard telephone cable which was heavily loaded so that the added inductance amounted to about 0·6 henry per mile. In this case, from Dr. Hayes's curves the received current was reduced to about ½ per cent. of the transmitted value at a distance of fifty miles with the cable unloaded, whereas with the loaded cable the received current was 7 per cent. Further, the great importance of terminal reflection where the loaded cable joins the transmitting and receiving apparatus is most marked, as by reducing the self-induction of the end loading coils so as to taper it off and avoid a sudden change in the self-induction the received current was increased to about 18 per cent.

It is also very interesting to note how the curves cross one another, so that short lengths of cable give better results without loading, whereas the cable with loading and terminal taper above six miles long produces less attenuation than the unloaded cable, the advantage in favour of the loaded cable increasing with its length.

There were many other papers of great scientific interest; among these may be mentioned Dr. Pender's paper on the magnetic effect of moving charges, which clears up many of the differences which existed between his results and those obtained by Crémieu, and suggests several other interesting problems; Prof. Wilson on condensation nuclei; two papers on the theory of conduction by Prof. Drude and Prof. Richards; and Prof. Arrhenius's paper on the electric charge of the sun.

In conclusion, it must be said that the congress was a complete success, perhaps more so than might have been expected, considering the great distance many of the members had to travel to attend its meetings, and this was greatly due to the indefatigable energy of its organisers, and especially to Prof. Elihu Thomson, the president, Dr. Kennelly, and Mr. Weaver. The attendance at the meetings was good, and if the discussions were not always as full as could be wished, this was not from lack of interest in the papers, but from lack of time. All the foreign members of the congress, irrespective of nationality, were received and entertained in the most hearty manner by their American *confrères*, fully bearing out the world-wide reputation that America has for hospitality.

W. DUDDELL.

PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF GLASGOW.

TOWARDS the close of his introductory lecture to the course of physiology in the University of Glasgow on October 13, Prof. McKendrick said:—

I think there can be little doubt that the next great advance in physiology will be from the side of physiological chemistry. The phenomena of vital activity depend on chemical processes in which there are either the building up of complex substances by the union of simpler ones, or the decomposition of complex bodies into simpler ones—in other words, processes that are of a synthetical or of an analytical nature. These chemical phenomena lead, on the one hand, either to the locking up, or, on the other, to the liberation of energy, and the energy in a living being may appear as mechanical motion, heat, electricity, and to some small extent, and in special cases, as light and sound. During the last sixty years many of the physical phenomena of the living being have been investigated by special methods. It seems to me that we cannot expect much more from the application of the graphic method of registration, nor from the examination of the phenomena of electrical action in living tissues. The microscope and the methods of histological research have left little to be desired as to our knowledge of the structure of the elementary tissues and the structure of organs. A new departure must be made. No method of research seems so inviting or so promising as the rigid and methodical investigation of the chemical phenomena happening in living matter.

Hence the extreme importance of the chemist and the physiologist working hand in hand for the future advancement of physiological knowledge. At one time it was supposed that the chemical phenomena happening in the living body were of a different order from those occurring in dead matter. In 1824, however, Wöhler pointed to the first example of a synthetical process discovered within the animal organism. He showed that when benzoic acid is introduced into the stomach it appears as hippuric acid in one of the excretions, after coupling, probably in the liver, with amido-acetic acid or glycocoll. About the same time Hennell effected the synthesis of alcohol, and Wöhler formed urea from ammonium cyanate. As urea was then known only as a product of the animal organism, its synthesis from inorganic substances, and in the laboratory, was a feat of the first importance. This synthesis was the precursor of many others, so that we have now, at the lowest estimate, between two and three hundred chemical substances found in plant and animal tissues that can also be built up synthetically by the organic chemist. Year by year we are adding to this extensive list. Some of these syntheses are striking examples of the knowledge and skill of the chemists of the present day. Such, to mention one brilliant series, are the artificial productions of the sugars by the labours of Fischer and his pupils. Take, again, the formation of the highly complex body camphor, realised by Komppa and Vorländer. It may not be a day-dream if we contemplate the time when even the starches, fats, and proteids we use in our food may also be artificially formed. Physiological chemists have also done much in the way of studying the chemical changes happening to a substance during its passage through the body, but this is a much more difficult branch of physiological chemistry than even the synthetic production of organic bodies.

And yet we are far from solving the mystery of what we may call vital chemistry. When we think, for example, of the synthetical processes by which the chemist constructs complex bodies hitherto only found in the tissues of plants and animals, the question naturally occurs: how does nature produce these complicated molecules without the use of strong reagents and high temperatures? This aspect of the question has been well discussed by my friend Prof. R. Meldola, first, in an address as president of the chemical section of the British Association at the Ipswich meeting in 1885, and, second, in an important work, soon to be published, the proof sheets of which he has kindly allowed me to peruse, entitled "The Chemical Synthesis of Vital Products." It is clear from a study of the examples given by Prof. Meldola that the synthetical processes worked out by the chemist in his laboratory are quite unlike those occurring in plant and animal tissues, and yet the result is the

same, namely, the production of a complex organic compound. We have been too much in the habit of supposing that when we could represent the process followed by the chemist by an equation, that this equation represented what occurred in the plant or animal tissue. Physiologists more than chemists have erred in this direction, and many of the statements in our text-books are either superficial or grossly misleading. The chemist attains his end by violent means and with considerable rapidity, whereas, in the silent laboratory of the plant and animal cell, molecular processes are slowly carried on of which we know at present next to nothing. It is strange, for example, that we cannot yet follow all the steps of the process by which, under the action of sun-light, the green colouring matter in a vegetable cell can fix the carbon of the carbonic acid of the air and liberate the oxygen. Nor can we follow satisfactorily the steps of the synthesis by which the carbon is built up into such a substance as starch or sugar. Yet this is a synthesis accomplished every day by every green plant. Such phenomena in all probability are accomplished through the agency of enzymes or ferments, but their real nature is still obscure.

I have said enough to show you the vast importance of chemical investigation in the physiology of the future. Chemistry is but a highly specialised branch of physics. In these days all the new discoveries in physical chemistry, such as the true nature of solution, the facts of dissociation as exemplified by such a common phenomenon as the splitting up of common salt into the ions chlorine and sodium, the charging of each ion during electrolysis, and the laws of osmotic pressure, which no doubt regulate nutrition and the interchanges of blood and lymph, must be taken into account by the physiologist. Such research demands adequate laboratory accommodation and highly trained specialists. I am glad to say our university will soon be in a position to take her share in this new development of physiological science. The splendid laboratories now being built for physiology, public health, and materia medica will be a home for work of this kind, and the endowment of a lectureship in physiological chemistry by the trustees of the late Dr. John Grieve (who left 8000*l.* for the foundation of a lectureship in connection with the medical faculty of the university) will enable us to obtain the services of a trained specialist, who will give his undivided attention to this department of physiology. No subject more than physiology illustrates the truth that all science is one. Physics, chemistry, physiology, and all the others are only different ways of investigating the phenomena of nature. The phenomena of life are, however, the most difficult of all to investigate, and it may safely be asserted that the highest skill in experimental research and the deepest knowledge of chemistry and physics are required for such work. Throughout the scientific world physicochemical researches are now in progress into physiological and bacteriological processes, lectureships and laboratories are springing up here and there, and it is gratifying to be assured that the University of Glasgow will be able to take her share in this work.

CONDENSATION NUCLEI.[1]

A FAMILIAR experiment was first shown illustrating the action of ordinary dust particles as condensation nuclei. From a large globe, which had been allowed to stand for some hours, some of the air was removed by opening communication with an exhausted vessel. Only a very few drops were formed as a result of the expansion. On allowing air to enter the globe through a cotton-wool filter, so that the pressure was brought back to its original value (that of the atmosphere), and allowing the air to expand as before, the drops formed were again very few. The ordinary air of the room was now admitted; an expansion of the air in this case resulted in the production of a thick fog.

When air has been freed from dust by filtering, or by repeatedly forming a cloud by expansion, and allowing it to settle, the vapour which, in the presence of the nuclei, would have separated out in drops, must be in the "supersaturated" condition immediately after the expansion is completed.

[1] Discourse delivered at the Royal Institution on Friday, February 19, by C. T. R. Wilson, F.R.S.

Another method of producing clouds was now shown. Air was allowed to escape through a fine orifice into an atmosphere of steam; the mixed air and steam were then passed through a Liebig's condenser, where the greater part of the steam was condensed, and then into a large glass globe, where the clouds were observed. From this vessel the air was drawn off by a pump which maintained the pressure in the globe and condenser at a considerable number of cms. of mercury below that of the atmosphere. Before reaching the jet the air of the room had to pass through a cotton-wool filter, and then through a long tube containing water; finally it was led through an aluminium tube to the orifice. The latter was about half a mm. wide. The fall of pressure in passing through the orifice was about 15 or 20 cm. In the absence of the filter, the air being admitted directly to the water tube through a tap turned just sufficiently to give the same flow as with the filter, a dense fog poured out from the end of the condenser tube; on closing the tap and letting the air enter through the filter the fog rapidly cleared, and only a fine rain continued to be produced. While the apparatus was in this condition an X-ray tube was set in action near the aluminium tube; the rain was succeeded by fog, which continued to pour out from the end of the condenser so long as the X-rays were kept in action. Condensation nuclei are, as this experiment proves, produced in air exposed to Röntgen rays. Later experiments will, however, show that they have entirely different properties from the ordinary dust nuclei.

When air has been completely freed from dust particles, so that a slight expansion of the air (initially saturated with water vapour) does not result in the formation of any drops, it is found that quite a high degree of supersaturation may be brought about without the appearance of a single drop. There is, however, a limit to the supersaturation which can exist without condensation of the vapour in drops resulting. To study this condensation in dust-free air, and to measure the expansion required to produce the necessary degree of supersaturation, a special form of expansion apparatus is required. The lantern slide thrown on the screen shows the construction and mode of working of the apparatus. The second slide is a photograph of the machine in action, the exposure having been made immediately after an expansion; the cloud formed (in this case on nuclei produced by the action of radium) is plainly visible along the path of a concentrated beam of light from a lantern.

Let us now try an actual experiment with the expansion apparatus. On making a slight expansion a cloud forms on the dust particles which are present; this slowly settles to the bottom of the vessel. The air is allowed to contract to its original volume, and a second expansion of the same amount is made. The drops formed are on this occasion comparatively few, and they fall rapidly; the dust particles have nearly all been carried down with the drops formed by the previous expansion. The fewer the nuclei on which water condenses the larger will be the share of water available for each drop, and the more rapid will be the fall. The next expansion produces no drops. While the air is in the expanded condition, the piston being at the bottom of the expansion cylinder, air is removed from the cloud chamber by opening the connection to the air-pump until the pressure is about 13 or 14 cm. of mercury below that of the atmosphere; the piston is again allowed to rise by putting the air space below it in communication with the atmosphere. The next expansion is thus comparatively large, the pressure after the expansion has taken place and the temperature has risen to its original value being 13 cm. or more below the initial pressure. Yet, in spite of the high degree of supersaturation reached, not a drop of water is seen. Making the fall of pressure 16 cm., however, we see on expansion a shower of drops; and although these drops are few and large, falling therefore rapidly, yet, however often the same expansion be repeated, the drops produced on expansion show no diminution in number. Thus the nuclei removed with the drops are continually replaced by others manufactured within the apparatus itself.

To produce the necessary supersaturation to cause condensation in the form of drops in dust-free air, the air must be allowed to expand suddenly until the final volume is 1·25 times the initial volume. The condensation is rain-like in form, and, moreover, the number of drops remains small although the expansion considerably exceeds this lower limit.

Expansions exceeding the limit, $v_2/v_1 = 1\cdot38$, however, give fogs, which increase rapidly in density, *i.e.* in the number of the drops, as the expansion is increased beyond this second limit. The expansions required for the rain-like and cloud-like condensations correspond to a fourfold and eightfold supersaturation respectively.

A further experiment will throw light on the nature of the nuclei associated with the rain-like condensation. Let us expose the moist air to the action of X-rays before causing it to expand. First let us try an expansion very slightly less than that required to give the rain-like condensation without the rays. You observe no drops are formed. Now let the expansion be slightly greater than the critical value 1·25. A fog is seen on expansion. Thus the X-rays produce in the air immense numbers of nuclei having the same properties, so far as their power of assisting condensation goes, as the comparatively few nuclei which the rain-like condensation makes visible. Now a gas exposed to X-rays conducts electricity, and the otherwise complicated phenomena of this conduction are all reduced to comparative simplicity by the theory that under the action of the rays equal numbers of freely moving positively and negatively electrified bodies (the ions) are produced from the originally neutral gas. It is at once suggested that the condensation nuclei produced by X-rays are simply these ions.

Let us now impart conducting power to the gas by exposing it to the action of the radiation from radium. Again we have the same result; no drops are produced if the expansion be less than 1·25, fog if the expansion exceeds this limit.

If we substitute for the glass shade, which has thus far formed the cloud-chamber, a glass cylinder with a horizontal metal top, we have the means of testing whether the condensation nuclei produced by Röntgen or radium rays are really electrically charged, whether, in fact, it is the ions themselves which act as condensation nuclei or other particles produced by the rays. If, for example, the roof of the cloud chamber be kept positively charged, the floor negatively, the negatively charged ions will travel upwards and the positively charged ones downwards. In the absence of an electric field the positive and negative ions produced by the action of the rays will go on increasing in number until as many are neutralised by recombination with ions of the opposite kind, or by coming in contact with the walls of the vessel, in each second as are set free in that time by the rays. If the rays be cut off, the removal of ions by recombination and diffusion will continue, and the number of ions in the vessel will diminish rapidly.

Experiment shows that, while in the absence of an electric field, quite a considerable fog is formed when an expansion, slightly exceeding 1·25, is effected ten seconds after the rays have been cut off, with 200 volts between the upper and lower plates the same expansion, allowed to take place three or four seconds after the stopping of the rays, produces only a very slight shower. Or, again, if the rays be kept on all the time the resulting fog is very much less dense with the electric field acting than without it. These results are easily explained if we assume that the condensation nuclei are the ions, and apply the result obtained by purely electrical methods, that the ions travel about 1·6 cm. per second in a field of 1 volt per cm. The nuclei causing the rain-like condensation without exposure to Röntgen or radium rays are also removed by the action of an electric field; we have thus the direct proof that they also are ions. Recent experiments have proved that a charged conductor suspended within a closed space loses its charge by leakage through the air, and that the conduction shows all the peculiarities of that met with in an ionised gas; and, indeed, it appears that this ionisation is due to the action of radiation of the radium type from the walls of the vessel and from outside the vessel. The condensation method of detecting ions is, it may be pointed out, a very delicate one; a single ion if present in the vessel will be detected.

The positive and negative ions are not alike in their power of acting as condensation nuclei. In most of the experiments shown to-night the negative ions alone have in fact come into action. The positive require a considerably greater expansion in order that water may condense upon them. The final volume must for the positive ions be about 1·31 times the initial instead of only 1·25, corresponding to a sixfold instead of a fourfold supersaturation.

To demonstrate the difference between the positive and negative ions the same form of apparatus is used as in the previous experiment. Instead, however, of a difference of potential of 200 volts, only 2 or 3 volts are applied between the plates; and in this experiment only a thin layer close to the lower plate is exposed to the action of the rays. Under these conditions, if the upper plate is the positive one, the negative ions will be attracted upwards out of the ionised layer, and will occupy the greater part of the volume of the vessel, while the positive ones will have only a short distance to travel before reaching the lower plate. If the rays be cut off before the expansion is made it is easy to arrange the interval to be of such a duration that all the positive ions have been removed, while only a small fraction of the negative ions have reached the upper plate before the expansion takes place. Thus we can try the effect of expansion when the vessel is charged with practically negative ions only. By reversing the electrical field the action of positive ions, almost free from negative ions, can be studied. When the expansion is between 1·25 and 1·31 a fog or a mere shower is obtained, according as the direction of the field is such as to drive negative or positive ions upward.

The ions are by no means the only nuclei which can be produced within moist air from which the dust particles have been removed. Among the most interesting of such apparently uncharged nuclei are those produced in moist air exposed to ultra-violet light. It is impossible in the time available to do more than allude to them here.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The reader in animal morphology (Mr. Sedgwick) gives notice that a special course of advanced lectures on certain general aspects of zoology will be given at the zoological laboratory during the Michaelmas and Lent terms, beginning Friday, October 28. The course will include lectures by the following, and will be given as nearly as possible in the order indicated:—Michaelmas term: Mr. Doncaster, the nucleus and heredity; Mr. Lister, Foraminifera and Mycetozoa; Mr. Punnett, metamerism. Lent term: Mr. Gardiner, the œcology of aquatic animals; Mr. Brindley, certain aspects of regeneration; Mr. Hopkins, animal pigments; Mr. Fletcher, cell-structure, cell-division, and maturation of germ-cells; Mr. Heape, some problems connected with the comparative physiology of the generative system.

Dr. Donald MacAlister, St. John's, who has represented the university on the General Medical Council since 1889, and is now chairman of the British Pharmacopœia Committee, was re-elected for a fourth period of five years on October 24.

A university lectureship in applied mathematics is vacant by the appointment of Mr. H. M. Macdonald to be professor of mathematics in the University of Aberdeen. The readership in botany is vacant by the resignation of Mr. Francis Darwin. These offices will be filled up during the present term.

The Gedge prize in physiology has been awarded to Mr. K. Lucas, fellow of Trinity, for his paper on "The Augmentor and Depressor Effect of Tensions on the Activity of Skeletal Muscle."

The number of students of the first year matriculated on October 21 was 884, or for the whole year up to that date 923.

The late Mr. Henry Evans, of Trinity College, bequeathed to the university his collection of British Lepidoptera.

The following examiners have been appointed for the natural sciences tripos:—Physics, R. T. Glazebrook and W. C. D. Whetham; chemistry, H. O. Jones and Prof. A. Smithells; mineralogy, Prof. W. J. Lewis and L. J. Spencer; geology, A. Harker and Dr. F. A. Bather; botany, A. C. Seward and H. Wager; zoology, A. Sedgwick and Prof. W. A. Herdman; physiology, W. M. Fletcher and Prof. E. Waymouth Reid; anatomy, Dr. E. Barclay Smith and Prof. A. Robinson.

LORD KELVIN will be installed as Chancellor of the University of Glasgow in the Bute Hall on Tuesday, November 29.

PROF. WINDLE, Dean of the Medical Faculty at Birmingham University, has been appointed to the presidency of Queen's College, Cork, in succession to Sir Rowland Blennerhassett.

PROF. HARRY E. CLIFFORD has been appointed acting head of the department of electrical engineering at the Massachusetts Institute of Technology, Boston, in succession to Dr. Louis Duncan, resigned.

AT a meeting of the governors of the South-Eastern Agricultural College at Wye, held on Monday, October 24, it was decided to develop further the forestry department, for which a grant will be sought from the Board of Agriculture.

MR. SIDNEY H. WELLS and the Rev. James Went have accepted the invitation of the President of the Board of Education to serve on the consultative committee in place of Prof. Henry E. Armstrong and the Rev. Dr. Gow, who retire in accordance with the terms of the Order in Council by which the committee was constituted.

YALE University, it is reported, will receive by the will of Mr. Levi Clinton Weits the sum of about 40,000*l*. We learn further from *Science* that the veterinary department of the University of Pennsylvania has received an anonymous gift of 20,000*l*., Columbia University a gift of 3250*l*. from Mr. H. E. Garth for the establishment of a scholarship, and 2000*l*. from an anonymous donor for the purchase of books.

A WELSH national conference on the training of teachers is to be held at Shrewsbury on November 10 and 11. Representatives from the Court and Senate of the University of Wales, from the Council and Senate of each of the Welsh university colleges, from the local education authorities, the local governing bodies, as well as from the educational associations throughout Wales, are expected to be present. The conference will be fully representative, and is expected to have important results.

BY the will of the late Dr. Isaac Roberts, the reversion of his residuary estate, probably between 30,000*l*. and 35,000*l*., is to be divided equally between the University of Liverpool and the University Colleges of North and South Wales, for the purpose of founding scholarships. In the award of the scholarships preference is to be given to persons studying or intending to study astronomy, biology, zoology, botany, chemistry, electricity, geology, and physics, under conditions determined by the councils.

NEW physical and engineering laboratories were opened at the York Railway Institute of the North-Eastern Railway Company on October 20 by Sir Edward Grey. During the course of an address, Sir Edward Grey said he was convinced that no country was more qualified by nature and brains to make use of good scientific training than our own, and, therefore, there was all the more reason why there should be good opportunities of acquiring it. In the great struggle for success everything depended on the use made of scientific discoveries.

DR. C. POMERANZ has been appointed assistant professor of chemistry in the University of Vienna, Dr. Johannes Königsberger assistant professor of theoretical physics at Freiburg, and Dr. Paul Rabe, of Jena, has been raised to the standing of assistant professor at Jena. Profs. H. Joly (mathematics) and A. Dommer (mechanics), of Lausanne, have been raised from the rank of assistant to that of ordinary professor. Dr. Sommer has been appointed professor of mathematics at the Danzig Technical College; Dr. Kurlbaum, of the Charlottenburg National Physical Laboratory, has been appointed ordinary professor at the Berlin Technical College; and Dr. Max Bodenstein assistant professor of chemistry at the University of Leipzig.

THE meeting of teachers engaged in London polytechnics, technical institutes, and schools of art, announced in our last issue, was held at Birkbeck College on October 22, to promote an association of technical teachers for the advancement of technical education generally, interchange of ideas on methods of teaching, and the safeguarding of professional interests. The following resolution was adopted by a large majority:—"That this meeting hereby decides to form an association of science, technological, and art teachers engaged in the London polytechnics, technical institutes, and schools of art, such association to comprise both permanent staffs and evening teachers, other than those engaged in purely secondary work." An executive committee of fifteen members was appointed to draft rules and constitution, and to report to a general meeting to be held in January.

A COPY of the prospectus for 1904–5 of the Leith Nautical College has been received. The college is devoted wholly to technical instruction in subjects directly connected with the sea. It is equipped with physical and mechanical laboratories and appliances for every branch of nautical education. Experimental work is provided in magnetism and electricity in regard to their seafaring application, in the teaching of seamanship, and in shipbuilding. The teaching arrangements are framed to suit the needs of the migratory seafaring community; for students can enter at any time, and can attend for long periods or for recurring short periods, as may be convenient to them. The work of the college, as the programme of instruction shows, is in no way limited by the requirements for the Board of Trade examinations, but every facility is offered in the numerous subjects of a higher naval education. Among courses of study included in this programme may be mentioned those on oceanic meteorology and instruments, with the bearing of meteorological elements on ocean routes, and on ship manœuvring in cyclones; on shipping and commercial law, including the commercial duties of a shipmaster; and on ship surgery, medicine, and hygiene at sea. Special classes have been arranged for fishermen in fisherman's navigation, weather knowledge, knotting and splicing, and in rigger's work.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 17.—M. Mascart in the chair.—On the four first numbers of the photographic catalogue of the heavens published by the Observatory of Toulouse: M. **Lœwy.** The parts now published contain the rectilinear coordinates of 32,275 stars, obtained from 186 negatives. The introduction to vol. ii., by M. Baillaud, also gives a complete account of the method of reduction followed at Toulouse, as well as of the special methods used in the measurements of the coordinates and for the calculation of the constants. An account is also given of the method adopted for measuring the relative magnitudes of the stars and of an experimental study of the photographic objective employed. Statistical studies made at the Observatories of Oxford, Toulouse, and Potsdam have shown that the mean distribution of the star images in the negatives of the catalogue is not uniform, and prove that the focal surfaces of the six objectives studied (Algeria, Oxford, Paris, Potsdam, San Fernando, and Toulouse) have an appreciable curvature.—The study of the third group of air bands with a strong dispersion: H. **Deslandres** and A. **Kannapell.** A detailed description is given of the study of the third group of air bands occupying the more refrangible half of the ultra-violet region (λ 3000 to λ 2000). The general result confirms the conclusions arrived at in 1885, each band under strong dispersion being always formed of eight series of rays in arithmetical progression. A drawing is given for the band λ 2370, in which this structure is clearly shown.—On a new system of micrometers: G. **Millochau.** The wire micrometer, which is attended with certain inconveniences, is replaced by an instrument based on the principle of the heliometer. Two identical plates of glass with parallel faces are placed in a plane perpendicular to the optical axis of the telescope employed, between the objective and the eye-piece. The plates turn round a common axis and give rise to a double image of the star, the distance between the two images being practically independent of small displacements of the telescope.—Observations of the sun made at the Observatory of Lyons with the 16 cm. Brunner equatorial during the second quarter of 1904: J. **Guillaume.** The results are summarised in three tables giving the number of spots, their distribution

in latitude, and the distribution of the faculæ in latitude.—The elements of molecular vibrations in relation with the sense of propagation of sound waves: L. **Bard.** In view of the impossibility of explaining the orientation of sound by the ear by the usual theories, the author propounds two hypotheses to explain this.—Researches on the boiling points of mixtures of volatile liquids: C. **Marie.** The boiling point constants of a given pair of volatile liquids and a non-volatile substance being given, the question is raised as to whether it is possible to calculate, *a priori*, the value of the boiling point constant corresponding to the mixture. This calculation has been made by Nernst, and an experimental study of this formula has been made by the author with mixtures of water and alcohol and resorcinol. The divergence between the theory and the results of the experiments is considerable, and an examination of the fundamental assumptions used in the formula is made to see if the cause of the divergence can be elucidated. Further experiments are required before the theory can be completely made out.—The action of solutions of organomagnesium compounds on the halogen derivatives of phosphorus, arsenic, and antimony: V. **Auger** and M. **Billy.** Phosphorus trichloride reacts violently with solutions of magnesium methyl iodide, giving the chloride of tetramethylphosphonium, phosphorus iodide, and magnesium chloride. With chloride of arsenic the chief product of the reaction is trimethylarsine oxide; with antimony trichloride several substances are formed, from which, by treatment with potassium iodide, the iodide of ethylstibine can be isolated.—On an organic persulphate: R. **Fosse** and P. **Bertrand.** The sulphate of dinaphthopyranol, obtained by treating dinaphthopyranol with dilute sulphuric acid, possesses oxidising properties, setting free iodine from an acidified solution of potassium iodide, and oxidising alcohol to aldehyde. It thus appears to be a true persulphate, analogous in composition with Caro's acid.—The constitution of rosaniline salts and the mechanism of their formation: Jules **Schmidlin.**—Anthracène tetrahydride and octahydride: Marcel **Godchot.** These hydrides have been obtained by applying the method of Sabatier and Senderens. The octahydride is the more stable of the two, and is the main product when the hydrogenation is carried out at 200° C. The oxidation products and the reactions with the halogens have been studied.—On the origin of the carbonic acid of the seed during germination: Edouard **Urbain.** It is established that the carbon dioxide is produced at the expense of the albuminoid materials of the seed.—Study on the successive states of plant material: Eug. **Charabot** and Alex. **Hébert.**—Vital periodicity of animals submitted to the oscillations of level in deep sea: Georges **Bohn.**—The agglutinating cells in the Eolidia: Paul **Abric.** Description of some new species of trypanosomes and parasitic Hæmogregarina of marine Teleostea: E. **Brumpt** and C. **Lebailly.**—On the auxospores of two pelagic diatoms: J. **Pavillard.**—The geology of the Ortler region: Pierre **Termier.**—On macles: G. **Friedel.**

DIARY OF SOCIETIES.

FRIDAY, OCTOBER 28.

PHYSICAL SOCIETY, at 5.—An Interference Apparatus for the Calibration of Extensometers: John Morrow and E. L. Watkin.—A Sensitive Hygrometer: Dr. W. M. Thornton.—Note on a Property of Lenses: Dr. G. E. Allan.

SATURDAY, OCTOBER 29.

ESSEX FIELD CLUB, at 6.30 (at Essex Museum of Natural History, Stratford).—Fresh-Water Biological Research and Biological Stations: D. J. Scourfield.

TUESDAY, NOVEMBER 1.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Inaugural Address by the president, Sir Guilford L. Molesworth, K.C.I.E.—Presentation of the Council's Awards, and Reception in the Library.

WEDNESDAY, NOVEMBER 2.

SOCIETY OF PUBLIC ANALYSTS, at 8.—The Detection and Estimation of Small Quantities of Maltose in the Presence of Dextrose: Julian L. Baker and W. D. Dick.—The Use of Palladium-Hydrogen as a Reducing Agent in Quantitative Analysis: Alfred C. Chapman.—Some Recent Abnormal Milk Results: Sidney Harvey.

ENTOMOLOGICAL SOCIETY, at 8.

THURSDAY, NOVEMBER 3.

CHEMICAL SOCIETY, at 8.—Note on the Action of Nitric Acid on the Ethers: J. B. Cohen and J. Gatecliff.—The Condensation of Formaldehyde with Acetone (Preliminary Note): E. A. Werner.—Union of Hydrogen and Chlorine. Rate of Decay of Activity of Chlorine: J. W. Mellor.—The Action of Phthalic Anhydride on α-Naphthylmagnesium-bromide: S. S. Pickles and C. Weizmann.—The Constitution of Nitrogen Iodide: O. Silberrad.—The Available Plant Food in Soils: H. Ingle.—The Combustion of Ethylene: W. A. Bone and R. V. Wheeler.—The Decomposition of Methylurea: C. E. Fawsitt.—The Influence of Certain Salts and Organic Bodies on the Oxidation of Guaiacum: Miss E. G. Willcock.—The Influence of Potassium Persulphate on the Estimation of Hydrogen Peroxide: J. A. N. Friend.—The Dynamic Isomerism of α- and β-Crotonic Acids (Preliminary Note): R. S. Morrell and E. K. Hanson.—The Influence of Sunlight on the Dissolving of Gold in an Aqueous Solution of Potassium Cyanide: W. A. Caldecott: (1) The Fractional Hydrolysis of Amygdalinic Acid; (2) Isoamygdaline: H. D. Dakin.

RÖNTGEN SOCIETY, at 8.15.—The Presidential Address: C. Thurston Holland.

FRIDAY, NOVEMBER 4.

GEOLOGISTS' ASSOCIATION, at 8.—Conversazione.

MONDAY, NOVEMBER 7.

ROYAL GEOGRAPHICAL SOCIETY (Albert Hall), at 8.30—The Work of the National Antarctic Expedition: Captain R. F. Scott, R.N.

TUESDAY, NOVEMBER 8.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Coast Erosion: A. E. Carey.—Sea-Coast Erosion on the Holderness Coast of Yorkshire: E. R. Matthews.

FRIDAY, NOVEMBER 11.

ROYAL ASTRONOMICAL SOCIETY, at 5.

CONTENTS.

SUPPLEMENT TO "NATURE."

LORD KELVIN ON OPTICAL AND MOLECULAR DYNAMICS.

Baltimore Lectures on Molecular Dynamics and the Wave Theory of Light. By Lord Kelvin, O.M., G.C.V.O., P.C., F.R.S. Pp. xxii+694. (Cambridge: University Press, 1904.) Price 15*s.* net.

IN the autumn of the year 1884 Lord Kelvin delivered at Johns Hopkins University a course of lectures "On Molecular Dynamics and the Wave Theory of Light," mainly *extempore,* which, having very fortunately been reported stenographically by Mr. A. S. Hathaway—one of his band of auditors, the famous "twenty-one coefficients"—were issued to the world unrevised in a papyrograph volume at the end of the same year, and have since been known as the "Baltimore Lectures." The report, being nearly *verbatim,* showed how comparatively slight were the immediate preparations that Lord Kelvin had made for some portions of his task, and thus had the great advantage of revealing the procedure and attitude of an investigator of transcendent genius in face of regions of his subject more or less new to him.

One result, in fact, of his enthusiasm for the new aspect of optical propagation revealed by the phenomena of anomalous dispersion, and of the wealth of mechanical illustration which, taking his audience into collaboration, he provided for this hitherto rather abstract subject, was to start a period of enlivened interest, illustrated by memoirs by Lindemann and others, abroad and in this country; this has now reaped a reward in fruitful comparison of the theory with experimental data obtained over the enormous range of six or seven octaves by Langley, Rubens, and other pioneers. Irrespective of this phenomenon of anomalous dispersion in the spectrum near a region of absorption of the light, Lord Kelvin's own estimates of molecular dimensions had already ruled out the earlier attempts of Cauchy and his followers to base dispersion on mere loading of the æther by massive molecules. On such a theory of inert molecular masses the proportional dispersion per octave could depend only on the ratio of the intermolecular distance to the wave-length, no other magnitudes coming into consideration, and it must depend on the square of this ratio; thus the actual 1 per cent. dispersion for glass would be explicable by about 10 molecules per wave-length, while with the real number, about 10^4, the circumstances would be practically the same as for a uniformly distributed load, which would give no dispersion at all. The modern theory of dispersion thus must rest on an investigation of the interaction between the forced internal vibration of the molecules, conditioned by their own proper periods, and the periodic impressed vibration of the wave-motion which produces it. So long as the internal dynamics of the molecule remain unexplored, only general principles can be applied, and it matters little to the argument whether it is conducted in terms of a mechanical conception of radiation or in terms of the electric theory; in either case only the general frame into which the facts are to be fitted can be supplied by theory. On a mechanical view, mere loading may produce refraction but not dispersion; so on the electric view, even if there were no free periods in the ordinary sense, there would remain an index of refraction equal to the square root of the dielectric coefficient.

In the preface to the present volume Lord Kelvin states that he chose for his lectures the subject of the wave-theory of light with the object of accentuating its points of failure, thereby intending to stimulate the activities of his audience towards extending further "the floods of new knowledge splendidly enriching the whole domain of physical science" that had flowed from the theory.

"We all felt that difficulties were to be faced and not to be evaded; were to be taken to heart *with the hope of solving them if possible*; but at all events with the certain assurance that there is an explanation of every difficulty, though we may never succeed in finding it. It is in some measure satisfactory to me, and I hope it will be satisfactory to all of my Baltimore coefficients still alive in our world of science, when this volume reaches their hands; to find in it dynamical explanations of every one of the difficulties with which we were concerned from the first to the last of our twenty lectures of 1884."

The sentences quoted contain the key to much (though far from all) of Lord Kelvin's mathematical investigation of the last twenty years. The result is this magnificent volume of more than 700 pages, which in its variety of contents and width of grasp forcibly recalls the original "Thomson and Tait" of forty years ago, except, indeed, that the form of a treatise being now dispensed with, the author is at liberty to go directly for the various subjects of interest that hold his attention without any necessity for preliminary didactic expositions.

The earlier lectures are reproduced here with additions within brackets, but the author soon found that it was easier to re-write the greater part of the material. His expression of distrust of "the so-called electromagnetic theory of light" (p. 45) stands as in the original. Along with it is the interesting statement that he had worked out for himself, as early as the year 1854, the result that an electric impulse is propagated along a cable with a velocity of the order of that of light, and that it only required a knowledge of the ratio of the electric units to lead to the result that for an air dielectric it would agree with the velocity of light in air. An investigation of such linear propagation, on the lines now familiar, and thoroughly developed by Heaviside, is inserted as the last appendix (L). The first published determination of this velocity is contained, as is well known, in Kirchhoff's memoir of 1857; there the result is deduced on the basis of Weber's theory of moving electrons, which act on each other instantaneously at a distance, the law of attraction involving their velocities as well as their distance apart. Neither there nor in the ordinary modern investigation for cables is there any reference to transmission of electric effects across space with finite speed; that makes no difference for the case of enclosed cylindrical dielectrics of diameter small compared with the wave-length, for with them it is only the adjacent parts of the electric distribution and

current on the conducting boundaries that are sensibly effective as regards the internal state of each element, and their mutual influences are adjusted in times which are in any case inappreciable in an estimate of the times required for transmitting effects along the cylinder. For wider cylinders or shorter waves, the Weberian formula of Kirchhoff gives a result differing from the velocity of radiation, of which Maxwell was of course well aware, while Lord Kelvin's approximate treatment is no longer applicable. We now know that, to transform the Weber-Kirchhoff formulæ into those of the modern electron theory, it is only necessary, in the integral expressions for the vector potential of the current and the scalar potential of the charges, to consider each element as propagated through space with the velocity of radiation instead of being transmitted instantaneously.

One of the great historical difficulties in optical theory, above referred to, was that of embracing the phenomena of propagation in crystals and of reflection from transparent bodies within the dynamics of ordinary elastic solid media. This problem was resolutely attacked by Green nearly sixty years ago with a brilliant but unsuccessful result, and no success in adapting his analysis was achieved by anyone else until some three years after the Baltimore lectures were delivered. Then Lord Kelvin produced his theory of an elastic medium with finite rigidity but perfectly labile as regards compression, and characteristically illustrated it by material structures, such as a mass of foam *in vacuo*, which resist distortion but are insensitive to shrinkage of volume. If luminiferous media were elastically like this, the necessity of continuity of displacement normal to a reflecting interface would no longer press upon the theory, for the two media would stretch locally in the direction of the normal without reaction on the other stresses, just as much as might be required. And it was promptly pointed out by Glazebrook that the arrangement which thus allowed Fresnel's laws for reflection was also competent to explain propagation in crystals by the simple expedient of making the inertia æolotropic, while the lability as regards compression is again all that is wanted to obtain the ascertained laws of MacCullagh's theory (Lord Kelvin's rotational æther) or the electric theory for crystalline reflection. In fact, one advantage accruing with the electric theory is that it dissects the accepted and unique formal analysis of propagation of light into a series of linear relations between various vectors, each of which has a distinctive name and quality; and according as we take one or other of these vectors to represent a displacement of an elastic medium, we have the various mechanical theories of Fresnel, MacCullagh, and Sarrau and Boussinesq, differing in the types of interfacial continuity that they require, but algebraically the same; the exact duality between the systems of Fresnel and Sarrau is in this way open to direct inspection. Such, then, was Lord Kelvin's solution of 1887, in which all media were taken to be labile as regards compression, the type which Green had rejected under the idea that it was intrinsically unstable; this classical objection Lord Kelvin at once removed by the illuminating remark that the medium only required to be held fixed at an outer boundary to prevent any internal collapse. There was something unnatural about this, as its author admitted, and it now appears that an æther so constituted would still absorb much condensational energy from vibrators; but here in 1904 comes the further crucial remark that only one of the two media need be thus labile in order to confer the requisite freedom for reflection without interference from compressional waves; the æther itself may remain incompressible, as Green took it to be, but the interaction of æther and molecules in every material body is to be such as always to make it labile or inelastic for compressional disturbance. It need not, however, be absolutely labile if Fresnel's laws are to be satisfied only within experimental limits. And here the remarkable peculiarity of highly refractive substances like diamond, the "adamantine property" discovered by Airy, which replaces an abrupt change of phase in passing the polarising angle by a gradual though rapid one, comes into consideration; if only the velocity of propagation of the condensational wave in material media is a small complex quantity, the complexity will introduce just the gradual change of phase that is required in order to include that property. Moreover, if this velocity is a pure imaginary, there will be no loss of energy involved; this happens for a granular or discrete medium whenever there are periods of free internal vibrations among its constituent granules that are longer than the period of the waves under consideration. If we cannot include the adamantine property as introduced in this way through total reflection for compressional waves, no resource is known except that of gradual transition at the surface; this Lord Rayleigh has shown to be the main cause for water, as careful cleansing of the surface almost entirely removes the phenomenon.

In this chain of simple, yet brilliant and attractive, ideas, Lord Kelvin has gradually forged a reconciliation between fact and theory that would probably have been received with universal acclaim thirty years ago. Nowadays, as regards most people, the need has ceased to be so strongly felt; for better for worse most of us are now wedded to the electric theory of light, the creation of Lord Kelvin's most famous disciple, which forms a consistent scheme of the relations of electricity and radiation, perfectly definite and unambiguous with the large simplicity of nature itself, that has led into no essential contradiction with fact, though it has many times predicted phenomena of the most essential and fundamental kinds.

Not that there is any difference of opinion as to the value of the electric theory. Lord Kelvin would doubtless agree that, as a new mode of grouping of the relations, it has placed them in a most fruitful light, and shown the directions of natural development. He would perhaps say that it is a successful description rather than an explanation, and he would probably desire to modify the terms of the description in order to bring it closer to the train of dynamical ideas in which he would search for the explanation. And here we are at the parting of the ways. Is it incumbent on us to treat the æther as strictly akin

to the material bodies around us? or may we assign to it a constitution of its own, to be tested by its success in comprehending the complex of known relations of physical systems? This is not the occasion to follow up that question. It would appear that Lord Kelvin cannot grant that such a constitution has been determined until it has made clear in full detail the mode of connection of the atom with the æther, so that a precise mechanical model of it could be imagined; whereas, on the other side, it may be held to be the merit of the scheme that it evades such a hopeless task, and defines physics as relating to the surrounding field of æthereal activity of the molecules rather than to the molecules themselves, which must remain in many respects inscrutable—a consummation that would hardly have been attempted had not the illuminating conception of Lord Kelvin's vortex-atoms shown the way.

The plan along which Lord Kelvin now finds it most hopeful to pursue ultimate physical synthesis admits the existence of "electrions," freely mobile through æther simply because two media can be superposed independently in the same space, which exert direct *force at a distance* upon the æther as also does the matter itself, that the forces are so enormous as sensibly to compress or expand the æther around these nuclei, and that the source of electric, chemical and elastic action is thus to be found. This conception is developed over many pages with the power and conciseness that are familiar to his readers; it remains a question for the future whether it will prove to be a fruitful theory; it certainly forcibly illustrates many deep molecular phenomena, and demands, and will doubtless receive, very careful study.

The point of view is illustrated in p. 300, in treating of the spheres of activity of the various kinds of molecules, where Lord Kelvin states that this "is a most interesting subject for molecular speculation, though it or any other truth in nature is to be explained by a proper law of force according to the Boscovichian doctrine which we all now accept (many of us without knowing what we do) as the fundamental hypothesis of physics and chemistry." When one reflects that to Lord Kelvin, more than to anyone else except Faraday, has been due the stimulus to replace artificial mathematical attractions by activity propagated according to simple relations, this sentence may perhaps be taken as expressing his belief that in probing into the details of the dynamics of the unexplored molecules we are still practically confined to the partial but fruitful conception of mutual forces.

Thus in the appendix entitled "Aepinus Atomized," a definite foundation is postulated by taking the electrion to be a very minute negative ionic charge, and an atom to involve a positive ionic charge rigidly distributed through a much larger sphere, but in normal condition neutralised by one or more electrions inside it, which may be occasionally shot out as kathode rays; and electrions and atoms can be wholly or partially superposed in the same space without mutual deformation. On this basis the statical configurations of electrions in the spheres, that can represent neutral atoms, are discussed and are applied to the dielectric quality of matter and its æolotropy in crystals, to the intricate and elegant details of the pyroelectric and piezoelectric quality in the latter, and in more general terms to the nature of conduction and its striking relation to temperature, so different in pure metals and in non-metals and alloys. In further appendices the same conception is applied to crystalline dynamics, where auxiliary Boscovichian laws of pure attraction are also introduced, because Lord Kelvin thinks a purely electric basis is too narrow, even when not restricted to spherical nuclei as here. The whole is developed on all sides with marvellous directness and facility in tracing out crystalline groupings in space, which, however, make it difficult reading, though relieved by frequent flashes when a vivid analogue of some ascertained experimental relation appears. It is a conception such as this that Lord Kelvin has in mind in his postulate, above referred to, that material bodies are labile to optical compressional waves. The free molecular vibrations that must correspond to a bright line-spectrum do not come in for consideration; nor does the now burning question of actual dissociation in typical chemical atoms.

The task of making a review of a book like the present one can at best be very imperfectly executed. The book is largely a new creation. It surveys a vast range, all the cognate subjects on which the author feels that he has something new to communicate—laws of diffusion of gases, transparency of the sky, detailed dynamics of optical chirality, motion of molecules through æther, front of a wave-train in a dispersive medium, the finiteness of the universe, atomic theory of electricity, regelation and plasticity of ice, waves and ripples on water and their dispersion, crystalline structure and iridescence, partition of energy in molecular systems, crystalline dynamics on Boscovich's principles, electric and magnetic screens. Instead of putting the question, Is this subject clearly and strikingly expounded? one has rather to ask, Is this new departure or revolutionary idea justified by its results? Any off-hand decision is, of course, impossible. When one is in difficulty over inscrutable or irreconcilable phenomena, it will be a book to turn over to see what the premier authority has to say on the subject in hand; for what he says is not lightly thrown from his pen, it is the work of twenty years, and withal it forms a consistent whole. In the remarks here made about only a few of the many themes of which it treats, it is the obviously revolutionary element that has attracted attention. There is, however, one very serious criticism as to which there can be no question. This book of seven hundred pages—dealing in concise manner with nearly all the most intricate topics of dynamical and molecular theory, with the cross references and recurrences to previous passages that are involved in twenty years of preparation—is without an index, and the detailed table of contents does not meet the want. The thanks of the scientific world will surely go to the veteran author, now by a happy choice Chancellor of the university which he has so long adorned, for this splendid gift, which stimulates and educates even where it fails to convince, and bears on every page evidence of profound and unwearying thought.

J. L.

BLOOD RELATIONSHIPS.

Blood Immunity and Blood Relationship; a Demonstration of Certain Blood-relationships amongst Animals by Means of the Precipitin Test for Blood. By George H. F. Nuttall, M.A., M.D., Ph.D. Pp. 444. (Cambridge: University Press, 1904.)

TSCHISTOWITSCH was the first to observe that if a rabbit were subjected to repeated injections of serum from an animal of a different species, it reacted to the introduction of the foreign proteid by forming and accumulating in its blood a substance which, when added to a solution of the particular serum injected, gave rise to a precipitate. These experiments at once aroused considerable interest, and were confirmed and extended by a number of observers on account of their importance in relation to the processes whereby the organism protects itself against the introduction of proteid poisons and micro-organisms by the formation of so-called anti-bodies.

The interest of the observations is not, however, confined to the doctrine of immunity, for fuller knowledge of the phenomena has shown them to have important applications to both forensic medicine and zoology. The value to the former was pointed out by Uhlenhuth and others, who directed attention to the fact that the serum of an animal previously subjected to repeated injections of human serum forms a very sensitive test for the same, and can therefore be used for the detection of human blood. The importance of precipitin phenomena to the zoologist has been particularly insisted upon by Dr. Nuttall, and the present volume is largely concerned with results of interest from this point of view.

When the precipitins were first discovered, it was concluded that the reaction was strictly specific, and that the serum of an animal injected with human serum only formed precipitates with the serum of man, and one injected with ox-serum only when added to the serum of the ox. Nuttall and Uhlenhuth showed, however, that no such hard and fast line could be drawn. Indeed, the development of our knowledge of the specificity of the precipitin reaction is in great measure due to the work of Dr. Nuttall and to that of his pupils, Drs. Graham Smith and Sangar. However, although not strictly specific, a precipitin precipitates the serum of the same species of animal as that used in its preparation more readily and in greater amount than that of animals of other species, and the difference is least marked when the animals are closely related, as in the case of the horse and the donkey. From these results, Dr. Nuttall conjectured that the varying degree to which a precipitin reaction occurred might afford a valuable indication as to blood relationship.

The present volume contains the results of experiments, undertaken by the author in conjunction with Drs. Graham Smith and Sangar, with a large number of anti-sera upon the blood of 586 different species of animals.

The book is divided into two parts. Part i. is devoted to a condensed summary of our knowledge on anti-bodies in general. It commences with a brief but clear account of Ehrlich's theory regarding the formation of anti-toxins and anti-bodies generally. This is followed by a series of paragraphs on ferments and anti-ferments, cytotoxins, hæmolysins, bacteriolysins, agglutinins, &c., which in style suggests the pages of a technological dictionary. Short sentences, each pregnant with some fact, and with reference attached, follow one another in bewildering succession. Many of these are contradictory, and it is to be regretted that there is no summing up by the author at the end of each paragraph.

This portion of the book does great credit to the author's industry and scholarship, but it makes impossible reading, and is only serviceable to one knowing the subject and wanting the references. After fifty pages one is glad to reach the end of part i., and to come to the subject-matter proper of the book, viz. the precipitins.

Part ii. commences with the methods for obtaining precipitating anti-sera. The style now leaves little to be desired, and this account is delightfully clear and complete, so that anyone wishing to repeat the experiments could hardly fail for want of adequate instructions. Sections ii. and iii. contain nearly all that is known of the nature of precipitin reactions and the effects of heat, peptic and tryptic digestion, filtration and putrefaction, upon both precipitins and precipitable substances. On p. 126, however, the statement is made that "no measurements of the amount of precipitin during the growth of immunisation have as yet been made which would correspond to those made upon antitoxin." One can only presume that this paragraph was written prior to the publication of von Dungern's quantitative experiments with the precipitins obtained by the injection of crab-plasma.

Section iv. deals with the specificity of the precipitins. After historically reviewing the views of different experimenters on this subject, and showing that increased knowledge has fully confirmed his earlier contentions against the absolute specificity of precipitin reactions, the author expresses himself as in entire agreement with the remark of Linoisier and Lemoiné: "Là où on a cru voir une action spécifique, un examen attentif ne permit de voir qu'une action particulièrement intense."

Section v. treats of precipitins obtained by the injection of other proteids from bacteria, milk, and higher plants. In section vi. are given in tabular form the results of 16,000 tests of 30 anti-sera with the bloods of a large number of animals. This particular series is not quantitative, and was presumably made before the author had devised his quantitative method, the reactions being entered as "full," "marked," "medium," "faint," and "nil." This is followed by a later series of 500 experiments made in conjunction with Strangeways with a quantitative method devised by the author, whereby the dilution of the serum and the time of reaction being constant, the actual volume of the conglomerated precipitate is measured in an ingenious way. The volume of the precipitate, with the homologous serum, is taken as the unit, and the volumes obtained with the sera of other animals are expressed in percentages of this unit.

The method and the interest of the facts brought to light by it will be clearer from two short examples.

Amount of precipitate obtained by adding anti-human serum to the serum of man and apes (expressed as percentages):—

Man	100
Ourang	80
Cynocephalus mormon	50
Cercopithecus petaurista	50
Ateles vellerosus	25

Amount of precipitate obtained in a similar way by adding anti-horse serum to the serum of horse, donkey, zebra:—

Equus caballus	100
Equus asinus	84
Equus grevyi	58

Tested in this way the indications of blood relationship between man and the ourang are comparable to those between the horse and the donkey. The serum of other mammalia gave but traces of precipitate with the above anti-sera, and that of other vertebrates none at all.

In these precipitin-phenomena we have perhaps a really physiological test of blood relationship, and that, as the author suggests, "a common property has persisted throughout the ages which have elapsed during the evolution of animals from a common ancestor in spite of differences of food and habits of life." Anomalies do undoubtedly occur when working with any particular anti-serum, so that all conclusions must be controlled by experiments with anti-sera prepared from different individuals. Section viii. contains the results of 2500 similar tests, undertaken by Graham Smith, in the application of the method to the lower vertebrates and invertebrates. These will be of no less interest to zoologists, but space prevents our entering upon further particulars.

The ninth and last section deals with the practical application of precipitin reactions to legal medicine. As the precipitable substance in sera is a relatively stable body, is very resistant to the action of putrefactive organisms, and is not destroyed by drying, the detection of human blood by this means is not confined to stains of recent origin. Indeed, Graham Smith and Sangar have examined a large number of articles from the collection of the Criminal Investigation Department, Scotland Yard, and have succeeded in identifying human blood stains which were thirty years old.

The fact that anti-human serum forms precipitates to some extent when added to the serum of monkeys does not seriously diminish the forensic value of the precipitin test for human blood, for the plea that suspected bloodstains were of simian origin would seldom be raised and hardly ever substantiated.

The volume concludes with an excellent bibliography on precipitins and allied subjects which occupies sixteen pages!

In addition to containing the methods and experimental results whereby the author and his associates, Drs. Graham Smith and Sangar, have tested and developed the precipitin reaction as an indication of blood relationship, the book contains practically all that is known on the subject of precipitins up to the present time, and will therefore be indispensable to anyone desiring to become acquainted with or to work upon this subject.

CHARLES J. MARTIN.

THE MOON.

The Moon. A Summary of the Existing Knowledge of our Satellite, with a Complete Photographic Atlas. By Wm. H. Pickering. Pp. xii+102; 100 illustrations. (New York: Doubleday, Page and Co., 1903.) Price 10 dollars net.

IT has so long been taught that the moon is a world on which nothing ever happens that it may come as a surprise to many to learn that the probability of frequent changes in the lunar surface is now seriously advocated. The author of this book, who is a well known American astronomer, is convinced that there are daily alterations over small areas which cannot be explained either by shifting shadows or varying librations, and therefore infers that there are real changes in the surface detail. The observations on which this conclusion is based are collected in the present volume, which also includes a more general account of our satellite, and contains the first complete photographic atlas which has yet been published.[1]

To make a thorough study of the moon, Prof. Pickering some years ago suggested the use of a telescope of great focal length, and, as so frequently happens in America in such circumstances, the generosity of two anonymous donors enabled him to try the experiment. The instrument actually employed was a 12-inch objective of 135 feet focal length, giving a direct image of the moon nearly 16 inches in diameter, and to obtain the advantage of such "steady" atmospheres as can only be found in low latitudes it was taken out to Jamaica and set up at Mandeville, 2080 feet above sea-level. The long telescope tube was erected on the side of a convenient hill with its axis in the direction of the pole, and light was reflected into it at the lower end by a clock-driven mirror. The instrument was so far successful that all the negatives for the atlas were obtained within seven months.

The atlas shows the lunar surface in sixteen sections, each of which is exhibited under five different conditions of illumination, and there is in addition a good picture of the full moon, with the necessary key maps, besides other illustrations of interest. Although the photographs are not all of the finest definition, the completeness of the series gives them a special value, and the atlas will doubtless prove extremely useful to all who are engaged in lunar studies.

Apart from the photographs, the chief interest of the book lies in the observations and arguments which are put forward in favour of lunar activities. The moon is so near that no improbably great area need be affected to make a change visible to an observer on the earth, but any real variations are liable to be

[1] The atlas is also published in the *Annals* of the Harvard Observatory, vol. li, 1903.

masked by the varying conditions of illumination. This difficulty does not, of course, disappear even when series of photographs are under examination; in the words of the author (p. 91):—

"It was soon found that for certain regions, notably those in the northern half of the disc, the change in appearance produced by the difference of lighting rendered it absolutely impossible to identify the same formation upon the plates taken at (lunar) sunrise and sunset and those taken at noon."

Photographs at intermediate phases were accordingly taken, and by aid of these the connection can be traced.

Photographs, indeed, introduce another difficulty. Slight changes in exposure and development were found sometimes to produce very misleading results, and it is pointed out that the only safe procedure is to confirm all suspected changes by extended observations under different conditions with the telescope. There is, however, no reason to suppose that the author is unfamiliar with the many pitfalls, and the interesting results of his labours may therefore be received with some confidence, or at least as demanding careful investigation by other observers.

Attention was directed by the author ten years ago to the variability of many of the dark spots which are dotted over the lunar surface, the three in Alphonsus being probably familiar to most observers. The view then expressed that these are patches of organic growth resembling vegetation, which spring up and die during the long lunar day, still seems to give the only simple explanation of the appearances observed. The spots are said to be darkest near full moon, when shadows are geometrically impossible, and a real change in the reflecting surface therefore seems to be highly probable.

On the question of active lunar craters, the chief facts relating to Plato and the much discussed case of Linné are summarised, and an account is given of phenomena observed in the crater forming the source of Schroter's valley which bear a striking resemblance to those accompanying the active eruption of a terrestrial volcano. Part of the description reads:—

"Dense clouds of white vapour were apparently rising from its bottom and pouring over its south-western crater wall in the direction of Herodotus" (p. 40).

The changes in this "vapour column" are said to be visible with a 6-inch telescope under ordinary atmospheric conditions, so that the reality of the phenomenon need not long remain in doubt, whatever explanation may be adopted. The author evidently believes that there is an actual emission of vapour, and he points out that as water cannot exist as a liquid on account of the rarity of the lunar atmosphere, it would take the form of snow or hoar frost.

Many of the changing appearances of lunar details are, in fact, attributed to deposits of snow and hoar frost which melt under the influence of the sun's rays, and are re-deposited when those rays are withdrawn. Among other evidence that there is snow on the moon, two photographs of the full moon are reproduced, one representing it as ordinarily seen, while the other is intended to exhibit the principal snow-covered areas; as these are differently printed copies from the same negative, the illustration is anything but convincing in the absence of details as to the printing processes. Other examples are more satisfactory. Linné, for instance, is surrounded by a white halo, which is stated to be not only now permanently smaller than it was thirty years ago, but to change with the altitude of the sun in a manner analogous to the seasonal variations of the polar caps of Mars. In this case the author had the happy thought to inquire if there were any variation during a lunar eclipse, the idea being that the withdrawal of sunshine for a couple of hours or so might produce an appreciable increase in size. Such an enlargement appears to have been established at the Lowell Observatory in 1898, and by the author himself in 1899, 1902, and 1903; another observer, Mr. Saunder, however, seems to have been somewhat doubtful as to the reality of the slight increase which his measures indicated in the eclipse of 1903, and as his observations would make the halo twice as great as those which the author made on the same occasion, further observations of this kind are evidently desirable.

It is also considered probable that many of the remarkable changes which have long been recognised in the craters Messier and Messier A are to be accounted for by varying depositions of snow.

Permanent deposits of snow in the craters themselves are believed to furnish an adequate explanation of the striking brightness of such craters as Aristarchus, and even the long bright streaks, such as those which radiate from Tycho, are attributed to the same substance. The long streaks are considered to be composed of a multitude of smaller snow streaks issuing from small white craterlets, usually less than a mile in diameter, many of which show a tendency to occur along lines which are probably cracks or lines of weakness in the lunar surface.

The "riverbeds" and lunar "canals," which the author has detected, present many features of interest, and the latter may be of special importance in view of the light which they may throw on the nature of the corresponding features of the planet Mars.

While some of his researches tend to modify the prevalent idea that the moon is a dead world, the author has no revolutionary views to put forward as to the general character of the lunar formations. He says:—

"There seems, indeed, to be no feature found upon the moon which is not presented by the Hawaiian volcanoes, and there is no feature of the volcanoes that does not also have its counterpart uuon the moon. Even the cause of the bright streaks upon the moon . . . is partly illustrated by Hawaii" (p. 25).

Sufficient has been said to indicate the interesting character of this work, but its value as a contribution to science can scarcely be gauged until independent observations of the unexpected phenomena have been made. It is fortunate that some of the investigations suggested are within range of very modest instruments, even as low as 4 inches aperture.

KINSHIP AND MARRIAGE.

Kinship and Marriage in Early Arabia. By the late W. Robertson Smith. New Edition, with Additional Notes by the Author and by Prof. I. Goldziher, Budapest. Edited by Stanley A. Cook, M.A. Pp. xxii + 324. (London: A. and C. Black, 1903.) Price 10*s.* 6*d.*

THIS new edition of a masterly work should be welcomed by all who take an interest in the study of primitive man, a study which, it is no paradox to say, has more practical bearing than academic history on the social problems of the future. Before his death Robertson Smith made corrections and added notes to the first edition of 1885, which are now incorporated. As anthropologists and orientalists know, the essay is an application of the theories of J. F. McLennan to early Arabia, conducted with the originality, insight, logical clearness and brilliance of exposition which are inseparable from the name of Robertson Smith.

Beginning with an exposure of the easy methods of the Arabian genealogists, he proceeds to argue that "female kinship" was once the rule. The strong Arab sense of blood-unity "can only have come from female kinship" and from a state of society where children were reckoned to the tribal kin, but not to a particular father. He regards the *mota* marriages, common in the time of Mohammed, as a last relic of McLennan's *beena* marriage, in which the husband goes to live with his wife's people. This system of *beena* or *sadica* marriage with female kinship and totemism was broken up by the growth of the idea of the family (*dar*), the result being male kinship and *baal* marriage, in which the husband has "dominion." The change was made through "marriage by capture," followed by marriage by purchase. But there is also to be explained the acceptance of male kinship in a state of society where there was "no notion that a man should keep his wife strictly to himself." The only possible explanation lies, the author thinks, in Tibetan polyandry, in which a group of brothers bring to their common home a common wife. This must have been preceded by Nair polyandry, in which a group of brothers is entertained in her home by a common wife. The whole doctrine of the paternal system implies that this polyandry was quite widely spread. Lastly, bars to marriage before Islam were made on female kinship alone; the early Arabians and northern Semites possessed totemism and exogamy.

How far the author might have modified his conclusions is an idle speculation. Criticism of one who has taught us all is especially invidious in the case of a book which in substance is nearly twenty years old. But it is only fair to science to point out that recent research has found grave objections to McLennan's theory of social development and to many of his "universal institutions" themselves. Much also of McLennan's evidence was bad; the author quotes (p. 98) one of his examples of "marriage by capture," which is nothing of the kind. The best authorities contradict the statement on p. 262 as to the prevalence of such "marriage" in Australia, and that on p. 267 as to "marriage by capture" being followed by exogamy. Objections may be raised to the suggestion that *beena* marriage with adoption into the woman's kin are proved by Genesis ii. 24—"a man shall leave his father and mother and shall cleave unto his wife, and they two shall be one flesh"; to the old idea that early man considered animals to be men in disguise; to the view that the Arabs "practised" cannibalism, and that "promiscuous" behaviour at religious feasts is a survival of polyandry; and to the acceptance of metronyms in the genealogies as proofs of female kinship, while patronyms are rejected.

Recent speculation, however, is but beginning to reconstruct the development of the primitive social organism. The great value of this book is to prove that the early Semites followed the same lines of development, whatever they were, as other races, and to provide the best exposition of the prevalent theory.

ERNEST CRAWLEY.

SYLVICULTURE.

Schlich's Manual of Forestry. Vol. ii. Sylviculture. Third edition. Pp. viii + 393. (London: Bradbury, Agnew and Co., Ltd., 1904.) Price 8*s.* net.

IN NATURE of July 23, 1891 (vol. xliv. p. 265), Sir Dietrich Brandis, K.C.I.E., reviewed the first edition of the above volume. He then prophesied a great future for Prof. Schlich's work. That the prophecy was not a vain one has been amply proved by the test of time. The book reached the second edition in 1897, and has now passed into the third. There is no preface to this edition, but the arrangement of the former editions has, on the whole, been retained; however, the subject-matter has been somewhat differently classified. The present volume consists of four parts—each part is divided into chapters and sections, which are further subdivided as occasion demands. Part i. deals with the foundations of sylviculture—this was formerly part iv. of vol. i. of the "Manual." Part ii. comprises the formation and regeneration of woods. Part iii. is devoted to the tending of woods, while part iv. consists of sylvicultural notes on British forest trees.

The author has condensed a marvellous amount of information into a small space. At the same time, each subject is dealt with at sufficient length to be quite intelligible to the student and practical forester. This is largely due to the admirable way in which Prof. Schlich has arranged his matter. One subject leads on quite naturally to another, so that there is no needless repetition and overlapping.

The author assumes that the student has already made some progress in other branches of science upon which sylviculture depends—"the forester requires to be well acquainted with the manner in which soil and climate act on forest vegetation, in order to decide in each case which species and method of treatment are best adapted, under a given set of conditions, to yield the most favourable results. The detailed consideration of the laws which govern this branch of forestry finds a place in the auxiliary sciences, such as physics, chemistry, meteorology, mineralogy and geology." Why not botany? especially plant physiology, the *bed-rock* upon which true scientific sylviculture must be founded. It has been for long a criti-

cism of foresters in this country that they are insufficiently acquainted with the life and form of plants —with botany, in fact—and the pages of this book seem to justify the criticism, at least there is occasionally a looseness of expression regarding botanical points which should not appear in a manual for students such as this. Take, for instance, the statement, "the atmosphere overlying the soil furnishes certain nourishing substances—heat, light and moisture" (p. 7), or again, "certain plants (Leguminosæ) can take nitrogen direct from the air by means of tubercles or nodules" (p. 11). The mention of the name Acacia up to p. 52 of the book instead of False-Acacia is botanically wrong and misleading, and the statement that elm does not ripen its seed in the north of England (p. 66) is also wrong because botanically unqualified. The identification of mistletoe with *Loranthus europoeus* (p. 324) is, we take it, a slip.

As regards sylviculture the book has been entirely brought up to date, and is eminently practical and suggestive. It may, with every confidence, be warmly recommended alike to the student, landed proprietor, forester and nurseryman. All doubtful or controversial matter has been carefully avoided, and every view stated, or method recommended, is founded upon the author's own direct observation and experience, as well as on that of others.

The various sylvicultural systems are clearly and concisely described, and their advantages and disadvantages amply criticised, so that the forester need have no difficulty in choosing the one best suited to his own locality and the objects of management. In the important sections dealing with the raising of plants in the nursery, much valuable and useful advice is given. The ultimate success of a wood depends, to a large extent, upon the health and vigour of the plants from which it originated—hence it is very important that young seedlings should be grown and handled with the greatest possible care. On p. 191, Prof. Schlich gives a timely warning to nurserymen in regard to the pernicious practice of laying down seedlings, when they are pricked out, into shallow trenches, involving the bending of the root-system to one side—a defect from which the tree does not recover for many years. He says, "unless nurserymen give up that vicious practice they must be prepared to see landed proprietors revert to the system of home nurseries."

Part iv. of the volume is replete with information. In fact, it is a condensed volume on sylviculture in itself. The notes on the Douglas Fir have been considerably extended, but in regard to the fungus enemies of this species, *Phoma Douglasii* might have been included, as this disease has been known in Scotland now for several years.

ENGINEERING IN SOUTH AFRICA.

The Engineer in South Africa. By Stafford Ransome, M.Inst.C.E. Pp. xx+319. (Westminster: Archibald Constable and Co., Ltd., 1903.) Price 7*s.* 6*d.*

AT the close of the war the author was appointed by the *Engineer* to visit all the British possessions in Africa south of the Zambesi River, and to write frankly and fully to that journal on the various problems which have been evolved by recent events. The result was a series of articles on "South Africa from an Engineer's Point of View." These articles were of a highly interesting nature, and were much appreciated at the time.

The volume before us combines the most interesting portions of these articles with much additional matter as well as most of the illustrations. Mr. Ransome is well known as a successful author of books of this type, and we are not surprised at the able way he handles the subject.

Any man seriously thinking of going to South Africa, be he an artisan or a trained engineer, should most certainly obtain a copy of this book; the information given on the cost of living and travelling, as well as on the prospects of employment, is very much to the point.

Chapter vi. deals with the labour question, a subject very much to the fore at the present time. Our author, after pointing out the prohibitive cost of white unskilled labour, discusses three alternatives, which are as follows:—(1) the importation of Asiatic labour; (2) the trusting to Providence to induce the Kaffir to work; (3) the taking of measures to make the Kaffir work, his conclusion being that the third alternative should be adopted, and that legislation should be introduced to this end. Chapter xiii. deals with the theory and practice of the railways, one of the most interesting in the book. The railway mileage at present open for traffic is 5457, under construction 2636, making a total of 8093 miles. Our author has much to say about the long delivery and high prices paid for railway plant when ordered in Britain, and no doubt has formed these views from conversations with men on the spot; he also compares American delivery of such material to our detriment. It is only fair to point out that the average locomotive built in Britain for these railways is the most expensive of its kind; its design usually emanates from the colony, and the locomotive builder here has to do what he is told. On the other hand, the American locomotive builder works with a much freer hand in every way. He supplies what he thinks best, and is not handicapped by a rigid specification; no wonder he can deliver sooner!

Judging from chapter xiv., the harbours of British South Africa are in a bad way, more especially those in Cape Colony, where for political reasons their development has been remarkably slow; and the author very reasonably argues that since the majority of imports are likely to be for the Transvaal, the harbours further up the coast are more likely to develop in the future; this applies to the Port of Natal, Durban.

Mr. Ransome gives us an excellent description of diamond mining in Kimberley in chapter xvi., tracing the development of the De Beers Company from the commencement, and explaining the various methods from beginning to end, and the same can be said of chapter xvii., which has for its subject "Underground at the Rand Mines."

This volume is of interest to all connected with South Africa, and Mr. Ransome may be congratulated on the production of so excellent a book.

N. J. L.

R. CLAY AND SONS, LTD., BREAD ST. HILL, E.C., AND BUNGAY, SUFFOLK.

THE MANUFACTURE OF

SCIENTIFIC APPARATUS

AND

LABORATORY FURNITURE

AN UP-TO-DATE MANUFACTORY

MESSRS. **PHILIP HARRIS & CO., Ltd.,** of 144 and 146 Edmund Street, **Birmingham,** and 179 Great Brunswick Street, Dublin, have recently removed their workshops from **Cornwall Street** (at the back of their Edmund Street premises) to new buildings in **Great Charles Street.**

These extensive premises have been designed and built by this enterprising firm to

EXTERIOR OF MANUFACTORY.

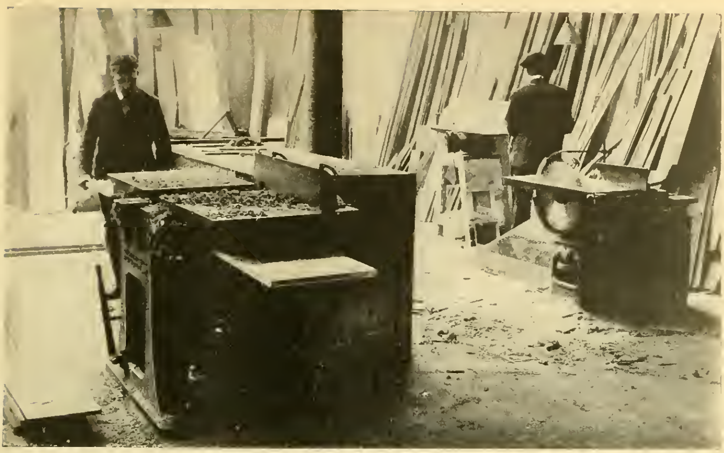
give them up-to-date premises for the manufacture of all the Apparatus (except glass) required in connection with **Technical Education,** and for making the **Laboratory Furniture** for which they are also so well known.

The buildings, which lie back from the street, are built in a substantial manner, have a frontage of 60 feet, and are lighted and ventilated upon the most improved principles. An ingenious use is made of the fall in road level, the ground floor being at the same level as the higher portion, allowing a loading and unloading deck, this being most useful for receiving timber and loading the finished fittings to the railway

PART OF WOODWORKING SHOP FOR LABORATORY FURNITURE.

wagon. The **Ground Floor,** which is devoted to **Wood Working,** is **60 feet long,** and with the extensions for Machinery has a total width of **74 feet**, so arranged that a good light is obtained all day.

In this shop **Laboratory Fittings** are manufactured throughout from the rough timber to the finished Bench, Fume Chamber, Lecture Table, &c., and here may be seen Benches and other fittings of the best workmanship possible. A close examination of some of these in course of construction proved to us that the finish of the interior was equal to that of the exterior in every respect, and from the way the joints and other parts were made we could see at once how it is that this firm have built up such a good reputation.



PART OF WOOD MACHINE SHOP.

PART OF WOOD MACHINE SHOP.

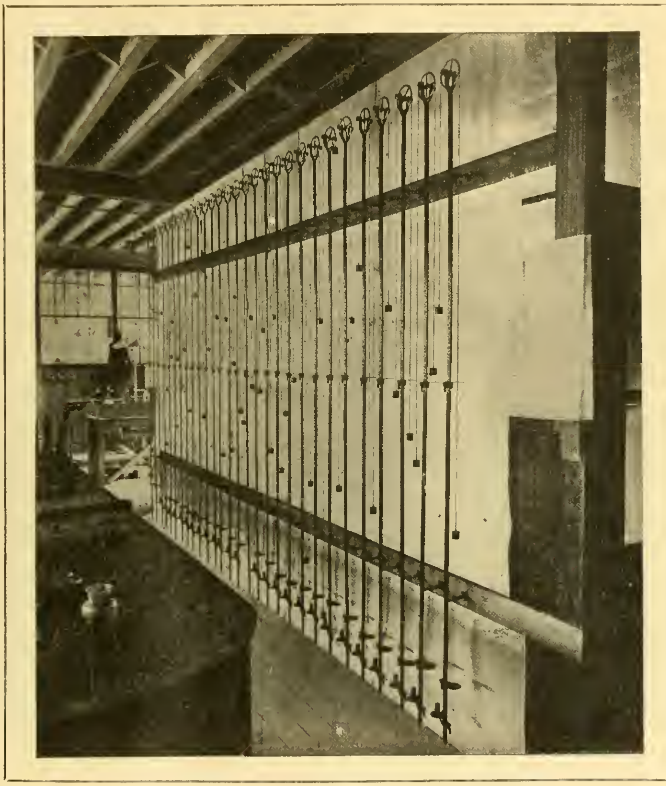
One most important point is that purchasers can inspect the Fittings whilst being made, satisfying themselves that everything is in accordance with the specification, in respect of workmanship and material being of the very best, and of full size details. In these shops are to be seen some fine stocks of Teak, Pitch Pine, &c., and here, to ensure material for the particular part in hand being of the right kind, the wood is specially selected for each job; and in the case of teak tops particularly, wide planks are used to ensure a minimum number of joints, which, however, when made as this firm make them, in our opinion, cannot possibly open. When a job is commenced the

DELICATE INSTRUMENT SHOP.

wood is first selected, care being taken to use nothing but well seasoned stuff; it is then sawn to the desired lengths, put through the planing machine (one of which, a self-feeder, will plane 18 inches wide and 6 inches thick); it is then machined according to what part of the bench, &c., it is intended for, and fitted together to form the desired piece of furniture by men who, being always engaged on this class of work, are really experts at it.

A portion of the works has been set apart for the manufacture of the smaller class of Woodwork, such as **Electrical Machines,** Balance Cases, **Resistance Boxes,** Gas Analysis Apparatus, &c., &c. **Machines** for Sawing, Planing, Mortising, Tenoning, Shooting, Sand-papering, Slotting, Grooving, Moulding, Surfacing, Turning, Thicknessing,

&c., may here be seen at work; these are driven from a line of main shafting extending the whole length of the basement under the machine shop. The motive power is supplied by a 50 H.P. Gas Engine, with extra heavy fly-wheels, built specially for this firm. This engine also drives a dynamo fitted with fly-wheel which supplies the electricity to run



A BATCH OF ATWOOD MACHINES READY TO BE TESTED.

electric motors for driving the machinery in positions to which it is difficult to take power from the main shaft, and also to light the whole of the building.

On the **First Floor** we find a goodly array of Foot Lathes, Vices, and Work Benches for the manufacture of the **finest Scientific Instruments,** such as Resistances, Wimshurst Machines, Atwood Machines, Galvanometers of all sorts, Aluminium Pulleys, Thermopiles, Optical Benches, Melloni's Apparatus, Polarimeters, Spectrometers, Microscopes, &c., &c.; also a Dark Room with electrical current from the main dynamo for testing Arc Lamps,

charging Accumulators, X-Ray work, &c., and testing appliances for the adjustment of instruments generally.

Pattern Room, fitted with receptacles for their costly and multitudinous patterns; and also **Wood Polishing Room.**

The Machinery on the **next floor** is driven by two motors connected through automatic overload cut-out switches to the main dynamo. This floor is devoted to the manufacture of the **heavier Brass, Iron, &c.,** such as Retort Stands, Clamps, Crucible Tongs, Tripods, Levelling Screws for apparatus, Bunsen Burners, Triangles, Taps, Bench Uprights, and all the commoner class of apparatus.

HEAVY METAL WORKING SHOP.

Power Lathes of various forms are used according to the work required; Disc Emery Plate for squaring, edging, shaping, &c., may be seen at work, and driven from a separate motor; Polishing Spindles, fitted to which are pipes taking away by means of an exhaust fan the dust from the mops (this fan also draws air away from the wood polishing shop below, keeping the atmosphere pure); Forge, Soldering Hearths, are evidences of the class of work done, and a row of Presses shows that P. H. & Co. are alive to the possibilities of cheapening apparatus by this means. An Atwood's Machine is a good example of the above: whereas a few years ago such a machine cost about £12, and even at this price was hardly accurate, now a machine at 30*s*. has just been put on the

market by this firm which gives most satisfactory results. This has been protected by patent; it is a modification of the pattern which was first originally made by them, and which they still sell at £4 15*s.* 0*d.*

Lacquering is done on this floor in a room set apart for the purpose. A flat roof serves the purpose of a store for Laboratory Sinks, Receivers, &c., of which a large stock is always kept.

On the front land, which Messrs. Harris, to allow of future extensions, were wise enough to secure, are Timber Sheds, Mess Room, &c.; and the whole is planned out to allow for extra storeys being built over the present workshops.

Stocks of Timber are also kept in Liverpool, Bristol, and Hull to ensure a well seasoned supply of whatever kind is necessary.

SOME OF THE STAFF.

It was interesting to see the smart manner in which the men did their work. The Manager informed us that those who had been technically educated were, as a rule, by far the best, and were more self-reliant and able at once to understand the requirements. We had no idea that Scientific Instruments were constructed on so large a scale, but we saw being finished thirty-six Atwood's Machines, twelve Spectrometers, and numbers of Galvanometers of various patterns. The greatest care is exercised in the manufacture, and every instrument has to pass a severe test before leaving the shop, a specialist in Physics who holds high qualifications being responsible.

Messrs. Philip Harris & Co., Ltd., still have their Warehouses and Show Rooms at 144 and 146 Edmund Street, Birmingham, and 179 Great Brunswick Street, Dublin and recently extensive alterations and additions have been made, to enable them to keep a larger and more varied stock than before.

Amongst the Specialities and Protected Designs of Messrs. P. Harris & Co. are :—

Atwood Machine.

Automatic Apparatus for starting and stopping Stop Watch to use with above.

D'Arsonval Galvanometer.

Deflagrating Spoons with removable Cups.

Balances for Students' use

Weights for Students' use.

Extensometers.

Minute Ammeter.

Laboratory Benches with patent arrangements for bottles.

Laboratory Fittings generally.

Manual Instruction Benches.

Birmingham Municipal Technical School Galvanometers, Bridges, &c.

Aluminium Pulleys.

Mechanics' Apparatus.

Pure Acids for Analytical Work.

Pure Reagent Chemicals.

Stroud and Rendell Lantern.

Stroud and Barr Lantern Copying Apparatus.

RICHARD CLAY AND SONS, LIMITED, BREAD STREET HILL, E.C., AND BUNGAY, SUFFOLK.
